Rejoice in the Lord always.
I will say it again: Rejoice!
Let your gentleness be evident to all.
The Lord is near.
Do not be anxious about anything,
but in everything, by prayer and petition,
with thanksgiving, present your requests to God.
And the peace of God, which transcends all understanding,
will guard your hearts and your minds in Christ Jesus.

For those I hold dearest: my wife Eleanor, mother Ingrid, daughter Helen,
son David and my seven grandchildren.

Preface

When people ask me what work I do, I say that I am an academic engineer, studying *Machine Vision* and therefore call myself a *Machine Vision Systems Engineer* (*Vision Engineer for short*). When asked to explain what that means, I reply in the following way:

"I study machines that can 'see'. I use a video camera, connected to a computer, to find defects in industrial artifacts as they are being made."

In my experience, this is just short enough to avoid total boredom in fellow guests at dinner parties. However, it is woefully inadequate, since it does not encompass many topics that are essential for building a successful Machine Vision system. Compare the "dinner-party definition" with the following, more formal statement, which introduces the broader concept of *Artificial Vision*:

Artificial Vision is concerned with the analysis and design of opto-mechanical-electronic systems that can sense their environment by detecting spatio-temporal patterns of electro-magnetic radiation and then process that data, in order to perform useful practical functions.

Machine Vision is the name given to the *engineering* of Artificial Vision systems. When browsing through the technical literature, the reader will soon encounter another term: *Computer Vision (CV)* and will quickly realise that it and *Machine Vision (MV)* are often used synonymously. This is a point on which I strongly disagree! Indeed, this book is founded on my firm belief that these subjects are fundamentally different. There is a certain amount of academic support for this view, although it must be admitted that the loudest voices of dissent come from within universities. On the other hand, most designers of industrial vision systems implicitly acknowledge this dichotomy, often by simply ignoring much of the academic research in CV, on the grounds that it is not relevant to their immediate needs. In the ensuing pages, I and my co-authors argue that *Machine Vision* should be recognised as a distinct academic and practical subject that is fundamentally different from Computer Vision.

Computer Vision, Artificial Intelligence, Pattern Recognition and Digital Image Processing (DIP) all contribute to MV, which makes use of algorithmic and heuristic techniques that were first devised through research in these other fields. Machine Vision concentrates on making them operate in a useful and practical way. This means that we have to consider all aspects of the system, not just techniques for representing, storing and processing images inside a computer. With this in mind, we come to the following working definition.

Machine Vision is concerned with the engineering of integrated mechanical-optical-electronic-software systems for examining natural objects and materials, human artifacts and manufacturing processes, in order to detect defects and improve quality, operating efficiency and the safety of both products and processes. It is also used to control machines used in manufacturing. Machine Vision requires the harmonious integration of elements of the following areas of study

- *Mechanical handling*
- *Lighting*
- *Optics (conventional, fibre optics, lasers, diffractive optics)*
- *Sensors (video cameras, UV, IR and X-ray sensors, laser scanners)*
- *Electronics (digital, analogue and video)*

- *Signal processing*
- *Image processing*
- *Digital systems architecture*
- *Software*
- *Industrial engineering*
- *Human-computer interfacing*
- *Control systems*
- *Manufacturing*
- *Existing work practices and QA methods.*

Machine Vision has also been applied successfully to several high-volume niche markets, including:

- Reading automobile registration plates
- Face recognition (security purposes)
- Fingerprint recognition
- Iris recognition
- Document processing
- Signature verification
- Security surveillance
- Print inspection
- Fabricating micro-electronic devices
- Karyotyping (chromosome identification and classification)
- Inspecting bare printed cicuit boards
- Controlling/checking the placement of components on printed circuit boards.

However, we shall not discuss these niche application areas, preferring instead to concentrate on manufacturing industry, which is distinctive in presenting *many millions* of low-volume potential applications. These vary from trivial to extremely difficult. Rather than solving one application at a time, I have spent my working life devising tools that are appropriate for a very wide range of situations. The aim of my work over the last 35 years has been to build versatile development systems that can be used in the study of newly defined industrial inspection, measurement or control tasks. Using such systems enables new applications to be solved, or dismissed as impractical, in a very short time. There is a never-ending stream of new industrial applications. In the 1980s, the 3M Company, with whom I was privileged to work, introduced more than 10 new products each day! The challenge we faced was to devise tools allowing the potential benefits of MV to be explored quickly and cheaply; we could spend no more than a few hours evaluating each new application. Contrast this with the niche markets mentioned above, where there is the potential for a high financial return for a single design. Unlike most industrial MV projects, these niche markets were able to justify the high design costs needed.

Let us be more specific about what we include within the scope of our discussion in this book. We concentrate on manufacturing industry: "metal bashing" and processing materials such as plastics, wood, glass, rubber, and ceramics. A similar approach is appropriate in the manufacture and packaging of food, beverages, pharmaceuticals, toiletries, clothing and furniture. Many of the same ideas are also applicable to processing fabrics, leather, minerals, plant materials, fruit, vegetables, nuts, timber, animal and bird carcasses, meat, fish, etc.

The problem of nomenclature arises because MV, CV and DIP are all concerned with the processing and analysis of pictures within electronic equipment. I did not specify computers explicitly, because Artificial Vision does not necessarily involve a device that is recognizable as a computer. Of course, it is implicit in the very name of CV that image processing takes place inside a computer. On the other hand, MV does not impose such a limitation. For example, it also allows the processing of images to take place in specialised electronic or electro-optical hardware.

Although MV, CV and DIP share a great many terms, concepts and algorithmic techniques, they require a completely different set of priorities, attitudes and mental skills. The division between MV and CV reflects the division between engineering and science. Engineers have long struggled to establish a clear distinction between engineering and science. This book tries to do the same for MV Systems Engineering and its scientific-mathematical counterpart: Computer Vision.

CV is usually concerned with general questions, such as *"What is this?"*. On the other hand, MV almost always addresses very specific questions, for example *"Is this a well made widget?"*. This reflects one very simple fact: in a factory, we know what product is being made at any given moment, so we know what an object should look like. As a result, MV systems are usually used for *verification*, not *recognition*. The reverse is often true for CV. As we shall see in the following pages, this has profound implications.

The people responsible for generating MV data (i.e. images) are usually cooperative. A manufacturing engineer *wants* to produce a good product and will, as far as is practical, modify the inspection millieu, or even the product itself, to improve matters. Contrast this with the task of designing systems for *recognising* military targets. The enemy does not want to cooperate and actually tries to obscure his presence and actions! Similar remarks apply to fingerprint identification and forensic image analysis. Not surprisingly, criminals show little interest in cooperating with those people who are trying to catch them! In medicine, the situation is little better; tumours do not cooperate with equipment designers, although a battery of techniques (e.g. staining) has been developed for highlighting the presence of cancer cells. On a continuum scale recording the degree of cooperation that we can expect, MV applications are clustered at one end and CV applications near the other.

In MV, the allowed unit cost for analysing each image is likely to be very low. In CV applications, such as military target recognition and oncology, the cost of making a mistake can be very high indeed, so a higher unit cost per scene inspected can often be tolerated. Most CV problems are "difficult" in terms of artificial intelligence, while MV is usually "easy".

The distinction between MV and CV can be illustrated by considering a seemingly simple task: determining whether a coin has its obverse, or reverse, face uppermost. (This might well be a component in the bigger process of inspecting proof-quality coins.) CV begins with an image that was obtained by somebody else, not the CV specialist. On the other hand, MV begins with an embossed metal disc. Deriving an image from it requires that the MV engineer designs the lighting, optics and mechanical handling of the coins, as well as choosing an appropriate camera. The crucial importance of lighting and optics is obvious from the fact that very different images of the same coin can be produced, simply by moving the lights very slightly. In the MV engineer's mind, consideration of the representation, storage, processing and analysis of images follows once a good image has been produced. Computer processing of images for MV is important but it is not the vision engineer's only concern. He cannot afford to concentrate on this, or any other part of a system, and then neglect all others. *This is the primary and inviolate rule for Machine Vision system design.*

During the 1970s and 1980s, Japan taught the rest of the world the importance of ensuring the highest quality in manufactured goods. The West learned the hard way: markets were lost to companies whose names were hitherto unknown. Many long-established and well-respected companies were unable to meet the challenge and failed to survive. Those that did were often faced with difficult years, as their share of the market shrank. Most companies in Europe and America have come to terms with this now and realize that quality has a vital role in establishing and maintaining customer loyalty. Hence, any technology that improves or simply guarantees product quality is welcome. Machine Vision has much to offer manufacturing industry in improving product quality and safety, as well as enhancing process efficiency and operational safety. Machine Vision owes its rising popularity to the fact that optical sensing is inherently clean, safe, and versatile. It is possible to do certain things using vision that no other known sensing method can achieve. Imagine trying to detect stains, rust or surface corrosion over a large area by any means other than vision!

The recent growth of interest in industrial applications of Machine Vision is due, in large part, to the falling cost of computing power. This has led to a proliferation of vision products and industrial installations. It has also enabled the development of cheaper and faster computing machines, with increased processing power. In many manufacturing companies, serious consideration is being given now to applying Machine Vision to such tasks as inspecting grading, sorting, counting, monitoring, measuring, gauging, controlling and guiding. Automated Visual Inspection systems allow manufacturers to keep control of product quality, thus maintaining / enhancing their competitive position. Machine Vision has also been used to ensure greater safety and reliability of the manufacturing processes. The whole area of flexible automation is an important and growing one, and Machine Vision will continue to be an essential element in future *Flexible Manufacturing Systems*. There are numerous situations where human inspection is unable to meet production demands. The advent of Machine Vision has often enabled the development of entirely new products and processes. Many companies now realise that Machine Vision forms an integral and necessary part of their long-term plans for automation. This, combined with the legal implications of selling defective and dangerous products, highlights the case for using Machine Vision in automated inspection. A similar argument applies to the application of vision to robotics and automated assembly, where human operators were previously exposed to dangerous, unhealthy / or unpleasant working conditions. Machine Vision is a valuable tool in helping to avoid this.

No Machine Vision system existing today, or among those planned for the foreseeable future, approaches the interpretative powers of a human being. However, current Machine Vision systems are better than people at some repetitive quantitative tasks, such as making measurements under tightly controlled conditions. Machine Vision systems can out-perform people, in certain limited circumstances. Industrial vision systems can generally inspect simple, well-defined mass-produced products at very high speeds, whereas people have considerable difficulty making consistent inspection judgments in these circumstances. Machine Vision systems exist that can inspect several thousand objects per minute, which is well beyond human ability. Studies have shown that, at best, a human inspector can only expect to be 70–80% efficient, even under ideal conditions. On many routine inspection tasks, a Machine Vision system can improve efficiency substantially, compared to a human inspector. A machine can, theoretically, do this for 24 hours / day, 365 days / year. Machine Vision can also be useful in detecting gradual changes in continuous processes. Tracking gradual colour, shade or texture variations is not easy for a person.

Currently, the main application areas for industrial vision systems occur in automated inspection and measurement and, to a lesser extent, robot vision. Automated Visual Inspection and measurement devices have, in the past, tended to develop in advance of robot vision systems. In fact, QC-related applications, such as inspection, gauging and verfication, currently account for well over half of the industrial Machine Vision market. This has been achieved, in many cases, by retrofitting inspection systems onto existing production lines. There is a large capital investment involved in developing a completely new robotic work cell. Moreover, the extra uncertainty and risks involved in integrating two relatively new and complex technologies makes the development of robot vision system seem a daunting task for many companies and development has often lagged behind that of inspection devices. The technical difficulties involved in controlling flexible visually guided robots have also limited the development. On the other hand, Automated Visual Inspection systems now appear in every major industrial sector, including such areas as consumer goods, electronics, automobile, aerospace, food, mining, agriculture, pharmaceuticals, etc.

Machine Vision systems for industry first received serious attention in the mid-1970s. Throughout the early 1980s, the subject developed slowly, with a steady contribution being made by the academic research community, but with only limited industrial interest being shown. It seemed in the mid-1980s that there would be a major boost to progress, with serious interest being shown in vision systems by the major American automobile manufacturers. Then, came a period of disillusionment in the USA, with a large number of small vision companies failing to survive. In the late 1980s and early 1990s, interest grew again, due largely to significant progress being made in making fast, dedicated image processing hardware. During the first decade of the 21st century, the growth of the Machine Vision market was unrelenting. This was helped considerably by the development of new technologies, especially plastic optical components, LED lighting, high-resolution cameras and fast computer hardware. For many applications, it is possible now to provide sufficiently fast processing speed on a standard computing platform. Throughout the last 35 years, academic workers have demonstrated feasibility in a very wide range of products, representing all of the major branches of manufacturing industry. I have been very privileged to have participated in this.

I have watched this subject develop and blossom, from the first tentative steps taken in the mid-1970s to today's confident multi-billion dollar industry. In those early days, industrial engineers and managers were mentally unprepared for the new technology. Although there is far greater acceptance of vision system technology nowadays, many customers are still unwilling to accept that installing and operating a vision system places a new intellectual responsibility on them. They often fail to understand that machines and people see things very differently. During the last 35 years, I have seen similar mistakes being made, through a lack of appreciation of this point. Sadly, customer education is still lagging far behind technological developments in Machine Vision. The responsibility for making Machine Vision systems work properly does not lie solely on the shoulders of the vision engineer. The customer has a duty too: to listen, read, and observe, Making the most from the strengths and weaknesses of Machine Vision technology involves appreciating a lot of subtle points. This book discusses just a small proportion of these. My colleagues and I have had great fun developing and writing about this amazing technology and hope that some of our excitement will be evident in these pages.

It is customary in many areas of writing to use so-called gender-neutral constructions, such as "*he/she*", "*s/he*", "*his/her*" etc. I regard these as being both clumsy and counter-productive. To improve clarity and to avoid placing women after men, I use the words, "*he*", "*his*" and "*him*" in the traditional way, to encompass both sexes, without granting precedence to either.

I am indebted to my friends and colleagues who have contributed to this handbook. Without exception, their enormous experience is evident in the splendid essays that grace this description of this exciting subject. I was inspired to study Machine Vision systems when I was preparing a book (*Pattern Recognition: Ideas in Practice*, Plenum, New York & London, 1978, ISBN 0-306-31020-1) with invited contributions from expert authors. One of them, Dr. John R Parks, offered a chapter entitled *Industrial Sensory Devices*, which so excited me that 37 years later I am still conducting research in that area. It is a pleasure to acknowledge John Parks, for his foresight, technical knowledge and humour. This book describes an interactive image processing system, called *QT*, which has its origins, in part, to work in the 1970s on *SUSIE* (*Southampton System for Image Evaluation*) by Dr. Jonathan Brumfitt. Toby Holland developed the video interface hardware for *SUSIE*, which inspired the development of the *AutoView Viking* system. (British Robotic Systems Ltd.) Peter Heywood, Dr. Graham Page, Dr. David Mott and David Upcott all contributed to that. In parallel, Tim Loker, Mike Rippingale and Martin Reeves, of Vision Dynamics Ltd, developed a similar system called *VCS*. The *Intelligent Camera* (Image Inspection Ltd.) also followed from *SUSIE* and was developed by Dr. Piers Plummer. Dr. David Mott integrated *AutoView Viking* with *Prolog*. Inspired by this work, *VCS*, the *Intelligent Camera* and *QT* (described in detail here) were, in turn, interfaced to Prolog. Dr. Andrew Jones, Ralf Hack and Stephen Palmer wrote an integrated package, called *PIP*, incorporating *LPA Prolog* (Logic Programming Associates Ltd) and our own image processing software, written in C. I built *QT*, on top of the *MATLAB*™ *Image Processing Toolbox* (Mathworks, Inc). Recently, *QT* has itself been extended by Dr. Simon Caton, who developed a multi-host, multi-process version. Dr. Luke Chatburn developed a web-based, multi-computer system, called *Myriad*, for image processing. Dr. Frederick Waltz and I worked together for many years, applying interactive image processing to real-world industrial inspection, measurement and control tasks. Michael Daley, Garry Jackson and Richard Crowther all worked with me, interfacing image processing systems to various electro-mechanical devices, including our model train. In addition, Dr. Barry Marlow, Dr. Simon Cotter, Dr. Chris Bowman, Dr. Tony McCollum, Dr. John Chan, Dr. Mark Graves, Dr. Graham Wilson, Dr. Robin Tillet, Prof. Paul Whelan, and Rolf Iverson all helped to guide my thinking. I am pleased to express my gratitude to all of the former colleagues that I have mentioned above. I recall with great pleasure the fulfilling times that I have enjoyed working with them all. It was great fun! My special thanks are due to Tim Loker, Peter Heywood and Fred Waltz who opened doors for me.

This book would not have been completed without the unerringly patient support and encouragement of my dear wife Eleanor. Gratitude is not enough for her love!

My clumsy attempts at building machines that can "see" simply emphasizes how wonderful and mysterious my own sense of sight is. It is humbling to realise that our supposedly sophisticated technology is no match for the gift of sight that our Creator graciously chose to bestow on us. It is well to remember that we can at best supplement but not replace human vision.

1 Machine Vision for Industrial Applications

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_1,

Abstract: Machine Vision is related to, but distinct from Computer Vision, Image Processing, Artificial Intelligence & Pattern Recognition. The subject is concerned with the engineering of integrated mechanical-optical-electronic-software systems for examining natural objects and materials, human artifacts and manufacturing processes, in order to detect defects and improve quality, operating efficiency and the safety of both products and processes. It is also used to control machines used in manufacturing. Machine Vision necessarily involves the harmonious integration of mechanical handling, lighting, optics, video cameras, image sensors (visible, UV, IR and X-ray sensor arrays, as well as laser scanners), digital, analogue and video electronics, signal processing, image processing, computer systems architecture, software, industrial engineering, human-computer interfacing, control systems, manufacturing, existing work practices and quality assurance methods. Machine Vision is not a scientific endeavour; it is a branch of Systems Engineering. Hence, consideration of application requirements pays a key role in the design of practical vision systems. The basic philosophy of Machine Vision is set out in this chapter and the structure of this book is outlined. This is a pragmatic, empirical, experimental subject and is not unduly burdened by the search for mathematical rigour, or theoretical purity. There is one simple design maxim: *if it works, use it!* This is justified here by consideration of lessons learned from four practical application studies. Later in the book these same ideas will emerge many times over.

1.1 Natural and Artificial Vision

Vision is critical for the survival of almost all species of the higher animals, including fish, amphibians, reptiles, birds and mammals. In addition, many lower animal phyla, including insects, arachnids, crustacea and molluscs possess well-developed optical sensors for locating food, shelter, a mate, or a potential predator. Even some unicellular organisms are photosensitive, although they do not have organs that can form high resolution images. Vision bestows great advantages on an organism. Looking for food during foraging, or prior to giving chase, is very efficient in terms of the energy expended. Animals that look into a crevice in a rock, to check that it is safe to go in, are more likely to survive than those that do not do so. Animals that use vision to identify a potential breeding partner are more likely to find a fit, healthy mate than those that ignore its appearance. Animals that can see a predator approaching are more likely to be able to escape capture than those that cannot. Compared to other sensing methods, based on smell, sound and vibration, vision offers greater range, versatility, sensitivity and resolution.

Of course, vision is just as important to *Homo sapiens* as it is to any other animal species; life in both the forest and a modern industrial society would be impossible without the ability to see. Human society is organised around the highly refined techniques that people have developed to communicate visually. People dress in a way that signals their mood, social standing and sexual availability. Commerce is dependent upon hand-written, printed, and electronic documents that all convey messages visually. Education relies heavily upon the students' ability to absorb information that is presented visually. Writers of technical books, such as this, exploit the reader's ability to understand complex abstract ideas through the visual medium provided in printed text, diagrams and pictures. The leisure and entertainment industries rely on the fact that vision is the dominant human sense. So important is vision for our everyday lives that its loss is regarded by most people as one of the worst fates that could happen to a human being.

Manufacturing industry is critically dependent upon human beings' ability to analyse complex visual scenes. This is exploited in innumerable and highly variable tasks, ranging from the initial design process, through initial forming, machining, finishing, assembly, and quality control, to final packing. The value of vision as a safe way to sense many of the dangers that exist in a factory does not need explanation. Vision is hygienic and does not pollute the object under observation. With very few exceptions, the light levels needed to inspect an industrial artifact do not affect it in any way. Vision is potentially very fast; propagation delays from the object under inspection to sensor are typically just a few nanoseconds. (The sensor and its associated processing system will normally introduce much longer delays than this.) Vision provides a great deal of very detailed information about a wide variety of features of an object, including its shape, colour, texture, surface finish, coating, surface contamination, etc. Vision is extremely versatile and we can employ a wide range of optical techniques to widen its range of application even further. For example, it is possible to use stroboscopic light sources, structured lighting, colour filters, coherent illumination polarised light, fluorescence and many other clever optical "tricks" to sense a very broad range of physical properties.

Human vision is truly remarkable in its ability to cope with both subtlety and huge variations in intensity, colour, form and texture. The dynamic range is enormous: about 10^{14}:1. People can see extremely subtle changes of colour that are difficult to detect in a machine. (This is why it is so difficult to match colours after automotive body repair.) People can identity faces they know in a milling crowd, despite great changes in appearance that have taken place since the individuals concerned last met. On the other hand, they can register two matching pictures with great precision. A person can drive a car at high speed, yet a watchmaker can make very fine adjustments to a mechanism. A player can strike the cue ball in the game of billiards, or pool, with exquisite accuracy. A painter can capture the subtlety of colour in a woodland scene on his canvas, while an experienced foundry worker can identify the temperature of an incandescent ingot from its colour very accurately. All of these visual skills are exercised for inspection, grading, sorting, counting and a great many other tasks required for manufacturing industry.

Despite its obvious benefit to industry, human vision has its limitations (➔ *Fig. 1.1*). Many factors contribute to this, most notably fatigue, discomfort, illness, distraction, boredom, and alcohol/drug use. People cannot work at the speed required to provide 100% inspection of the products of many fast manufacturing processes. Boring repetitive tasks, such as examinig high-speed conveyors carrying unstructured heaps of raw materials, are particularly prone to unreliable performance. Many inspection tasks require precise dimensional/volumetric measurement, which people cannot perform accurately. For safety's sake, people working in factories must not be exposed to high temperatures, toxic/stifling atmospheres, high levels of smoke, dust and fumes, biological hazards, risk of explosion, excessively high noise levels, and ionizing radiation. On the other hand, people can damage delicate products, by clumsy handling and readily infect biological materials, by coughing, sneezing, shedding skin and hair. Furthermore, people cannot always apply objective inspection criteria rigorously, particularly when aesthetic properties of highly variable items are to be judged. For these reasons, engineers have long dreamed of building a machine that can "see." Such a machine should be able to sense its environment optically, using a video camera, or other imaging sensor, interfaced to an electronic information-processing system: a standard computer, or dedicated electronic hardware.

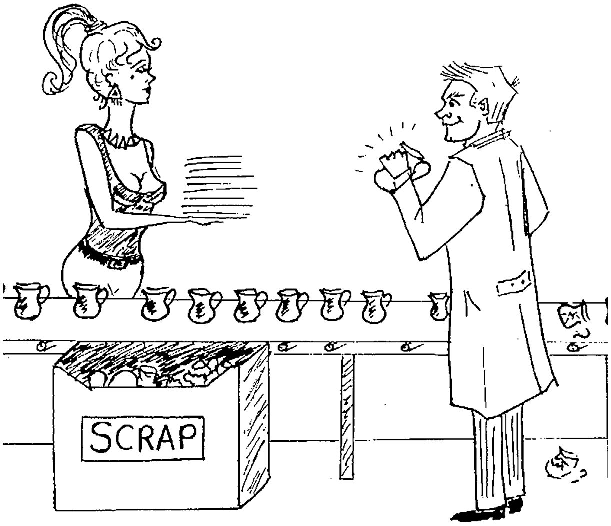

Fig. 1.1
Human beings are easily distracted from boring tasks. Almost anything, for example attractive members of the opposite sex, are more exciting to look at than objects moving past on an industrial conveyor belt! (This diagram simply reflects the reality of life and is not intended to denigrate either sex)

1.2 Artificial Vision

For the moment, we will use the phrase *Artificial Vision*, since we do not yet want to get into a detailed discussion about the precise meanings of the more commonly used terms *Computer Vision* and *Machine Vision*. The application of Artificial Vision systems to manufacturing industry motivates the techniques described in this handbook. This is an area where machines are beginning to find application, in preference to people. Artificial Vision does not necessarily attempt to emulate human, or animal, vision systems. Indeed, the requirement that industrial vision systems must be fast, cost effective and reliable, together with our rather limited knowledge about how people and animals actually see, make this approach unprofitable. By studying vision in nature, we may gain insight but we must be flexible and pragmatic when designing industrial vision systems.

When the author of this chapter is asked by a non-technical person what he does for a living, he replies that, as an academic, he studies *machines that consist of a television (more properly, video) camera connected to a computer and uses them to inspect objects as they are being made in a factory*. Such a definition is acceptable around the dinner-table but not for a technical book, such as this (➲ *Fig. 1.2*). In fact, designing a vision system that is of practical value in manufacturing applications requires a multi-disciplinary approach, encompassing aspects of all of the following technologies:

- Sample preparation
- Sample presentation to the camera
- Illumination

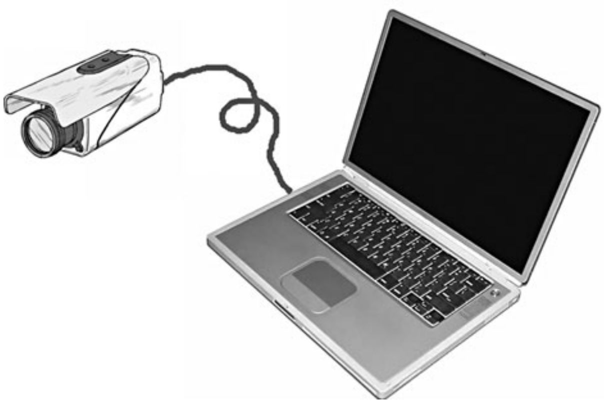

Fig. 1.2
This is not a Machine Vision system! The usefulness of pictures like this is limited to introducing total novices to image processing

- Optics
- Image sensing
- Analogue signal processing
- Digital information processing
- Digital systems architecture
- Software
- Interfacing vision systems to other machines
- Computer networking
- Ergonomics: interfacing vision systems for easy use by operating personnel
- Manufacturing and Quality Assurance practices.

These points must also be considered when a human being performs a visual inspection task. *Figure 1.3* illustrates this. However, the real significance of this cartoon is that the same features are needed in an automated visual inspection system. To justify the remainder of these points, in the context of Artificial Vision, the reader is referred to *Fig. 1.4*, which illustrates a range of typical industrial vision applications.

Lighting is obviously of critical importance when inspecting transparent, glossy and glinting artifacts, such as glass bottles, coins and electric light bulbs. Specialised lighting and viewing methods are needed to examine inside deep holes or crevices. In some situations, we may need to use sensing techniques based on ultra-violet, infra-red, or x-ray imaging, to detect details that we could not otherwise see. The safety implications of using ultra-violet and penetrating radiation are of crucial importance, since even the most technically successful project will be judged a failure, if the equipment does not meet certain minimum legal safety requirements.

Mechanical, rather than human handling of the parts to be inspected is vital when the process would place the operator in danger, for example when x-ray sensing is used or inspecting 25 ton slabs of red-hot steel.

We may need to apply a high level of intelligent interpretation to analyse images of natural products, such as growing plants, since they are totally unpredictable in form. Inspecting cake decoration patterns also requires intelligent analysis, because they are highly variable, as are the

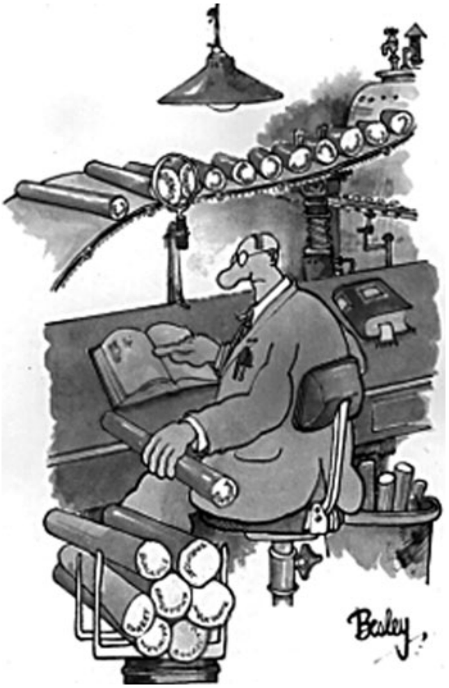

Fig. 1.3

The essential elements of typical Machine Vision system translated into human terms. Notice the presence of the following: object transport mechanism (*conveyor belt*), dedicated lighting, optics (*spectacles*), image sensor (*eyes*), product information database (*book*), data processing unit (*brain*), device for rejecting faulty product (*left arm*), reject bin. (Original caption: "*Checking the spelling of sea-side rock.*" Rock is a confectionary bar, typically with the name of a holiday resort spelled out by lettering that runs internally along its whole length. Reproduced by kind permission of the artist, Rupert Besley)

shapes of baked products, such as loaves, cakes, croissants, etc. Intelligence is also needed to determine the time from an analogue clock. Although not important in itself these days, this task is a model of a range of instrument calibration tasks.

Complex analytical methods of a different type are needed to analyse the surface texture of a slice of bread, or cork floor tiles. Certain tasks may apparently require complicated solutions, if we do not pay due attention to the application requirements. However, the solution may be quite straightforward if we constrain the task in some way. For example, an electrical connector (*Fig. 1.5*) would be difficult to inspect, if it were presented haphazardly to the camera. On the other hand, if it is delivered to the camera in a well-controlled manner (i.e., its position and orientation are both fixed), the inspection task becomes almost trivial.

In some applications, defining the inspection task unambiguously clearly requires a sophisticated user interface. For example, to define suitable criteria for inspecting the hydraulics manifold shown in *Fig. 1.4a* (second row/second column), we would need to tell the inspection machine which holes to measure, how large they are, whether they are

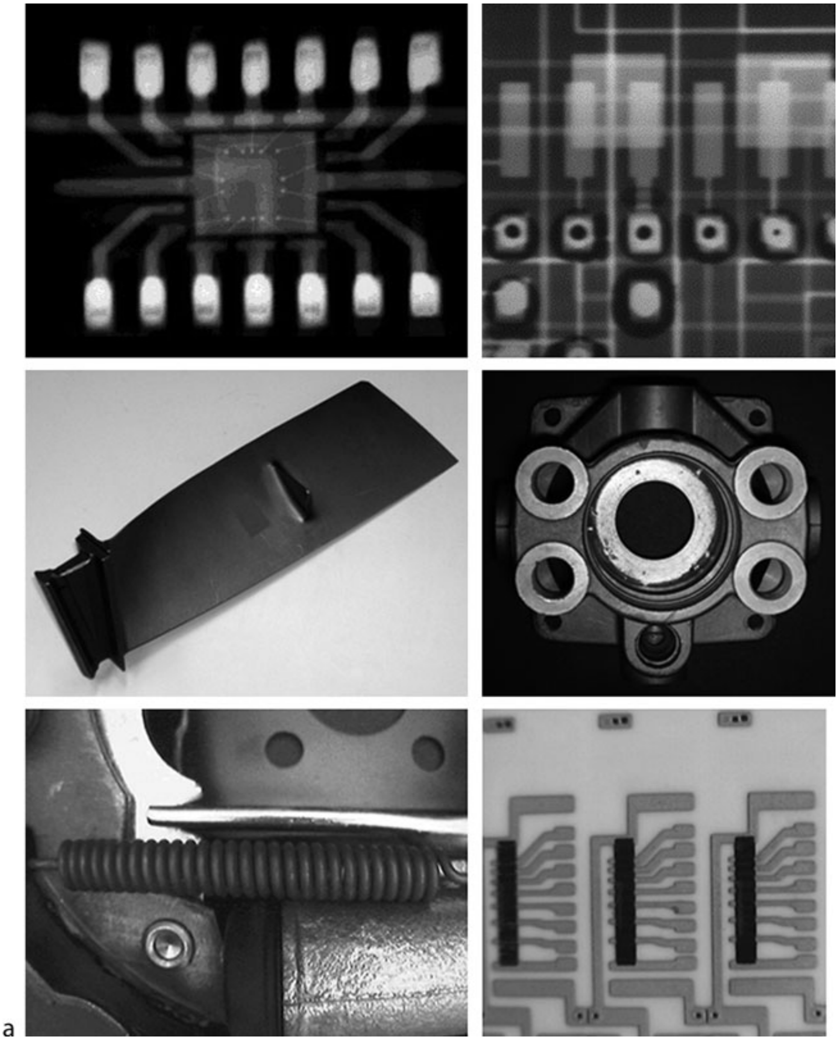

Fig. 1.4 (Continued)

tapped and chamfered and how their positions relate to one another. This requires close interaction between the user and the inspection machine. Sometimes detailed information about a product's specification is available in the form of a CAD model. Interpreting this to guide an inspection system clearly requires sophisticated software.

In our present state of knowledge about this subject, it is absolutely essential that we tailor each system to the specific demands of the application. In this respect, the design process is driven by the application requirements in the broadest sense, not by the computational procedures alone. We cannot, for example, design a "universal" vision system. Neither can we devise a system that can tolerate uncontrolled lighting, ranging from moon-light, through standard room-lighting to sun-light. We *must* control the light falling on the scene that is to be examined. We do this in two ways:

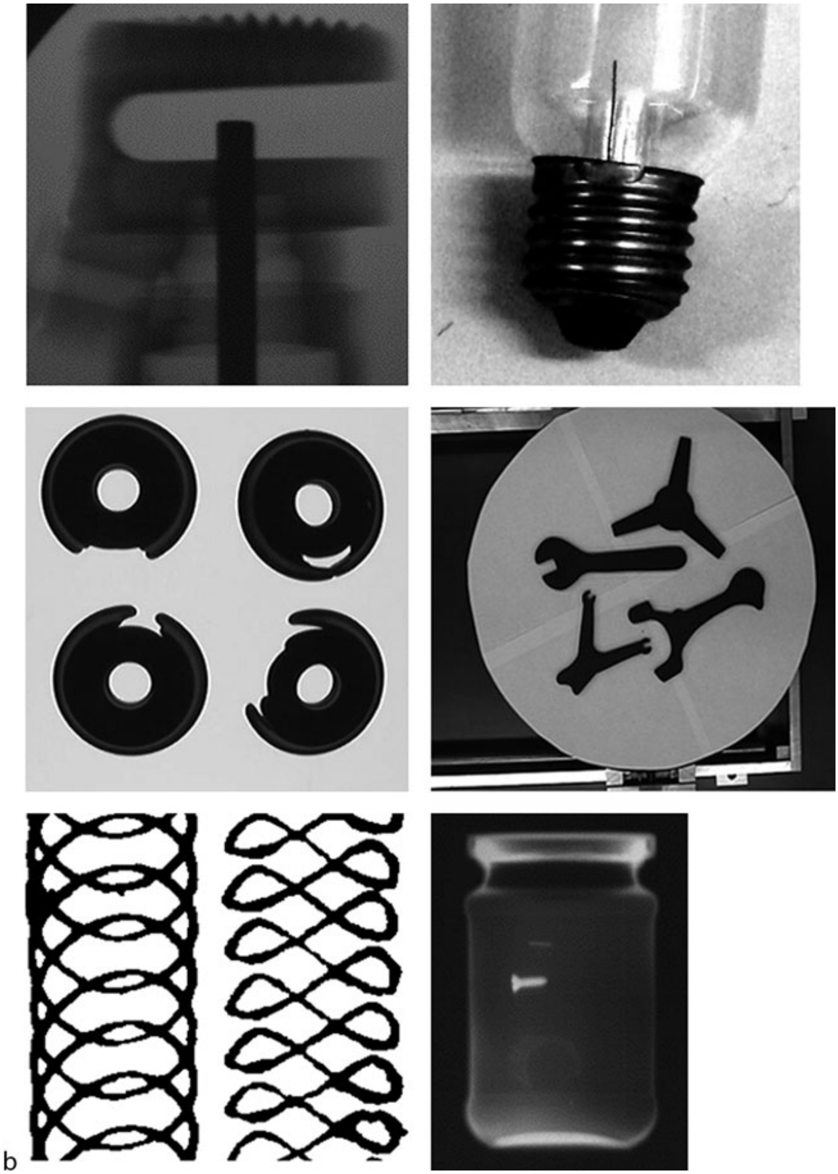

Fig. 1.4 (Continued)

1. Use curtains, boards, or other rigid sheeting to block ambient light.
2. Apply light from stable lamps, driven by regulated power supplies. Feed-back control of the light levels is highly desirable.

Nevertheless, we should, wherever possible, use illumination invariant image processing algorithms as well (see Chap. 13).

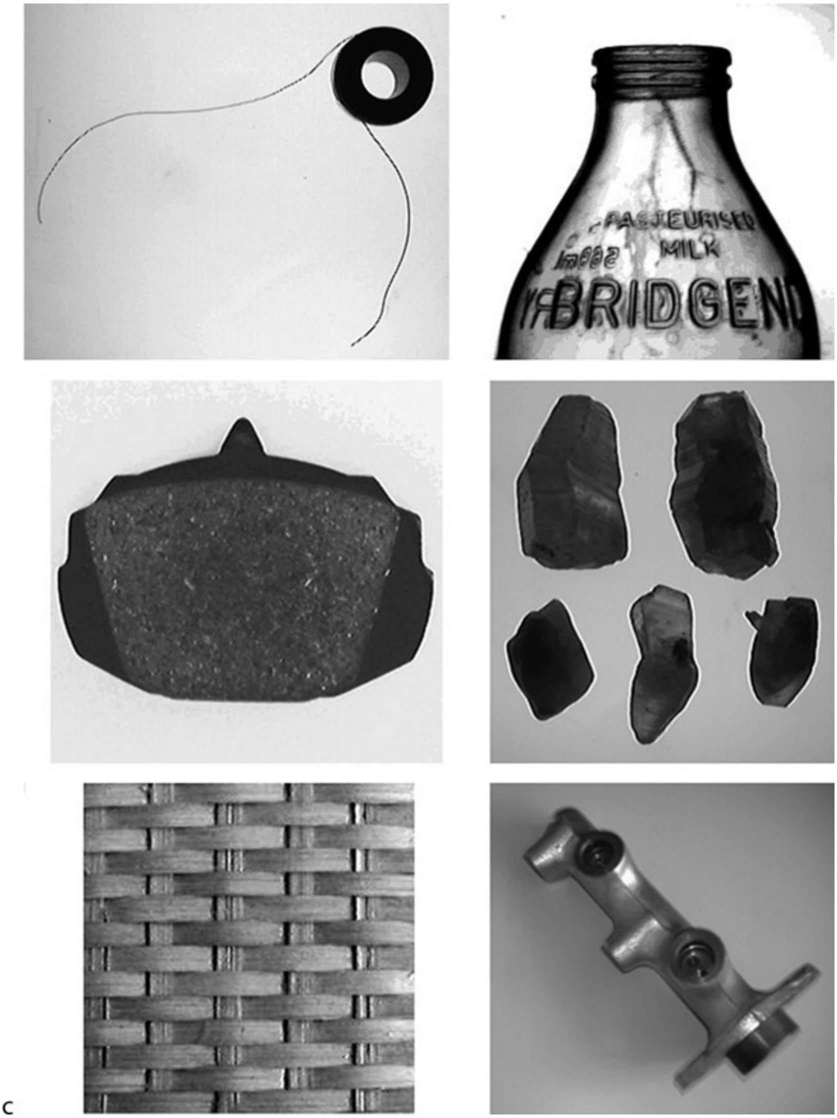

Fig. 1.4 (Continued)

1.3 Machine Vision Is Not Computer Vision

During a recent conversation, the author discussed the meanings of the terms *Machine Vision* (*MV*) and *Computer Vision* (*CV*), with another researcher, who is a very able and active worker in the mathematical and algorithmic aspects of Computer Science. (That is, he works in what the author maintains is *Computer Vision.*) He regards the terms *Machine Vision* and *Computer Vision* as being synonymous. In order to highlight the difference between them, the author

Fig. 1.4 (Continued)

challenged his colleague to design a vision system that is able to decide whether a bright “silver” coin is lying with its obverse or reverse side uppermost. He could not do so! The reason for this is simple: this very intelligent man lacks training in an appropriate experimental subject (e.g., engineering or physics). Since the starting point for this challenge is a coin, not a computer file, the lighting and optical sub-systems must be designed first, before any work on image processing algorithms is contemplated. We will present several further anecdotes to support our contention that MV requires skills and knowledge that CV largely ignores. We do not intend to belittle the intellectual component of Computer Vision. On the contrary, it is our

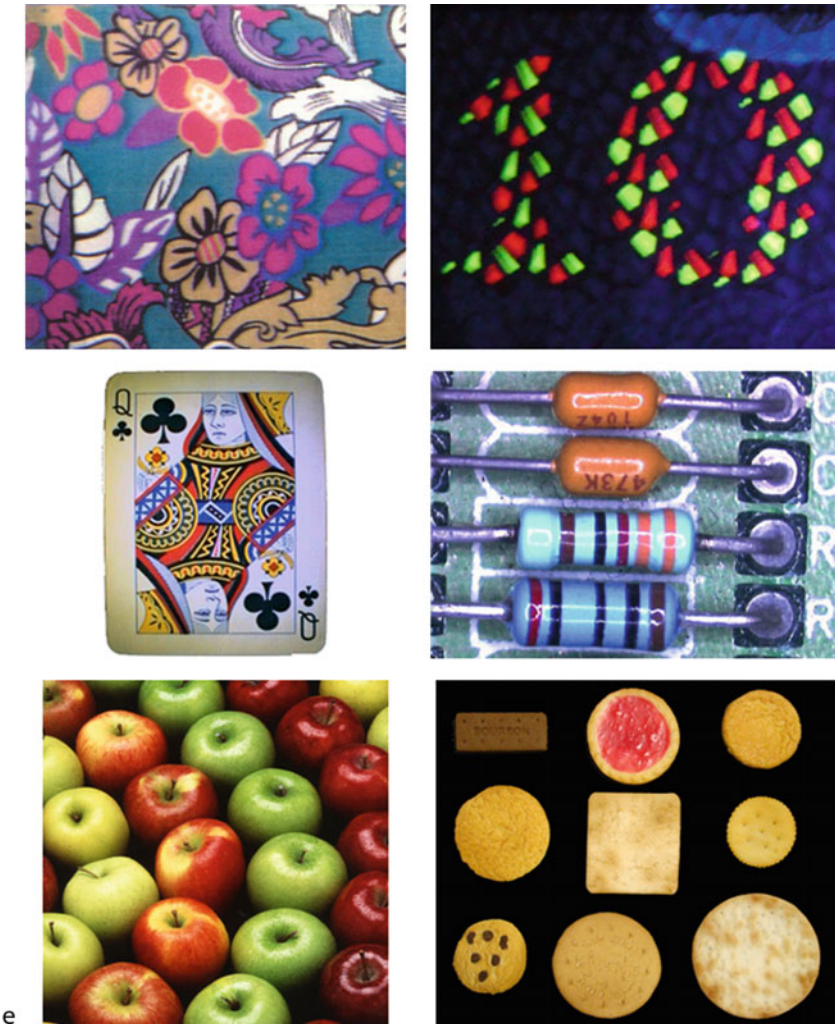

Fig. 1.4
A sample of the industrial applications of Machine Vision that the author has encountered during his career (5 pages). Further details are given in *Table 1.1*

belief that CV is intellectually “deep,” while Machine Vision requires a broader range of skills. There should be mutual respect between the practitioners of these two subjects. Unfortunately, this is not always so. We will argue that MV should be regarded as a distinct academic and commercial subject, deserving its own institutions for organising meetings, publishing results, honouring its leading exponents and with its own funding programme for research and advanced development.

There is a natural assumption among non-specialists that MV and CV are synonymous, because they both refer to Artificial Vision. In addition, many researchers blur the

Table 1.1

Details of the machine vision applications illustrated in ➋ *Fig. 1.4*. The *left-most column* (labelled R/C) indicates the row/column position for the sub-images. In the *right-most column* of this table, safety critical inspection tasks are indicated by ''Yes,'' while possible indirect safety concerns are signalled with ''Maybe.'' For example, PCBs are used in a variety of situations, including safety critical applications. Numerous other examples are given in [1– 6]

R/C	Description	Check/measure/operation	Safety
(a)			
1/1	Integrated circuit, x-ray	Bonding of wires	Maybe
1/2	Bare printed circuit board	Conductor integrity	Maybe
2/1	Turbine/compressor blade	Precise dimensions	Yes
2/2	Hydraulics manifold (casting)	Internal threads, debris, swarf, etc.	Yes
3/1	Automobile brake unit	Correct assembly	Yes
3/2	Thick film circuit	Component assembly	Maybe
(b)			
1/1	Aerosol assembly, x-ray	Complete/correct assembly	Yes
1/2	Light bulb	Loose wires	Yes
2/1	Battery tops	Moulding integrity	
2/2	Robotics (XYθ-table)	Automated handling	
3/1	Cake decoration patterns	Cosmetic appearance	
3/2	Food container (glass jar)	Foreign bodies	Yes
(c)			
1/1	Coil with flying leads	Automated assembly	
1/2	Glass bottle	Cracks, splinters, moulding faults	Yes
2/1	Automobile brake pad	Correct type, integrity of assembly	Yes
2/2	Uncut gems (sapphires)	Sorting/grading/measurement	
3/1	Rattan cane web for chairs	Appearance and integrity	
3/2	Car brake cylinder	Internal scratches on bore surface	Yes
(d)			
1/1	Aerosol spray jet	Measurement of jet	
1/2	Plant, micropropagation	Automated dissection	
2/1	Food containers (6 cans on a tray)	Foreign bodies (internal)	Yes
2/1	Sports shoe upper	Automated stitching	
3/1	Diamond grind wheel	Automated placing of diamonds	
3/1	Shoe components	Sorting	Yes
(e)			
1/1	Dress fabric	Colour imprint alignment	
1/2	Fluorescent security marking	Verify presence/shape	Maybe
2/1	Packaging (representative image)	Colour imprint alignment	Maybe
2/2	Populated PCB	Assembly of components	Maybe
3/1	Fruit	Grading, counting, sorting	
3/2	Baked goods	Size, shape, filling, contamination	Yes

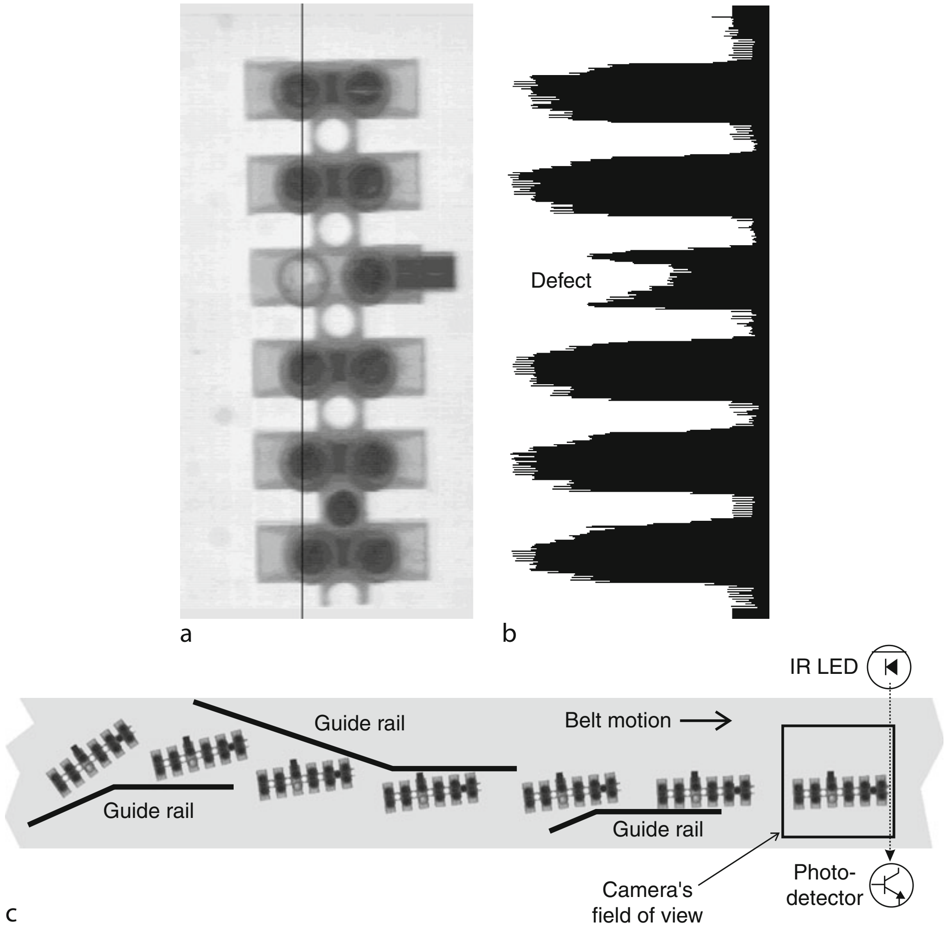

Fig. 1.5
Making inspection easier by standardising the orientation and orientation of an object. The alternative may be some quite slow and/or costly image analysis. (a) Electrical connector block. (b) A simple intensity profile along the vertical black line in (a) is able to detect the defect. (c) Using guide rails on a continuously moving conveyor belt limits the variation of orientation. The horizontal position is "fixed" using the photo-electric proximity sensor which triggers the image inspection process

boundaries separating *Machine Vision* from the subjects of *Artificial Intelligence (AI)*, *Digital Image Processing (DIP, or simply IP)* and *Pattern Recognition (PR*, alternatively called *Neural Networks)*. Of these, DIP is most often confused with MV because it too is concerned with Artificial Vision. Photoshop™ and similar packages perform DIP, although this is not the limit of its scope, which also encompasses tasks such as contrast enhancement of medical x-rays and images from security cameras. DIP is an essential component of both CV and MV, which is the cause of the confusion between these terms. PR and to a smaller extent AI, are sometimes perceived as encompassing aspects of MV, although the distinction is greater than for CV. Several other terms need to be mentioned before we begin our discourse in earnest. *Automated Visual Inspection (AVI)*, *Robot Vision* and *Visual Process Control/Monitoring* are sub-sets of MV. However, the term *Robot Vision* is also used when referring to the theoretical aspects of robot control, as a sub-set of AI.

All of the terms mentioned above are frequently used in an imprecise way, by both writers and speakers at conferences. There is no doubt that the sloppy use of these terms has been the cause of a considerable amount of confusion, in the past. This has often resulted in unsatisfactory service being provided to would-be customers of vision systems. It has also hampered research, and has probably hindered career progression of engineering practitioners.

The problem of nomenclature arises because MV, CV, DIP and sometimes AI and PR are all concerned with the processing and analysis of pictures using electronic equipment. Notice that we did not mention computers explicitly, since not all processing of pictures takes place within a device that is recognisable as a digital computer. Of course, CV assumes that these activities do take place inside a computer. On the other hand, MV does not impose such a limitation, although computer-based processing of images is encompassed by this term. MV allows the processing of images to take place in specialised digital networks, arrays of field-programmable gate arrays (FPGAs, ➲ Chap. 25), multi-processor configurations, optical/opto-electronic computers, analogue electronics, or hybrid systems.

It must be understood that MV, CV and DIP share a great many terms, concepts and algorithmic techniques but they have a completely different set of attitudes and priorities (see ➲ *Table 1.2*). To summarise, the division between MV and CV reflects the separation that exists between engineering and science. Just as engineers have long struggled to establish the distinction between their activities and science, we are trying to do the same for MV and its scientific/ mathematical counterpart (i.e., CV). See ➲ *Table 1.3*.

This confusion of terms is even manifest in the names of learned societies. For example, the *British Machine Vision Association* holds a series of conferences in which almost all of the papers are in what the author maintains is CV. There is certainly a great difference between the articles included in the proceedings of the BMVA on the one hand and those organised by *SPIE – The International Society for Optical Engineering*. Indeed, it is doubtful whether many of the papers that are acceptable to a BMVA audience would be welcomed at an SPIE conference, or vice versa. This fact does not, in any way, detract from the worth, or intellectual content of either "camp"; it merely reflects a difference of approach and priorities. In the case of Machine Vision, the latter are usually manifest in terms of the design criteria imposed by the application.

1.3.1 Non-industrial Applications

In this handbook, we concentrate our attention on industrial applications of vision system, for such tasks as inspecting, measuring, verifying, identifying, recognising, grading, sorting, counting, locating and manipulating parts, monitoring/controlling production processes, etc. Vision systems may be applied to raw or processed materials, piece parts, assemblies, packing, packaging materials and structures, continuous-flow products (webs, extrusions, etc.), simple and complex assemblies, or to tools and manufacturing processes. They can also be applied to complex systems (e.g., complicated physical structures, pipe-work, transport

Table 1.2

Machine vision compared to computer vision. Entries in the machine vision column relate to factory-floor target vision systems (TVS), unless otherwise stated. IVS denotes Interactive Vision System

Feature	Machine vision	Computer vision
Cost	Critical. Cost-effectiveness is central consideration	Secondary importance compared to performance
Dedicated electronic hardware?	Possible. This is becoming less common as CPU speeds increase.	No. Required flexibility and intelligence require software
Engineering or science?	Systems Engineering, practical, pragmatic, experimental	Computer Science, academic, strong research element
Image acquisition and image processing sub-systems designed independently	No; lighting-optics sub-system designed experimentally using an IVS.	Yes; pre-existing image acquisition sub-system cannot be modified after analysing images with IVS
In situ reprogramming to accommodate new applications	Possible. System should be extensible and reusable	Unlikely. Single difficult application solved
Input ''data''	Piece of metal, plastic, glass, wood, etc. to be inspected	Computer files holding digital images
Knowledge of human vision influences system design?	Unlikely but this is not an excuse for seeking inspiration from nature	Possible. Much of CV research is directed specifically to understanding human vision
Motivation	Solving practical problems, to improve safety and/or reduce costs, or for social reasons (e.g., improve environment)	Search for knowledge, or solving complex academic problems
Multi-disciplinary subject?	Yes. Holistic design is essential	No. IP sub-systems designed with scant regard for other modules
Nature of an acceptable solution	Satisfactory performance at affordable price, with acceptable processing speed	Optimal performance of paramount importance
Nature of the subject	Pragmatic. Practical consideration usually take precedence over academic rigour	Academic research. Publications normally contain a lot of ''deep'' mathematical analysis
Operator skill level required	(a) IVS medium/high (b) TVS must be able to cope with low skill level	May be very high
Output data	Simple logical or quantitative signal (e.g., ACCEPT/REJECT, or position coordinates to control robotic equipment)	Complex output signal, may be symbolic qualitative, intended for human being
Practitioner's skills	Multi-disciplinary: Systems Engineering, optics, lighting, computer architecture, software. Practical and experimental skills essential	Computer Science/mathematics, theoretical, software

Table 1.2 (Continued)

Feature	Machine vision	Computer vision
Principal criteria by which a system is judged	(a) Ease of use, (b) Cost-effectiveness (c) Consistent and reliable operation	Performance
Role of image processing	IP is just one of many technologies but is not more important than others	Image processing is dominant
Speed of processing	(a) IVS must be fast enough for effective interaction (b) Speed is critical factor for TVS.	Not normally of prime importance.
System operates free standing?	(a) IVS interacts with human operator (b) TVS must be able to operate free-standing	May rely on human interaction or operate autonomously, depending on the application
User interface	Critical feature for both IVS and TVS but for different reasons	May be able to tolerate weak interface as system is probably used by experts in application area

mechanisms, etc.) and to a wide range of factory-management tasks (e.g., monitoring material stocks, checking the floor for debris, controlling cleaning, ensuring safe working conditions for human operators, etc.)

Machine Vision is also applied to a variety of other areas that have considerable significant commercial importance and academic interest:

- Aerial/satellite image analysis
- Agriculture
- Document processing
- Forensic science, including fingerprint recognition
- Health screening
- Medicine
- Military applications (target identification, missile guidance, vehicle location)
- Research, particularly in physics, biology, astronomy, materials engineering, etc.
- Security and surveillance
- Road traffic control/monitoring (the London Congestion Charge is an example)
- Personal identification using biometric data

It would be possible to analyse each of these non-industrial applications areas, in order to establish a broader horizon for Machine Vision.

Systems Engineering is at the very heart of Machine Vision. For this reason, it is unacceptable to limit our concern to the mathematics and algorithms, or any other single aspect of the system design task. What is unique about industrial Machine Vision is the huge variety of potential applications. While there is a large market for machines that can detect tumours in mammograms, read car registration plates, or identify people from iris scans, these are niche markets. On the other hand, a large manufacturing

Table 1.3
Technologies needed to design a machine vision system

Technology	Remarks
Algorithms/heuristics for image processing	One of the principal subjects in this book. Notice that Machine Vision and Computer Vision are likely to place emphasis on different image processing methods.
Analogue/video electronics	Analogue pre-processing can be a cost-effective way to reduce the data rate and/or improve signal-to-noise ratio. Nowadays, many proprietary cameras generate digital outputs, so modifying the analogue preprocessing is impossible.
Communications/ Networking	TVS may be networked to stock-control, work-control, and management computers. May also be interfaced to real-time factory control systems, PLCs, etc.
Digital electronics	Digital pre-processing can provide a cost-effective way reduce the data rate and improve signal-to-noise ratio.
Industrial engineering	TVS must be robust and provide reliable operation in a hostile factory environment
Lighting	Lighting is a critical component for any Machine Vision system. (N.B. Shrouding is needed to eliminate ambient light and is just as important as the applied lighting.)
Mechanical Engineering	• Good mechanical handling is essential for presenting objects to the camera in a controlled manner (N.B. Defective parts must not jam the handling unit) • Vibration-free mountings are needed for widget, lights, optics and camera
Optics	Numerous special effects can be provided by lighting and optics and can often convert a very difficult problem into a trivial one.
Quality Control and Production Engineering	TVS should comply with current operational and environmental working practices, QC protocols, etc.
Sensor	• The imaging sensor may detect 1-D, 2-D, or 3-D spatial patterns using one of the following physical sensing media: gamma ray, infra-red, magnetic field, microwave, electron beam, pressure, surface profile, ultra-sonic, ultra-violet, visible, x-ray, etc. • Various image formats are possible provided by: array-scan camera, line-scan camera, flying-spot scanner,
Software	The software should be well engineered as it is likely to be reused for new applications
Systems Engineering	It is essential to maintain a good overall "balance" throughout the TVS; no component should be under stress because other parts have been neglected during the design.
User interface	An ergonomic interface is essential as users may be untrained.

company may introduce many hundreds of very different products every year, each with a life-time of no more than 2–5 years. Designing reliable, versatile and reusable inspection equipment for these presents a challenge that is unique to industrial applications.

1.3.2 Does It Matter What We Call Our Subject?

The answer is most emphatically *YES*! There are several reasons why MV deserves to be identified as a subject in its own right.

- To ensure proper refereeing of academic papers
- To promote appropriate funding of research
- To protect potential customers of vision systems from claims of expertise in MV, by workers who have a narrow field of expertise and are therefore not competent to design a complete system
- To protect the careers of its practitioners

Most technical papers in Machine Vision are not intellectually "deep," as those in CV usually are; papers on MV are usually much broader in their scope. It is usual, for example, to find a rather small amount of detailed mathematical analysis in a paper on MV. If mathematics is present at all, then it is almost certainly directly relevant to the solution of a practical problem. On the other hand, many papers in CV seem to be written with the deliberate intention of including as much mathematics as possible, seemingly to impress the readers with the author's erudition. The author of this chapter has on several occasions received quite critical comments from referees of academic papers who are clearly unaware of the distinctive nature of MV. (It should be made clear that, in several cases, the same article was subsequently published in a forum that is more sympathetic to "systems" issues.) There is a distinct tendency for workers in CV to dismiss papers in MV as being trivial, or shallow, because they do not contain a lot of analysis. On the other hand, a well-written paper on Machine Vision is likely to cover a wide range of practical issues, such as object transportation, lighting, optics, system architecture, algorithms, human factors, etc. Hence, papers that concentrate solely on the mathematics and algorithms of image processing may not be acceptable in a journal or conference on Machine Vision.

In similar way, the assessment of applications for grants or promotion can be biased, if the referee thinks his or her skills are appropriate when in fact they are not. For this reason, the distinction between MV and CV is crucial. A mistaken impression of a person's total contribution to a project can be gained by someone who does not understand the full scope of his work. Just as it would be unsuitable for a person trained in, say, mathematics to judge a hardware engineer, so it is inappropriate for a CV *specialist* to make categorical judgments about an MV *generalist*. (The significant words are set in italics.)

There is good reason to believe that research grant applications are sometimes rejected because the referee fails to understand the full significance of a new approach. Referees who look for significant new techniques in algorithms will not normally be impressed by grant applications that concentrate on "systems issues," such as the inter-relationships between the choice of mechanical handling device, optics, camera, and computing system architecture. As a result, perfectly sound MV grant applications are sometimes rejected. Of equal significance is the problem of inferior grant applications being accepted because the referee is unaware of broad "systems" issues, or new developments in MV thinking that make the proposed approach less than optimal. For example, a new kind of camera may eliminate the need for a certain type of image processing operation. Or, a new type of lamp, or optical filter, may enhance image contrast to the point where only the very simplest type of processing is necessary.

Perhaps the most important single reason for needing to protect the identity of MV is to avoid the damage that can be done to its reputation by charlatans. Indeed, a great deal of harm has already been done by specialists in CV, DIP, PR and to a lesser extent AI *dabbling* in Machine Vision when they are not competent to do so. Ignoring image acquisition issues is a sure way to generate an over-complicated image processing solution to a problem. Often, the requirements of an application could be satisfied better by a simple adjustment to the lighting or optics, rather than adding sophistication to the image processing. The classic problem of this type is that of thresholding an image. There are *many* ways to achieve high-contrast images, some of which do not require the use of conventional back-illumination (➔ Chaps. 8 and ➔ 40). Ignoring such a possibility and then resorting to an over-complicated dynamic thresholding technique is simply poor engineering practice. There is no doubt that many installed vision systems use excessively complicated algorithms to compensate for poor lighting. From time to time, over-zealous and ill-informed salesmen have claimed that their vision product is able to operate in uncontrolled ambient light. This is simply not true. Given the present state of our knowledge of the subject, claims of this kind are fraudulent! Many other vision systems are less reliable than they could be, had they been designed from the outset with a good appreciation of all of the systems issues involved.

To summarise, there is no excuse for fooling a customer who has no detailed knowledge of our subject, into thinking that a specialist in CV is competent to design a system for use in a factory. Unfortunately, intellectual honesty is not a universal virtue and the consequences of misleading customers like this can have a major impact on the wider, long-term public perception of a maturing technology such as MV. There are subtle ways in which erroneous views can be propagated and perpetuated. Every MV engineer knows that very subtle points can sometimes lead to the undoing of an otherwise successful application. For example, static electricity may make it very difficult to keep optical surfaces clean. This can reduce image contrast sufficiently to render a certain algorithm unreliable. Another example is the potential health hazard that can arise when inspecting objects transported on a fast, continuously moving conveyor. In order to "freeze" the object motion for viewing with an array-scan camera, stroboscopic illumination could be used. However, flashing lights can induce migraine attacks, epileptic fits and cause rotating shafts to appear stationary. On the other hand, using a line-scan camera, or an array-scan camera with a fast electronic shutter, avoids this altogether.

1.4 Four Case Studies

Lest the reader is still unconvinced, we will now consider four practical applications which highlight the essential identifying feature of Machine Vision: the need for a Systems Engineering approach to design. We have attempted to encapsulate the experience that is needed to design a successful Machine Vision system in a series of proverbs (➔ Appendix C). Five of these relate specifically to the need to define the intended function of a vision system.

- The specification of the vision system is not what the customer wants.
- No machine vision system can solve the problem that the customer forgot to mention when placing the order.
- The specification of a vision system should indicate its functionality and performance.
- Beware when the customer says "By the way! . . . We would like to be able to inspect some other objects as well."
- The customer said his widgets were made of brass. He did not think to state that they are always painted blue and are oily.

Another Proverb has gained particular resonance with the author's colleagues working in MV and summarises a danger that is peculiar to the design of vision systems:

- Everybody (including the customer) thinks he is an expert on vision and will tell the vision engineer how to design the machine.

That is totally wrong! Such an opinion has to be firmly corrected and then reinforced over and over again.

In order to emphasise that MV is an aspect of Systems Engineering, we will trace the history of four very different industrial projects in which vision systems were commissioned:

1. The project specification was drawn up without reference to what is technically possible, or economically feasible. No experienced MV engineer was involved.
2. The vision system was designed successfully by an experienced team working full-time in MV. An unusual image-acquisition sub-system was designed in a series of experiments using very simple equipment. This greatly simplified the image processing required.
3. The client specified the problem in a totally inappropriate way. Good engineering practice detected the problem before it was too late.
4. The specification of an AVI system evolved during the preliminary contract negotiations and the final machine was very different from that first envisaged. This dialogue would never have taken place without an experienced MV engineer being involved.

In each case, the engineers working in the client company had no previous experience with Machine Vision technology. They differed in their willingness to learn and accept the advice given by an experienced vision engineer. As a result, these four projects reached very different conclusions.

1.4.1 Doomed to Failure

The first project epitomises an approach that almost inevitably leads to failure and disillusionment with MV technology.

A certain company makes complex, high-precision components for domestic goods, by a process involving several stages of pressing and punching sheet steel. Some of the products display a variety of faults, including both functional and cosmetic defects. The company, in association with a well-respected university department, set up a joint project. The investigator was a young graduate in Production Engineering, with no prior experience of Machine Vision. In addition, his supervisors had very limited experience in this technology. Inexplicably, the university-company partnership succeeded in gaining funding for this project from both government and board-level company sources. The university also had an established link with a major electronics company that lead to a decision, quite early in the course of the project, to purchase a certain (old-fashioned) turn-key image processing system. This decision was made for political rather than sound technical reasons. The specification of this system was far inferior to that available from a modern general-purpose computer costing about 25% of the price. At the stage when this decision was made, the lighting-optics-viewing arrangement had not been considered seriously and no image processing algorithm had been designed or selected. There was no evidence at all that this turn-key system would be able to implement the necessary image processing functions, since the requirements at this stage were simply not known. It is interesting to note that, during the middle phase of the project, two highly experienced MV engineers were given privileged access to the work of this group and counselled strongly but unsuccessfully against the approach being adopted. (Recall the Proverb which states that everyone thinks that he or she is an expert in vision.) The system specification was drawn up without any reference whatsoever to what is possible in technical, financial or human terms. The outcome in such a situation is inevitably failure and disillusionment with MV technology. The project failed!

1.4.2 A Successful Design

In the mid-1980s, engineers in a certain company were in the late stages of building a fully automatic flexible-manufacturing system, designed to produce over 50 different products, when they realised that they would be unable to complete the task without a non-contact parts-location system. The requirement was well-specified and was highly suitable for a vision system. The client company contacted a company specialising in designing and building Machine Vision systems. The latter company could not, at first, see a path leading towards a successful solution and, in turn, consulted a very experienced MV researcher. He devised an experiment involving a plastic meal-tray, a dress-maker's tape measure, a desk lamp and a standard surveillance-type video camera. (He needed to simulate a motorised turn-table, a line-scan camera and oblique lighting.) Acquiring each image took over an hour, with three people participating. Nevertheless, a series of test images was obtained and a suitable image processing algorithm devised, using an interactive Machine Vision system of the type described in later pages of this book. On the basis of these seemingly clumsy experiments, the vision company was able to design, build and install a well-engineered target system. It worked very well, except that sun-light caused intermittent optical interference. However, a solution was soon found. This consisted of a metal screen placed around the camera and object to be inspected, to block out ambient light. The final vision system was highly successful and worked reliably for several years. The important point to note is that consulting a suitably experienced Machine Vision engineer early in the project lead to a highly successful solution. Although the resources used in the early experimental stages of this project were severely limited, they were appropriate for the purpose and a good system design ensued.

1.4.3 Mouldy Nuts

A highly experienced and well-respected MV engineer was commissioned to design a machine to inspect nuts (the edible variety), to detect patches of mould on the surface. He was supplied with a large bag of nuts, to enable him to design the inspection machine. He expended a lot of effort on this exercise. When he had completed the task to his satisfaction, he contacted the client, to arrange a demonstration. When the engineers from the client company arrived for the demonstration, they brought with them another large bag of nuts, hoping to test the vision system on previously unseen samples. (This idea is, of course, very sensible, in principle.) The vision system did not respond well in these tests and failed to satisfy the client's expectations, for one very simple reason: the new sample of nuts had fresh mould which was *green*. The samples originally supplied to the vision engineer to help him in the design process had older *brown* mould. The client had omitted to tell him that the green mould quickly changes colour to brown. This fact was obvious to them but they had not thought it important to tell the vision engineer. Since brown mould patches can be identified by eye, it was "obvious" to the client that the green mould could be detected just as easily by a Machine Vision system. It is a universal truth that, whenever the client tries to tell the vision engineer how to do his job, trouble is about to occur.

The lesson for us is that although the system was not designed appropriately in the first instance. The good engineering practice of testing the system on data independently of that used during the design highlighted a serious problem. The result was annoying but not disastrous, as it was fairly easy to redesign the system to recognise the coloured mould. In fact, the revised design was considerably simpler than the first one!

1.4.4 A System That Grew and Grew

In this section we describe how one application, which was initially conceived as requiring a single-camera vision system, grew to much more massive proportions. As we will see, the original concept grew very considerably, during the dialogue between the customer and the vision engineer. Of course, this is the best time of all for the specification to change! In this project, the vision engineer, was encouraged by the client to explain how Machine Vision could form part of a much larger system. In this case, the system that was eventually built was a complete parts-handling machine, which just happened to incorporate Machine Vision, among several other functions. In the machine that was finally delivered to the customer, the vision sub-system was fully integrated into the larger machine and was no more, nor less, important to the overall function than that of the other equipment. In other words, the vision engine formed just one of many components of the larger system. The specification of the system was developed during several conversations, involving the MV engineer and his client. Here is a brief history of the project:

1. The MV systems engineer was invited to provide advice about the provision of an Automated Visual Inspection system for components used in the automotive industry. At first sight, the task seemed straightforward: the customer wanted to ensure that certain safety-critical components met their specification, but wanted to avoid the long and tedious tests then being performed manually. A significant speed increase (greater than 100%) was also expected. The initial specification was for a machine that could locate four fixing holes at the corners of the component, which consists of a flat, nearly-rectangular, metal plate, with a central cylindrical spindle, normal to the plate (➋ *Fig. 1.6*).

   In the first instance, measuring the positions of the centres of these holes appeared to be a straightforward task. However, the project became ever more complex as successive meetings took place between the MV engineer and the client.
2. The *Production Engineer* had ambitious ideas! He reasoned that, if the inspection system could perform this task, then why not others, as well? So, he added the requirement to check that the holes are tapped. Clearly, the camera used to locate the holes could not be used to check these female threads, as the latter task requires an oblique view and a different lighting arrangement.
3. The third requirement, also suggested by the Production Engineer, was for another camera, with its associated image processing sub-system, to check and measure the male thread at the end of the spindle.
4. Then, a requirement was drawn up for yet another camera, to check that the heat treatment that this part receives during its manufacture has been completed. (Heat treatment causes perceptible colour changes.) Up to now, the object to be examined could be inspected while it was static.

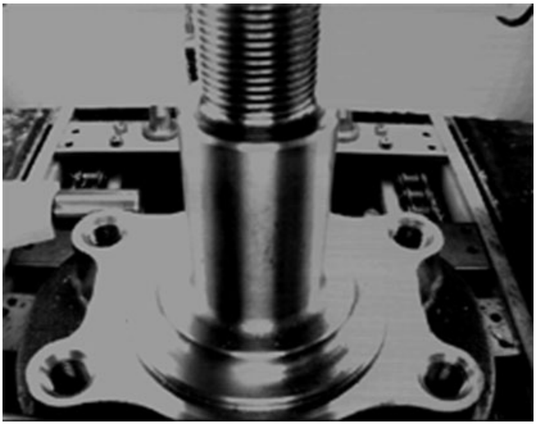

Fig. 1.6
Subject of a simple task that grew and grew as more inspection functions were added

5. Since the spindle diameter is critically important, yet another requirement was introduced. However, this one was satisfied without the use of vision. Four swinging arms, each carrying a digital micrometer, were used to measure the spindle diameter. The result is more accurate than a simple vision system could achieve. Requirements 1 to 5 were all suggested by the Production Engineer.
6. Next, came the requirements defined by the *End-of-line Packer*: The parts are sprayed with an anti-corroding agent, prior to shipping out of the factory. Before they are sprayed, the parts must be cleaned. This involves an all-over spray, with particular attention being paid to the four fixing holes. (These might contain swarf and other particulate debris.) The cleaning process was to take place in an on-line washer, with the parts being transported on a continuously-moving conveyor belt. The cleaning process also imposed a need for a component drying station.
7. The *Quality Control Engineer* was the next person to participate in specifying the system requirements, by suggesting an additional function for the new machine. He pointed out that there is a need for a marking system, enabling defective components, the machine and shift responsible to be identified later. Since the parts are painted shortly after they have been made, the marking must be engraved. In order to accommodate this function, the conveyor belt had to be lengthened. This had an unfortunate effect on product safety: objects that have already been rejected as faulty could mistakenly be returned to the *ACCEPT* region of an unguarded conveyor. To prevent this, faulty parts should pass into a secure cabinet that is accessible only to a trusted member of staff.
8. The *Line Supervisor* provided the last suggestion for embellishments to the planned machine. With only a little additional complication, the machine can be made totally automatic, with no operator intervention whatsoever. This required the provision of loading and ejection bays.

So far, we not even begun to discuss the attitude of the accountants to all this! That is another story that need not concern us here. Let it suffice to say that the accountant did finally agree that the (enlarged) machine should be built. To a novice, this story may seem exaggerated. However, it is a real-life experience and, in general terms should be regarded as typical, rather than exceptional. Notice how much of the specification of this machine is concerned with nonimaging tasks. Of considerable importance in the negotiations is the improvement in confidence that results from the vision engineer being able to demonstrate each step in the developing inspection strategy. (We will return to this particular point many times later in this handbook.)

1.5 Machine Vision Is Engineering, not Science

The experience outlined in these four case studies is not unique. They all emphasise the importance of proper initial planning. One crucial part of this is reaching a clearly defined agreement between the customer and the vision engineer about the real objectives of the exercise. In ➜ Appendix B, we include the Machine Vision System Design Questionnaire. This was specifically designed to assist during the negotiations that will take place in the initial phases of a Machine Vision project. It does so by high-lighting a broad range of issues that might otherwise have been overlooked in the discussion between the vision engineer and his client. The use of a pre-defined structure for the system and contract specifications should not be taken as an excuse to stifle dialogue between the vision engineer and his customer. The specification for the system described in ➜ Sect. 2.4.4 evolved during several weeks of detailed discussion between these parties working closely together. Dialogue is an essential feature of a successful design, since neither the vision engineer nor the client has access to all of the information necessary to complete the task without the involvement of the other.

Another point to note is that an experienced vision engineer may not always give the answer that the customer would like to hear but it may save a lot of problems later. One of the most valuable pieces of advice that a vision engineer can give is "*Don't use vision.*" Blunt words are sometimes necessary, to counter the prejudiced opinions of technically naive people who have an over-optimistic view of what Machine Vision can accomplish. Remember the maxim

- ▶ Wanting something does not mean that it is both technically possible and economically realistic

Excessive optimism arises whenever people try to translate what they *think* they see into terms relating to a machine. When they first perceive the possibility of using MV technology, would-be customers often expect miracles, because they think of themselves as being experts in vision. As a good working rule, it may be assumed that this is *never* the case, since introspection is a very unreliable method of determining how we perceive the world around us. Would-be customers are almost always totally unaware of both the limitations and potential of modern vision systems. Even if they have read about the subject, they are unaware of many of the subtle points of detail that can destroy a vision system's chances of ever working effectively and reliably. Very often during the course of the initial discussions between the customer and vision engineer, various requirements, not directly related to image processing, become apparent and from thereon form an integral part of the specification of a system with a far broader function than was at first imagined.

1.5.1 Systems Engineering

➜ Appendix D summarises the inter-relationship existing among those areas of study that a vision engineer must expect to encounter some time in his work. He should have, at least, a broad understanding of each one. ➜ *Figure 1.7* shows the general structure of two vision systems intended for use on the factory floor. ➜ *Figure 1.7a* relates to area-scan sensors and ➜ *Fig. 1.7b* to line-scan sensors. These are perhaps the most important diagrams in the whole

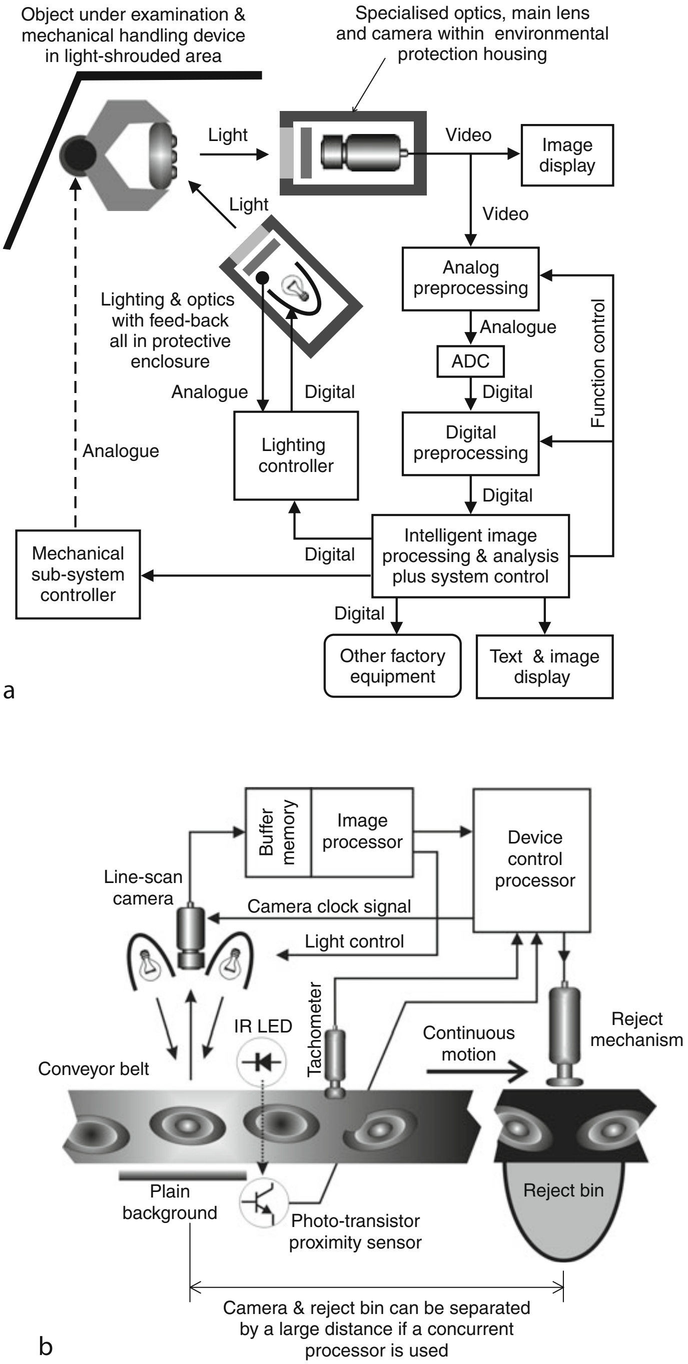

Fig. 1.7

Archetypal Machine Vision system (a) General scheme, applicable to a wide range of industrial applications and using an area-array sensor. (b) Typical on-line Automated Visual Inspection system based on a continuously moving conveyor belt

book. Like ➲ Appendix D, they emphasise that Machine Vision system requires a multi-disciplinary approach, combining and harmonising skills and knowledge of several different areas of engineering: mechanical, video, electrical, analogue and digital electronics, control, illumination, optics, software (not visible in either diagram), ergonomics (human-computer interfacing), production/Quality Assurance and, of course, systems integration. A machine intended for the factory floor will be termed a *Target Vision System* (*TVS*). (This name was chosen because a TVS is the end result of the design process.) Some systems may not require all of the modules depicted in ➲ *Fig. 1.7a* and there may be other minor modifications to take account of application specific issues. For example, when low-speed processing is acceptable, a standard computer may be able to perform all of the image processing operations required. When high speed is essential, dedicated image processing hardware may be necessary (➲ Chap. 25). In many instances, a separate intelligent processing module is not needed. ➲ *Figure 1.7* encompasses systems that employ visible light (VIS), microwave, infra-red, ultra-violet, x-ray and gamma-ray sensing and requires only minimal changes to cover neutron-beam, electron-beam and ultra-sonic imaging systems as well. The same diagram also covers systems that exploit fluorescence and phosphorescence.

No diagram can properly convey the critical point that it is the *interplay* between the different parts of a vision system that determine whether it is successful or not. Designing a system requires a mixture of experience, knowledge, intelligent analysis and experimentation. (➲ Appendices C and ➲ D) How the design process is performed is discussed in detail in these pages. There are two crucial parts to the design process: choosing the image acquisition sub-system and analysing the image data that it generates. All of this must be done with the sole objective of producing the design for a robust, reliable machine that serves the agreed purpose. In ➲ Chaps. 8 and ➲ 40, we list and illustrate about 130 different lighting-viewing configurations. These can be used singly, while two or three may be combined for some applications. There is no algorithm for choosing the most appropriate one, or combination. Neither is there any prescription for analysing the images so generated. Moreover, the choice of the image acquisition hardware and the image analysis software/hardware are intimately bound together. In these pages, we describe how optical components, cameras and image processing procedures work. We also explain how experimentation helps in the design process. We cannot fully encapsulate the experience, nous and low cunning of an experienced vision engineer in a computer program. The best we can do is make good use of human intuition by building appropriate tools to assist in the design process.

1.6 Design Tools

Despite the rapid progress that has taken place in Machine Vision technology in recent years, there remains a significant and pernicious problem: the very large amount of highly skilled engineering effort needed to develop systems for each new application. It has been claimed many times, by numerous salesmen, authors and conference speakers, that Machine Vision is a very flexible technology, ideal for sensing defects in a very wide range of industrial products and manufacturing processes. The fact that Machine Vision is potentially able to fulfill the needs of a very diverse range of industrial inspection, monitoring and control tasks has already been established in numerous laboratory-based feasibility studies. However, this oft-claimed versatility is merely an illusion, if there are not enough people with the necessary systems engineering skills to design and build machines that will continue to operate effectively and reliably on the factory floor. Bearing these ideas in mind, it becomes clear that a variety of computer-based design tools for Machine Vision would be valuable. If properly implemented, such tools would reduce the skill level for many of the sub-tasks in the design process. In this way, we hope to improve the overall effectiveness of the available pool of skilled labour.

The major tasks for which help is most needed may be included under the following headings:

- Overall planning of a vision system, given a range of general application constraints
- Configuring the optical sub-system (i.e., placing the lighting, optical elements and camera)
- Calculating field-of-view, depth of focus, camera/image resolution, etc.
- Choosing an appropriate image sensor (camera)
- Designing the optical sub-system (i.e., choosing the lens and mirror configuration, coatings, mountings and performing the detailed design of multi-element systems, etc.)
- Selecting and designing an appropriate image processing algorithm.
- Designing and programming a target system, for use on the factory floor.

1.6.1 Image Acquisition

➋ Chapter 40 contains a catalogue of over 150 different lighting/viewing methods (read ➋ Chap. 8 first). These are presented in the form of descriptive text, optical layout diagrams and in some cases sample images.

Another important development that is intended to assist in the design process is prototyping systems for lighting and viewing. One of these, called Micro-ALIS, consists of an optical bench and a range of high-precision fibre-optical illuminators, with rapid-release clamps to hold them in situ. The other system, called ALIS 600, is a light-proof cabinet containing a range of different light sources, which are operated under computer control. [*ALIS600* and *MicroALIS* (Application Lighting Investigation Systems) were previously products of Dolan-Jenner Industries, Inc, URL http://www.dolan-jenner.com/ They are no longer included in the product list of that company.]

1.6.2 Algorithm Design

The design process for a TVS has been summarised in the form of a flow chart (➋ *Fig. 1.8*). It is not possible to design a vision algorithm as one would, for example, write a program to perform statistical data analysis. The reason is exactly the same as that which prevents a person from becoming an expert on vision simply by introspective analysis of his or her own thought processes. A person writing a vision program needs to see the results of each step in the procedure. With very few exceptions, a person cannot simply look at a picture, mentally analyse it as a computer would and then decide what algorithmic steps are needed to extract a given item of information from it. Interactive image processing was devised in the mid-1970s and has been found to be a valuable tool for designing/choosing a vision algorithm. Its rôle in designing an industrial vision system is illustrated in the following anecdotes, which describe actual projects in which the author has been involved.

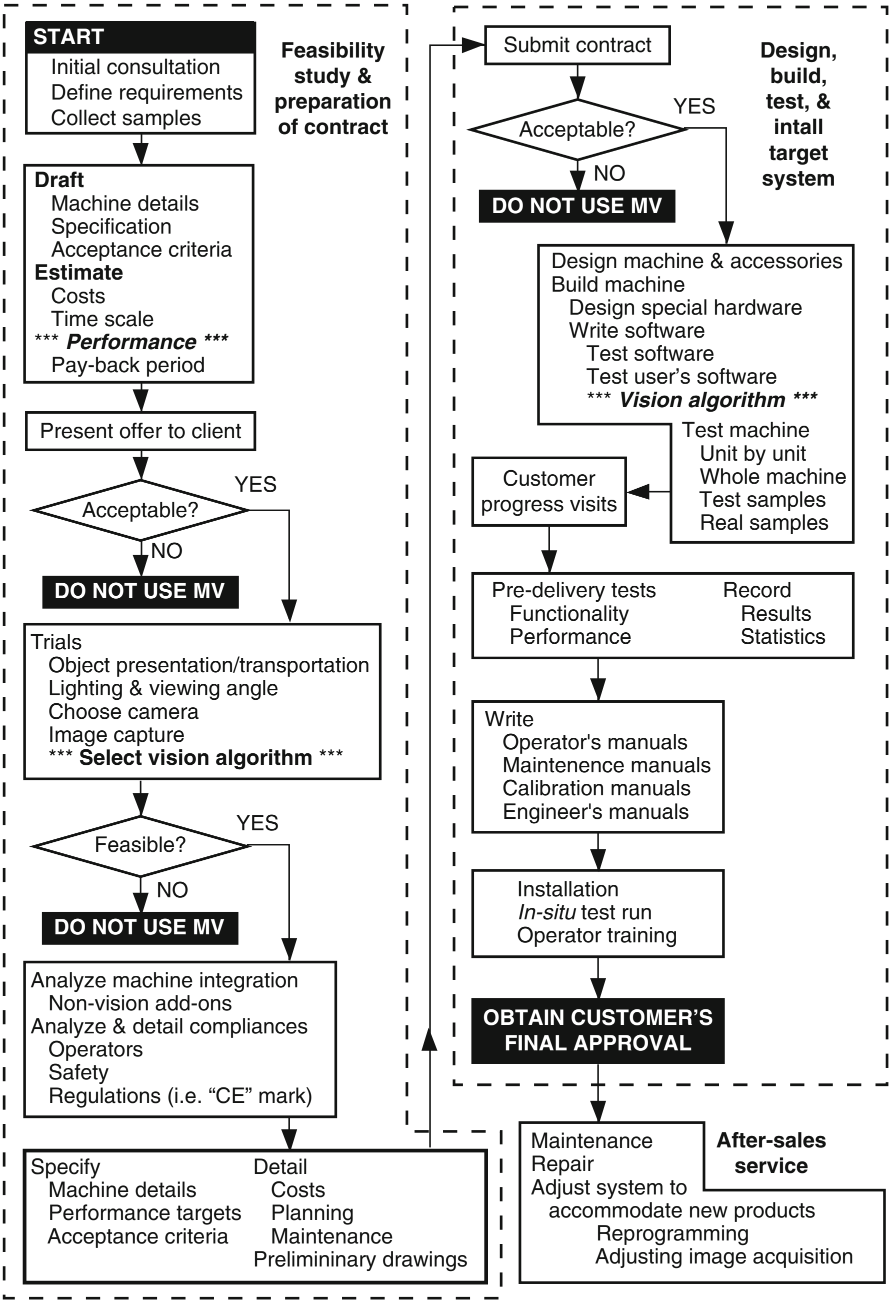

Fig. 1.8

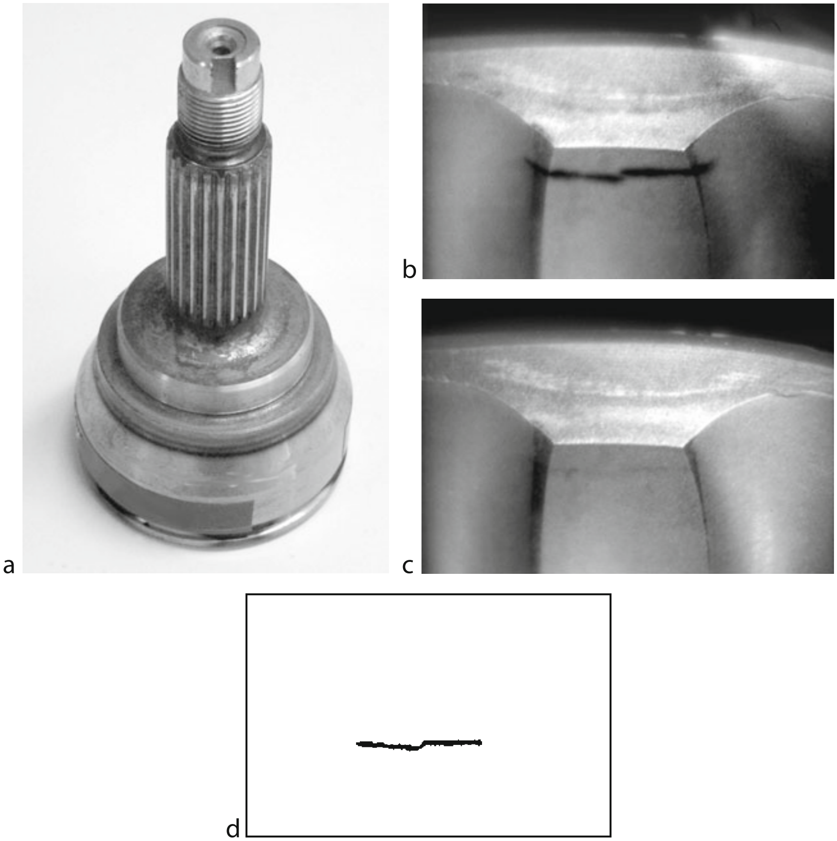
Designing a target vision system for use in a factory

1. A certain company wished to build a system for checking the characteristics of an aerosol spray. Among other parameters, the spray-cone angle was to be measured. The particular spray material that interested the client would have been rather unpleasant to use. Instead, the client was prepared to study the application by using a less noxious material: furniture polish. A simple set-up was arranged, consisting of a light immediately above the spray cone. A black board, located behind the spray, acted as the visual background (➋ *Fig. 1.4d*) shows the negative image. Using this simple arrangement, several images were digitised and then processed, using an interactive vision system (IVS), which was used to explore various processing options. On this occasion, it took the author only a few minutes to derive a suitable image processing algorithm that could estimate the spray-cone angle and derive a measure of its symmetry. On the basis of this quick test, the client was convinced of the merit of using vision for his application. A *TVS* was then commissioned, designed and built.
2. A company wished to detect cracks in forged steel connecting rods for automobiles. In this instance, the client already employed a sophisticated method for detecting cracks, the so-called *Magnetic Particle Indicator* method. This involved magnetising the component, then immersing it in a suspension of very fine ferro-magnetic particles that are also fluorescent, within a kerosene base. The components are then shaken to remove excess "ink" and are dried in hot air. They are then illuminated by ultra-violet light, but with no applied visible light. The cracks fluoresce (in the visible wave-band) because the magnetic-fluorescent particles tend to adhere to the surface in regions where there is a high remnant magnetic field. The cracks highlighted in this way were then viewed using a video camera. The images were analysed using an IVS and an effective algorithm for detecting and measuring cracks was found within a few hours. On this occasion (early-1980s), an entirely new algorithm was developed and has subsequently been employed in many other industrial vision systems. Another technique for highlighting crack visibility is called the *Dye Pentrant Method.* In this case, a non-magnetic "ink" is used that has a high surface tension and low viscosity. ➋ *Figure 1.9* shows how effective the dye penetrant method is. Clearly, to ignore this type of "trick" is sheer folly!
3. A flattened toroidal alloy casting (➋ *Fig. 1.10a*) was presented to the author and his colleagues as a sample of a range of circular objects that were to be handled by a robot vision system. The client asked for a vision system that could measure the orientation of these components to a tolerance of 0.5°. An experiment was devised, simulating a line-scan camera observing the intensity profile along a radius of a turntable. As the component, located nearly concentrically on this turntable, was rotated (by hand), the virtual line-scan camera was sampled repeatedly, enabling a polar-coordinate intensity map to be created (➋ *Fig. 1.10b*). High contrast images were created by using low-angle illumination. The images were analysed by an IVS and an algorithm was devised in a few minutes. On this basis of this experiment, the client ordered a TVS to be built. The interesting feature of this exercise was the crude experimental rig, which had to be set up in a hurry, at minimal cost. The turn-table consisted of a plastic meal tray, with a dress-maker's tape measure stuck around the rim. This enabled the make-shift turntable to be rotated manually, by a fixed amount, after every line-scan. The virtual line-scan camera was, in fact a standard area-scan camera but only one scan line was kept. Since more sophisticated equipment was not immediately available during the afternoon when the hoped-for clients were available, a great deal of time and effort was saved by this exercise.



■ **Fig. 1.9**

Cracks in a forged-machined ferrous component. ("Tulip" for an automobile constant velocity joint) (a) "Tulip." The cracks are located just below the rim of the cup and are not visible from this view. (b) With a narrow band filter in the optical path. Some ambient light was deliberately tolerated here, to produce an image that is able to show off the power of the image processing. The ambient light reduces the image contrast. It is also possible to obtain a very high contrast using fluorescence: UV illumination and viewing in the visible wave-band. (c) Normal view, i.e., with no filter present. (d) Crack detected, using the QT command sequence *[crk(5), thr(145), kgr (50), dil(4), ero(4), rbe]* applied to (b) (see ➲ Chap. 21 for details)

1.7 Overview of This Book

Throughout this book, algorithms are frequently expressed using command sequences for the QT image processing software introduced in ➲ Chap. 21 and described in more detail in ➲ Chap. 41. This is done so that the reader can repeat the experiments. This will allow him to become much more familiar with image processing concepts. The reader is urged to experiment: adjust operating parameters, process new images, combine different functions. The best way to learn about QT is to "play" with it! QT's history and rationale are described in previous books by the same author [1–6].

1.7.1 General Principles

1.7.1.1 Chapter 2: Inspecting Natural and Other Variable Objects

Many chapters of this book concentrate on inspecting, or manipulating, mass-produced engineering products, such as parts for automobiles, washing machines, computers, etc. Their components are typically manufactured to close tolerance. There is another large and as yet largely undeveloped area of potential vision applications, including the inspection, grading and sorting of vegetables and fruit, finding foreign bodies in food materials and monitoring the manufacture of food products. This group is typified by applications in which tolerances are normally large, compared to engineering components. Nuts, apples, carrots and potatoes are not made in a mould. Peas, even in the same pod, are very variable, in size, shape and colour. Pizzas, pies, loaves and cakes are all manufactured on an industrial scale but they may well show significant variations in size, shape and general appearance, compared to the equivalent parameters for plastic mouldings, metal stampings, bottles, nuts, bolts, springs, etc. The high variability of natural products and manufactured food products introduces challenges for the designer of an inspection system that is unknown when tolerances are tighter. Furthermore, it is often difficult to standardise the presentation of a natural object to the camera for inspection. If the shape is variable, it may be difficult to find reference points with which to establish a safe grasping position. Grading fruit and vegetables is a task that is often defined in terms of rules originally written for human inspectors. These must then be translated into a computer program. This suggests the need for a different type of decision-making from that required for close-tolerance engineering components. Prolog-style reasoning is often appropriate in this type of situation (➲ Chap. 23) [1, 3, 5]. This is significantly different from, for example, the image filtering techniques introduced in ➲ Chap. 14 and implemented in software packages such as NeatVision (➲ Chap. 22), or QT (➲ Chaps. 21 and ➲ 41). Parts of some engineering components/assemblies show significant variability. Examples include welding, rivets, wiring, flexible tubing, solder joints, etc. During the manufacturing process high levels of variability may exist temporarily, for example when extruding dollops of semi-fluid material (adhesive, molten glass, clay), or when removing a casting from its mould. To monitor a material-removal process, we might usefully monitor the debris produced (swarf, dust, sprue) as well as the product itself. Waste material can be a useful indicator of the state of the tooling used in the production process. These are also situations in which we might apply the lessons of this chapter. In many applications where there is high variability, it is convenient to use fast hardware to obtain a standard set of measurements that are passed, in parallel, to a Pattern Recognition module (➲ Chaps. 19 and ➲ 25). The latter learns from its own experience to perform the required discrimination task, which cannot be defined explicitly by a human being (➲ Chap. 24 and the supplement to ➲ Chap. 16). Self-adaptive learning using feedback guided by a human teacher is a more effective alternative to rule-based methods for tasks such as colour recognition (➲ Chap. 16) and texture analysis (➲ Chaps. 30 and ➲ 38).

1.7.1.2 Chapter 3: Human and Animal Vision

Since this is a book about artificial vision, it may seem strange that we include an essay on vision in the natural world. The reason is simple: we need to convince the reader that there is no single model for vision that is ideal for all circumstances. Our own visual system, sophisticated though it is, would not suit a housefly, eagle, owl, chameleon, or even a horse. Each of these animals has managed to thrive within a specific type of environment, for far longer than human beings have existed. Even though it is very limited in its visual capability compared to human beings, a frog has a vision system that has served it well for many millions of years. In many instances, an industrial Machine Vision system is like a frog: both can do certain well-defined tasks, without attempting to achieve the subtlety of discrimination and the high level of intelligent scene analysis that a human being can accomplish. In nature, there are four scenes that nearly every organism has to recognise: food, threat, mate and shelter. This is not so very different from an inspection system that is merely intended to distinguish between "good" and "faulty" products. Animals do, however, have to cope with highly variable environments and cannot change the viewing conditions as a vision engineer can do to make his/her creation cheaper, faster, or more reliable. So, our task is usually simpler than designing a machine as complex as a frog. We must never make the mistake of thinking that only we see the world as it really is. We are only sensitive to a narrow range of optical wavelengths. We cannot sense polarisation, whereas bees and appropriately designed machines can. We cannot sense very low light levels like some animals. Why should we want to replicate a system like ours that is confused by numerous visual illusions? The natural world has produced many different models for vision. For example, there are over 40 different types of eye in the animal kingdom. The compound eye of insects and our own are obviously very different. Even the eye of a relatively close relation, the cat, is significantly different from our own, having a vertical pupil in bright light. Some animal eyes move the lens to focus on objects that are moving along the line of sight, rather than alter the shape of the lens, as our own eyes do. There is nothing particularly special about our colour vision either. Mantis shrimps for example have 12 different colour pigments in their eyes. Spiders are not content with just two eyes as we are; they have eight! This variety does more than present us with a collection of interesting curiosities; it provides inspiration! Vision engineers can benefit from learning about non-human vision systems. Perhaps the most important point of all is that vision engineers should have the confidence to be different; we should not be constrained always to try and emulate human vision. Nature isn't! Although it is immensely powerful, human vision is sometimes ineffective, and in other cases grossly over-sophisticated for the humble tasks required of industrial vision systems. It is always vain to do with more what can be done with less. So, if frog-vision works, use it!

1.7.1.3 Chapter 4: Colour Vision

Colour vision has been studied extensively by psychologists, physiologists and physicists. Philosophers have also pondered over the nature of colour. Photographers, printers and video engineers try to reproduce colours encountered in nature. The result is a large but still incomplete body of knowledge termed Colour Science. When the editor was initially considering the content of this Handbook, he felt that a chapter on the science and practice of colour reproduction was essential. However, on reflection, he modified this view, since Colour Science is concerned primarily with understanding colour vision in humans for the specific purpose of *reproducing* colours. That is not our interest here! Our preoccupation in Machine Vision is *verifying* that coloured features are of the correct size, position and shape. To do this, we need to be able to segment an image according to the colours that it contains. For example, we might need to distinguish "*red*" printing from "*blue*" printing; identify "*yellow*" tablets lying on a "green" surface (to count them); or measure the area covered by red raspberry jam on a cake. Performing tasks such as these does not require detailed knowledge of many of the subtleties that have been discovered about human colour vision. We are faced with stark questions, such as "*Is the feature XXX red, or is it green?*" But, what is "*green*"*?* My wife and I often disagree, in the nicest possible way, about the names of colours, particularly in the blue-green part of the spectrum. Who is correct? My concept of "green" is different from hers – and yours! So, we can all be correct, because human understanding of the term "green" is different from person to person. Having deliberately ignored much of Colour Science, we proceed by discussing some of the different colour models that have been developed. However, even this is not straightforward, because Machine Vision must use the available technology. Colour cameras operate by sensing the optical energy in three overlapping wavebands and thereby generate three separate signals, RGB. There is little point, therefore, in over-reliance on other colour models, since they have to be calculated in terms of the RGB signals coming from a video camera. One other model does stand out as worthy of detailed attention: HSI (hue, saturation intensity). This chapter lays the foundation for ❯ Chap. 16 where the RGB and HSI models are used extensively and should be read in conjunction with ❯ Chap. 3.

1.7.1.4 Chapter 5: Light and Optics

Photographers and video engineers have long been aware of the critical importance of optics. Since forming and conditioning images is an essential feature of all camera-based Machine Vision systems, the ability to produce a sharply focussed image, without significant aberrations, or vignetting, is critical. Poor image quality degrades overall system performance. While it is possible to use software to compensate for mis-focussing, it is far better to design the optics so that this is not necessary. Deconvolution, the computational process used to improve focus, is relatively slow and fails to produce results that are of comparable quality to those obtained by selecting a good lens and using it in the most appropriate manner. While programmable colour-selective filters are very versatile, they cannot compete for speed, or cost-effectiveness, with a simple piece of coloured glass, or for more sophisticated colour separation, an optical interference filter. Elsewhere in this book, a Machine Vision system is pictured as an electronic image processing engine, interfaced to an image acquisition system (i.e., the optical "front end"). Let us instead think of an MV system as an integrated hybrid processor, incorporating the following "computing" elements:

- Optical signal generator (lamps, Chap. 7)
- Optical signal conditioning (illumination optics, Chaps. 6 and 7)
- Data input (mechanical handling system, moving the widget to/from the inspection area)
- Optical processing (imaging optics, Chap. 5)
- Translating the information domain from light to electrical form (cameras and scanners, Chaps. 9–12)
- Signal conditioning (Chaps. 10, 11 and 13)
- Conversion from analogue electrical to digital image format (Image formats Chap. 11)
- Digital image processing (Chaps. 14–19)
- Software for image processing and interpretation (Chaps. 21, 22 and 41)

The data processing rate at the front end of this hybrid processing chain is very large, compared to that in the later stages. An optical processor offers a limited repertoire of available functions, compared to software but is able to handle truly huge volumes of data. Considerable cost/speed benefits can therefore ensue if we can perform most of the processing in the optical domain. Among the limited set of processing steps that can conveniently be performed optically, we can include:

- Image size adjustment
- Image aspect-ratio adjustment
- Trapezium and parallelogram image warping
- Compressing an image into a single line
- Rotating an image
- Inverting one, or both, image axes
- Adjusting the balance of signal levels spatially and temporally (LCD modulators, LED illuminators, Chap. 7)
- Fourier transform (performed on transparent objects/media)
- Generating variable waveband lighting patterns (LED illuminators, Chaps. 7, 8 and 40)
- Filtering images on the basis of wavelength (optical filters, also see Chaps. 5 and 40)
- Filtering images on the basis of polarisation.

The catalogue of lighting viewing methods in Chap. 40 is built on an understanding of the optical components described in this chapter. The lesson here is simple: good optical design will greatly improve image quality and can achieve some valuable special effects that can lead to greatly improved system performance and cost/effectiveness.

1.7.1.5 Chapter 6: Telecentric, Fresnel and Micro Lenses

In our everyday experience, looking into a deep well produces two concentric rings: the outer one corresponds to the top of the well and the inner one to the well bottom. An ideal telecentric lens superimposes these contours. This can only be approximated using a conventional lens when the well is viewed from far away. Telecentric lenses do not conform to our normal expectations. They may not be familiar to some readers, because they do not have the same importance for general photographic, or video, applications as they do for Machine Vision. Within the restricted world in which industrial vision systems normally operate, telecentric lenses offer important advantages compared to conventional lenses: size constancy as the object-lens distance varies, freedom from parallax, high measurement accuracy and the ability to detect subtle local defects in transparent sheet materials and on plain mirror-like surfaces. Telecentric lenses have been central to the success of many installations. Gauging has benefitted particularly from their use, since they provide a much better estimate of the real position of the edges of an object than a conventional lens can. For the greatest precision, a collimated light beam is used to back-illuminate shiny objects. A collimator is a telecentric device (➲ Chaps. 5 and ➲ 7). Although not uniquely associated with Machine Vision, telecentric lenses have taken a pivotal role in our subject. Without their use, the algorithmic techniques for measuring object size and position from an image would be more complicated. The cone of visibility for a telecentric lens is a cylinder, while that for a fish-eye lens is a diverging cone. (Its apex is at the camera.) Hypercentric lenses have a converging cone of visibility; the apex is near the object. Such a lens allows the top and sides of a cylinder, or cube, to be viewed simultaneously, albeit with considerable distortion of perspective. A certain type of hypercentric lens can be used to view through a small aperture, for example, through a letter-box to obtain a wide-angle view of the side walls of the lobby inside. Hypercentric lenses are well suited for tasks such as inspecting the side-walls of sewers and pipes. The lens and camera do not have to be inserted into the bore. To be effective, both telecentric and hypercentric lenses require large front (objective) lens elements. This can be a problem when big objects are to be imaged, as large conventional lenses are expensive. Fresnel lenses provide an attractive alternative. This type of lens is made in the form of a flat plate with numerous specially shaped grooves on its surface. These act as tiny prisms and collectively focus a parallel light beam just like a conventional lens. Apart from being used in telecentric and hypercentric assemblies, Fresnel lenses are used in projectors, and wherever a large or light-weight lens is needed. They can be made inexpensively in bulk. A microlens array resembles a Fresnel lens and consists of a flat plate with numerous individual moulded lenslets covering its surface. The lenslets are normally very small but are large enough to avoid creating diffraction effects. Such arrays can perform some remarkable functions, and are used in diffusers, beamsplitters and for anamorphic imaging. Many solid-state photo-detector arrays have single lenslets placed over each photo-sensitive site (➲ Chaps. 10 and ➲ 11). This increases the light-collecting power of the camera and avoids blurring due to "spill-over" of light scattered within the sensor chip.

1.7.1.6 Chapter 7: Illumination Sources

Most of the other chapters in this book emphasise the critical role that lighting has for Machine Vision. In order to obtain the benefits of detailed optical design (➲ Chaps. 5 and ➲ 6) and careful camera selection (➲ Chaps. 10 and ➲ 11), equal consideration must be given to the choice of lamp. *A desk-lamp is never the answer!* Paradoxically, to many people, lighting is a "black art"; our everyday experience does not alert us to the subtleties that we need to study. For example, in ➲ Chap. 3, the ability of the human eye-brain complex to compensate for changes in the colour and intensity of ambient lighting was emphasised. Most people are unaware of the slow degradation of the room lighting at home, as lamps get older,. Many people change a light bulb and then remark with surprise how bright the room suddenly appears. When trying to discriminate colours using a machine (➲ Chap. 16), precise control of the colour of the lighting is crucial. Until the end of the last century, most people were aware of just a few types of electric lamps. Incandescant filament bulbs and fluorescent tubes were used in the home, while mercury discharge lamps were common in places of work, such as factories and warehouses. Street lighting used mercury and sodium lamps, while advertising relied heavily on "neon" displays. (These devices use other gases, in addition to neon, to produce a range of colours.) Nowadays, there is a greater variety of lamps available, including a wide range of LED-based lighting units, cold cathode tubes, compact fluorescent bulbs and plasma panels. For a long time, arc lamps have been used in specialised scientific and industrial applications. To most people, lamps have just four important properties:

- Brightness, with no regard for the spatial radiation pattern
- Efficiency, measured by the ratio of the optical emission power to the electrical power consumed
- Life-time, measured simply by how long before it becomes so dim as to be useless, or stops emitting altogether
- Colour. This is usually just a vague notion, based on descriptions such as *soft*, *harsh*, *cold*, *warm*, etc.

For Machine Vision, a more scientific specification is needed and must take into account

- 3D radiation pattern
- Ability to control brightness
- Driver (AC/DC, frequency, closed-loop control)
- Electrical noise generated
- Heat produced
- Infra-red content
- Long-term degradation of emitted power
- Shape
- Short-tem stability of emitted power
- Spectrum (This requires a much more detailed analysis than simply stating the "colour.")
- Ultra-violet content
- Power-line ripple

In recent years, there have been major advances in the design of LEDs specifically for Machine Vision. It is possible to build arrays of any given shape, consisting of numerous individual LED "point sources," each of which has precisely known spectral characteristics. They are efficient and stable over a long life-time. The lighting pattern can be adjusted dynamically, under software control, thereby providing a powerful new dimension to Machine Vision system design that was previously unavailable.

1.7.1.7 Chapters 8 and 40: Lighting-Viewing Methods

The image acquisition sub-system consists of one, or more, light sources (➲ Chap. 7), lenses and possibly other optical components (➲ Chaps. 5 and ➲ 6), as well as one, or more, opto-electronic transducers (cameras, ➲ Chaps. 10 and ➲ 11; or scanners, ➲ Chap. 9). Simply knowing what "building bricks" are available is not enough: we must be able to build them into an integrated system. There is another facet to be considered: object presentation and transport. This requires that we address issues such as holding the object and moving it before, during and after image capture. The type of viewing background is also important, as are seemingly mundane issues, such as eliminating ambient light, building vibration-proof optical rigs and keeping optical components clean, dry and cool. In many applications, the placement of the camera relative to the object under inspection and the lights is critical; the image quality derived from the same object may vary from very poor to excellent under different lighting-viewing conditions. The chapters just cited are concerned with "component level" factors, while this one deals with high-level issues. On the other hand, ➲ Chap. 11 and the Machine Vision System Design Questionnaire (➲ Appendix B) present practical advice for optical system engineers. This is based on common sense, experimentation and experience. ➲ Chapter 8 introduces the much larger catalogue of Lighting-Viewing Methods (LVMs) presented in ➲ Chap. 40. To understand the importance of choosing an appropriate lighting-viewing method, consider the task of inspecting objects on a continuously moving conveyor belt. (This is a popular method for transporting objects around a factory, since it avoids building a more complicated, less efficient and less robust parts-handling system that would be needed if an indexed image acquisition system were used.) This allows various options, possibly based around line-scan cameras, progressive scan (array) cameras, cylindrical optics, strobed lighting, etc. Questions regarding system synchronisation, conveyor-speed measurement, parts-present detectors, and visual background also arise. The LVM catalogue addresses these issues. often necessarily presenting information in qualitative, pragmatic form. There can be no rigid formula-based approach to optical system design. This does not, in any way, diminish the need for sound mathematical analysis, where it can be applied appropriately, as for example, in lens design. There can be no equation to tell us when it is sensible to use, say, diffuse, or dark-field illumination, monochromatic or polarised light, or a combination of these. The author has long contemplated trying to embody information of this kind in an expert system but still believes that it would not match human intuition, and intelligence.

1.7.1.8 Chapter 9: Laser Scanners

Although solid-state digital cameras are the most frequently used image sensors in Machine Vision systems, scanners have much to offer, particularly in certain specialised applications. Scanners provide an attractive alternative to solid-state cameras for detecting changes in reflectance, colour, surface roughness and polarisation. Of course, scanners are familiar in our everyday lives, as they are used in retail bar-code readers. They are typically used for inspecting flat, web (sheet) materials, such as rolled steel, plastic film and paper. They have been used to examine large internal bores, such as hydraulic cylinders, pipes, tunnels, sewers, etc. Scanners are able to generate high resolution images. A laser scanner is able to measure surface reflectance over a single very narrow and precisely defined wave-band. It can also be used to obtain a number of exactly registered images simultaneously, each derived from a different narrow spectral band. These may have wave-lengths below, within, or above the visible part of the spectrum (VIS). It is also possible to obtain several images, again aligned exactly with one another, and derived from specular and near-specular reflections. Moreover, it is possible to separate the light reflected from the surface under investigation into two orthogonally polarised beams. This is useful, for example, to detect defects in transparent coatings.

The scan pattern can be varied; it may be linear, circular, spiral, helical, or radial. It may even be random, or follow a complex path, such as a Hilbert curve, although the data rate is rather low in these last two cases. The same optical arrangement might be used in some applications for both sensing, and marking. When used with light-sensitive coatings, scanners can be used to create complex patterns, such as those found on printing plates and printed circuit boards. The same scanner might then be used to inspect them, or burn patterns. Laser scanners have even been used to examine photographic film! There are two "tricks" to this: select the scanner wavelength carefully and keep the laser spot moving very rapidly. Laser scanners are ideally suited for surface-inspection applications, such as examining floor tiles, paper, plastic sheeting, plain wooden surfaces, animal hides, fabric, products made in the form of a flat strip and those where it is not possible to put a camera close to the object undergoing inspection. They are ideal for examining red-hot metal and working in areas where there is a high level of radioactivity and where there is a toxic, explosive or biological hazard.

Scanners can be made highly specific to suit particular applications. It is possible, for example, to use UV or VIS light with a narrow spectral peak, to excite fluorescent, phosphorescent and photochromic materials. (The last mentioned switches colour in a reversible manner.) This has potential applications in security applications, such as checking document/product authenticity. The scanner light source (laser) can be pulsed, which is particularly useful for detecting phosphorescence. A scanned laser beam can be projected through a very narrow slit, making it possible to keep light levels low everywhere, except at the immediate point of inspection. It is possible to build a laser scanner that can examine objects that are a long way away. Hence, it is possible to use a scanner to detect oil leaks in remote and complex pipe-work. Since organic substances often fluoresce, laser scanners can detect infection by micro-organisms on food-materials and products. Scanners can also be used to measure range and 3D shape (➋ Chap. 15). There are two distinct ways to do this: by trangulation and by measuring time-of-flight of the light beam. (This is the principle of operation of Lidar.) Laser scanners are often used in automatically guided vehicles to detect obstacles.

1.7.1.9 Chapter 10: Cameras

A solid-state camera forms the very heart of most modern vision systems. Huge advances have been made in sensor technology since the cathode ray tube (CRT) was the only realistic way to acquire image data. CRT cameras are large, heavy, physically fragile and susceptible to defects such as blooming, comet-tail, image burn-in and non-linear spatial sampling. They require high power to heat the filament and use dangerously high operating voltages. They are also sensitive to magnetic fields. On the other hand, solid-state sensors are much smaller, lighter in weight, physically robust and provide very accurate spatial sampling. They require less power and use safe, low operating voltages. Modern cameras are reasonably tolerant of optical overload but they do not tolerate high temperatures so well as CRTs and are more easily damaged by high-energy particle beams.

Although there are several different types of solid-state sensor, nearly all rely on the generation of hole-electron pairs in silicon as a response to incident light. There are several different ways to access the charge pattern developed by the photo-detector array and convert it into a video signal. Photo-detector elements can be arranged in a single row (line-scan camera), multiple rows (time delay integration camera) rectangle/square (area-scan camera), circle (circle-scan camera), along the "spokes" of a wheel-spoke, or around concentric circles. Colour filters can be built into a camera, making it sensitive to different wave-bands. These can cover the near infra-read (NIR) and near ultra-violet (NUV) wave-bands (Chap. 5 and Appendix I), or generating the familiar RGB signals from the visible (VIS) band.

This chapter concentrates on the physics and construction (architecture) of solid-state sensors, while Chap. 11 discusses their characteristics and the implications for their application in Machine Vision. A camera is not nearly as sophisticated as the human eye (Chap. 3). In particular, it does not possess such a wide dynamic range. For this reason, algorithmic techniques that are relatively insensitive to varying light levels are important (Chap. 13). Cameras are always fitted with lenses and these are, of course, an integral part of the lighting-optical sub-system (see Chaps. 5–8, 40).

Since they are sensitive to heat, cameras must be kept cool. This can be achieved using a hollow-walled metal box with cold air, water or even liquid nitrogen circulating within its cavity (Chap. 40). Chapter 9, which describes laser flying spot scanners, alerts the reader to other possible ways to obtain image data. These devices and more conventional cameras provide solutions for different niches, scanners being more suitable for high-speed inspection of fast-moving web-like materials. Modern cameras have contributed a great deal to the development of Machine Vision; without them, it is doubtful whether it would be worthwhile writing a book like this!

1.7.1.10 Chapter 11: Selecting Cameras for Machine Vision

Modern solid-state cameras are tiny devices that rely on detecting quantum-level energy changes occurring when photons cause the creation of electron-hole pairs in a semiconductor. The physical basis of this process is described in Chap. 10, while this chapter discusses the practical issues that impinge on the design of Machine Vision systems. Cameras have many subtle features that should be understood in order to obtain the best possible results. For example, the generation of electrical noise is an inevitable consequence of the photo-detection process. Its effects can be minimised by operating the camera at the optimal light level. This must be low enough to avoid saturation, blooming and "bleeding" of charge from one photo-detector site to another. While the geometry of the photo-detector array is defined very precisely during manufacture, its sensitivity varies slightly from one pixel to another. A simple algorithm can compensate for this. Furthermore, a fixed noise-like pattern is effectively superimposed on every image that the camera "sees." This can be removed very effectively by the simple expedient of storing and subtracting an image of the noise pattern. Many other subtleties about camera design and operation are discussed. Taking them properly into account can make a big difference to the quality of the digital images that ensue. Camera designers have done much to compensate for their variations and quirks. Many of the innovations in solid-state photo-sensors have been directed towards improving personal digital cameras and camcorders but we must not take it for granted that these are always appropriate for Machine Vision applications. Automatic Gain Control (AGC) is one example of an " improvement" that rarely suits our particular needs. The reason is fairly obvious: in a typical inspection cell, the camera, lights and object being examined are all in fixed position relative to one another, the products are very much alike and the lamp brightness does not (should not!) vary much. Viewing under nearly constant conditions, like this, makes

AGC unnecessary. Indeed, it can actually make matters worse, because it can obscure changes, such as lamp aging, that we need to know about. In the early days of Machine Vision, the advantage of having pixels that are square, not rectangular, was not universally understood. This is widely appreciated now and is reflected in the layout of nearly all photo-detector arrays. This is such a simple change that its real significance could easily be lost again. Line-scan cameras offer some important and distinctive features, particularly for inspecting continuous webs and objects on a conveyor. However, to realise these benefits, it is necessary to know the relationship between the frequency of the camera clock signal and the speed of the conveyor belt. This is needed to ensure that the pixels are square. If they are not, the image processing algorithms become more complicated. Subtleties and interactions like these are the very essence of Machine Vision. Line-scan cameras allow cylindrical lenses and mirrors to be used (➲ Chap. 40). It is possible to build very large 1-dimensional optical systems quite cheaply. For example, it might even be possible to use very cheap, extruded Fresnel lenses (➲ Chap. 6). Individual line-scan cameras can be butted end to end, effectively to build very long line-scan sensors. In this way, it is possible to build a very high resolution but modestly priced line-scan system that is able to inspect wide webs and continuously moving objects.

1.7.1.11 Chapter 12: X-ray Inspection

Automated X-ray Inspection (AXI) is particularly useful for two types of application: detecting foreign bodies in food and examining the internal detail of safety-critical, high-value products. It may seem that AXI is simply a straightforward extension of Machine Vision techniques as discussed elsewhere in this book. Most x-ray systems project a beam through an attenuating medium. This appears to be very similar to viewing a transparent object with back-lighting (➲ Chap. 40). For most materials, there is very little deflection of the x-ray beam due to refraction (➲ Chap. 5). However, there are practical issues that complicate this naive view. There is only a limited scope for altering the energy spectrum (wave-band) of the beam nor is it easy to build x-ray mirrors and lenses. Since the x-ray source, a specially designed cathode ray tube, generates a divergent (conical) beam, the images are not quite as simple as we might imagine. This introduces parallax errors. Moreover, objects near the source appear to be bigger than those further away. Features along the system axis are superimposed, often creating a jumbled picture that is difficult to analyse so that we can associate object edges with image contours. A useful approach to understanding x-rays images is to construct a synthetic image by emulating the x-ray source and target object. We may produce a crude approximation so that the vision engineer can associate object and image features together. A more refined model can generate an image that is close to that produced by an ideal (perfect) object. This image can be used as a reference for comparison with the images produced by test samples. If the objects being inspected are manufactured to close tolerance and are accurately registered each time, a point-by-point comparison of the test and reference images may suffice as a basis for the inspection algorithm. This is known as template fitting, which is normally deprecated in Machine Vision (➲ Chaps. 14 and ➲ 19). In some cases, it is necessary to warp one of the images slightly, so that it will fit onto the other. The warping and fitting of a rubber template can be quite complicated, compared to most of the algorithms described in ➲ Chaps. 14, ➲ 18 and ➲ 19. More sophisticated image processing procedures are probably needed when the objects being examined exhibit even a modest level of variability. To summarise, AXI has its own set of issues that distinguish it from other areas of Machine Vision. There is one particular point that emphasises this more than any other: the danger that ionising radiation presents. Subsequently, there is a need for good radiation screening and safety features, such as cut-off switches on equipment doors. This is not an option; it is a legal requirement!

1.7.1.12 Chapter 13: Illumination-Invariant Image Processing

Machine Vision is necessarily concerned with four different media in which we represent the appearance of an object: optics, analogue electronics, digital electronics and software. Thus, there are several ways in which significant information can become corrupted. The importance of the lighting-viewing configuration cannot be overstated; the maxim "*Rubbish in, rubbish out*" should always be remembered. For this reason, there can be no excuse for taking a casual approach to image formation and acquisition. First, we must choose the most appropriate light source (➲ Chap. 7). Then, we should experiment with the lighting-viewing arrangement (➲ Chaps. 8 and ➲ 40), before adopting a proper scientific approach to the detailed design of the optical sub-system (➲ Chap. 5) We then choose the most suitable camera (➲ Chaps. 9–11 and ➲ 14). The output of the camera is digitised and the resulting image array is ready for processing (➲ Chaps. 14, ➲ 21 and ➲ 22). However careful we are in the design process, the result will be a series of digital images varying over time, as a result of ambient light fluctuations, lamp ageing, variations in lamp drive current, accumulation of dirt on optical surfaces, variations in the gain of the camera, changes in the reflectivity of the object under inspection and its background. All of these can give the same effect as changing lamp brightness. It is possible to compensate for these effects, by judiciously choosing the image processing strategy. It has been emphasised repeatedly that, despite its obvious attraction, simple fixed-level thresholding is not reliable as a way to segment a grey-scale image (➲ Chap. 14). To overcome the problems, several methods for improving thresholding are used extensively elsewhere in this book: contrast enhancement [QT: *enc*], histogram equalisation [QT: *heq*], morphology (➲ Chaps. 19 and ➲ 20) and high-pass filtering (➲ Chap. 14). This chapter investigates the general problem in more depth and in a formal manner. Human beings are normally insensitive, even to quite large variations in lamp brightness (and colour). Being able to compensate for diurnal fluctuations in natural light levels (➲ Chap. 8) has obvious advantages for an organism but does mean that we are probably unaware of the need for the methods described here. However, a few minutes working with an image processor (➲ Chaps. 21, ➲ 22 and ➲ 41) will clearly demonstrate that many of our prior conceptions are wrong.

1.7.1.13 Chapter 14: Basic Machine Vision Techniques

The ability to process digital images within a computer is the youngest of the enabling technologies needed for Machine Vision. Twenty years ago, the concepts of digital image processing were almost unknown, except to a small number of researchers. With the advent of digital cameras and photo-editing programs, such as Photoshop™, there is less mystique – but there is still a lot of mist! A very common mistake that newcomers to our subject make is to expect that Machine Vision will necessarily emulate human vision as they perceive it to be. As we have already seen in Chap. 3, there is a wide diversity of vision paradigms in the biological world; human vision is not the only success story. There is no fundamental reason why we should constrain Machine Vision to emulate human ability. It could be inspired by other biological systems, such as those of a fish, frog or insect, or it may owe nothing to nature. This chapter begins with a discussion of ways of representing images in a form suitable for manipulation within a computer. The most commonly used format is that of a 2- or 3-dimensional array, although others present advantages in certain specific situations. Sometimes a conventional digital computer is simply not fast enough and dedicated electronic systems are required. The array format is often suitable in that situation too. The real "value" of an image processing operator depends on its ability to perform some useful function *and* its cost/speed of implementation. A large range of image processing calculations can be performed in an array of logic gates, registers and accumulators. These are commonly referred to as "low-level" functions and are discussed in this chapter. On the other hand, some functions require abstract logical reasoning. This lies within the subject domain commonly called *Artificial Intelligence*. Discussion of this topic is deferred until Chap. 23. Chapters 18 and 19 provide more detailed coverage of two important topics introduced here, while Chaps. 17 and 20 explain how algorithms can often be reformulated to improve speed, or replaced by faster but approximate methods (heuristics). Nearly all of the low-level operations mentioned in this chapter can be implemented using the QT software (described in Chaps. 21 and 41), or NeatVision in Chap. 22. A great deal of time, effort and money has been devoted to building special hardware for low-level image processing. This includes designing special-purpose integrated circuits for tasks such image filtering and edge detection. The design of Field Programmable Gate Arrays (FPGAs) for high-speed image processing is discussed in Chap. 25. A popular approach has been to provide image processing board that can be installed in a general-purpose computer. A decade ago this was of crucial importance but, with the advent of high-speed general-purpose computers, there is less need for add-on hardware. Of equal importance is the fact that a wide range of cameras can be connected to a general-purpose computer, via a USB, Ethernet or Fire-wire interface.

1.7.1.14 Chapter 15: Imaging and Range Image Processing

The ability to acquire, process and analyse 3D range information is important for a great many practical applications, including industrial parts inspection and robotic parts handling. The creation of so-called *range images* (also called *range maps*, or *depth maps*) cannot be achieved by simply pointing a camera at an object; special optical-illumination arrangements are needed. Several different methods have been devised for acquiring range information, including: measuring time of flight of a laser or microwave beam (mm/cm wavelengths), triangulation using one/several projected white or coloured light stripes (Chap. 40), triangulation using active pattern projection, Moiré patterns, Talbot fringes and optical interference fringes. Time-of-flight range-finding methods are faster but are built around a laser scanner (Chap. 9). Whichever method is used, the resulting range image is likely to be quite noisy. Hence, noise removal in range image data is an important first step in the analysis sequence. Some 3D sensing methods do not differentiate between positive and negative range changes, which leads to complications in the analysis of depth maps. Another difficulty is caused by occlusion near step-like edges in the object surface. These occur quite frequently in depth maps generated using triangulation as a result of parallax. (The illumination path and camera axis are at about 45° to one another.) Depth maps have potential uses in a very wide variety of practical applications, including grading fruit, weighing meat, inspecting baked goods, inspecting car-body panels, measuring aircraft turbine blades, guiding autonomous vehicles and robots, reverse engineering (starting with hand-carved prototypes) and manufacturing prosthetic devices (e.g., fitting artificial limbs for amputees). Some applications require only low-precision measurement of range. For example, the manufacture of food products, such as loaves, cakes, pies, etc. is quite satisfactorily served with millimetre-level precision. Typical objectives in the baking industry include weighing, estimating product volume, measuring size (to ensure that the product will fit into its wrapping) and simply judging aesthetic appeal. Examining agricultural and horticultural products does not normally require high precision. This is in marked contrast with the automobile and aircraft industries, where high-precision measurements (micron level) of surface form are needed. A depth map can be processed as if it were a standard monochrome image (➋ Chap. 14). Isophotes in a depth map correspond to height contours on the object under examination. Although the relationship between surface height and depth map intensity is monotonic, it may not be linear. Once a ranging system has been calibrated, the mapping function between these variables is fixed and can be stored in a look-up-table. Simple thresholding provides a convenient means of locating surface features, while edge detection and morphology (➋ Chaps. 19 and ➋ 20) are important for feature location.

1.7.1.15 Chapter 16: Colour Recognition

Despite its many references to the firmament, the Bible does not mention the fact that the (cloudless) sky is blue. Nor does Homer say so in the *Iliad*. Everybody with reasonably good sight knows the colour of the sky at noon, so saying "*The sky is blue*" makes a point about the colour term "*blue*" but does not tell us anything about the sky – except that there are no clouds. Saying that a banana is "*yellow*" indicates that it is ripe and ready to eat but it does not tell us precisely what a banana is really like. A sulphur-coloured banana would appear very odd but it would still be "yellow." There is no absolute truth involved in the naming of colours. In English, we say that the sky is "*blue*" and in Welsh "*glas*." However, "*glas*" can also be used to refer to grass and trees. In other words, "*blue*" and "*glas*" do not have the same meaning. I was taught at school that the French word for "*yellow*" is "*jaune*," which is not strictly true. To summarise, the names of colours have no fixed immutable meaning, so we can only build machines that recognise colours by emulating a human being, whom we trust to be acting reasonably. The ephemeral nature of colour must not deter us from using what is a very powerful way to describe the world. Colour is an important feature of many artifacts and natural products, as well as a large proportion of the packaging materials used for them. Verifying that an industrial artifact has its coloured features intact and correctly placed is, of course, important commercially. The ability to segment an image on the basis of the various colours it contains allows standard (binary) image analysis software/hardware to be used for inspection. For example, measuring the areas and aspect ratios of each of the various "yellow" features on the printed labels for cartons containing pharmaceutical materials, may be a useful way to guarantee that the product has been packaged properly. This is typical of what the author calls "*coarse colour discrimination*." This may be as simple as deciding whether each pixel is "*red*," "*blue*," "*yellow*" or "*something else*." Isolating "*yellow*" features enables us to generate a binary image, which can then be analysed using the binary image processing operators described in ➲ Chap. 14. Colour recognition can be based on standard Pattern Recognition techniques (➲ Chap. 24), or on interactive adjustment of a so-called *Programmable Colour Filter* (➲ Chap. 16). The latter relies on the use of a look-up-table (LUT) to associate RGB or HSI vectors with symbolic colour names. Finding appropriate entries for this LUT relies on human intuition and intelligence, rather than mathematical formulae, so skill and experience is needed to design a PCF. This chapter should be read in conjunction with ➲ Chap. 4.

1.7.1.16 Chapter 17: Algorithms, Approximations and Heuristics

Just as there are numerous ways to describe something in English, there are many options when defining an image processing algorithm. Ideas outlined in ➲ Chap. 14 do not necessarily indicate the optimal implementation. Of course, that depends on the hardware-software platform that is being used. This is a choice that has to be made early on in the design process and probably has little to do with Machine Vision *per se*. It might, for example, be based on commercial/managerial criteria, such as long-term stability of equipment supply. During the early stages of an application study, a prototypical algorithm might be devised, using an interactive image processing system, such as QT (➲ Chaps. 21 and ➲ 41), or NeatVision (➲ Chap. 22) The obvious approach is to recode that algorithm directly in whatever language is currently preferred by the company: C, C++ and Java are obvious favourites. Another possibility explored in this chapter is to reformulate the algorithm itself. This may be a trivial change, such as using logarithms and addition, rather than multiplication. In some instances, we might decide to use a simple look-up table to perform multiplication instead. This is perfectly feasible for short-integer (8 bit) arithmetic. Since digital memory is inexpensive nowadays, this might be a preferred option even when using 16 bit arithmetic, perhaps when building dedicated hardware. Imagine that we needed to square a large number of integers (X^2) on a regular basis. Clearly, we could multiply, use logarithms or a look-up table (LUT). Another option is to use an approximation, such as the modulus function ($|X|$). In some cases, this is perfectly reasonable as, in many calculations, there is no fundamental reason why X^2 is any better than $|X|$. Sometimes, a more fundamental reformulation is needed to achieve an efficient implementation. A prime example of this is the SKIPSM algorithm described in ➲ Chap. 20. Making appropriate approximations is an integral part of almost every engineering design exercise. In MV, this may involve substituting one image filter, such as edge detector (➲ Chap. 14), for another that is easier to implement on a given platform. The term "algorithm" is often used even where there is no mathematical justification for believing it to be anything more than a "good idea"; the word "heuristic" would be more appropriate. A heuristic is a rule of thumb (an informally defined procedure) that usually provides the result we desire – but it may not always do so! A heuristic may actually be optimal (algorithmic) without our being able to prove it. A heuristic may be used directly to calculate the result we need, or it may be used to decide which computational process is most appropriate to apply. An analogy may help to highlight the lesson of this chapter: to fasten two pieces of material together, we might use a rivet, nut and bolt, welding, pop-rivet, a clamp or glue. Similarly, in MV, there are often many procedures that can achieve results that would be "good enough." (Note the use of that term; we did not say "optimal." After all, this is engineering, not science, or pure mathematics!)

1.7.1.17 Chapter 18: Object Location Using the Hough Transform

A broad range of image processing operators was introduced in Chap. 14, while a detailed discussion of morphology to follow in Chap. 19 (also see Chap. 20). In view of its importance for Machine Vision, another important family of functions is discussed in depth here. One of the prime uses of the Hough Transform (HT) is to identify and reconstruct "broken" lines. When an edge detection operator is applied to a noisy monochrome image, the contours that it highlights are unlikely to be continuous; typically, we find that functions such as the Sobel or Canny operators, produce a set of bright spots concentrated along a series of discontinuous lines and arcs. Detecting linear structures within noisy images like these is of considerable importance, particularly when the object under inspection is placed in front of the camera in an unknown position and/or orientation. This is the realm of the HT. Imagine an object being dropped haphazardly onto a table. One of the first tasks for almost any inspection algorithm is to determine the position and orientation of that object. If it has one, or more, straight edges, the HT can be used to estimate their orientation and position coordinates. The physical position and orientation of the object can then be estimated. Notice that this relies on the presence of straight-line features. In this role, the HT competes with the heuristic ad hoc methods outlined in Appendix F as well as the Radon transform (Chaps. 14 and 41). Each has its own application domain. Throughout this book we constantly remind the reader that Machine Vision is a specialised area of Systems Engineering. Here is a prime example of a situation in which remembering this general principle is vitally important. Ingenious design of the mechanical handling sub-system can, in some applications, circumvent the need for sophisticated computational techniques such the Hough Transform. Sometimes, it is possible to build a transport mechanism that limits the degree of variation of the object's orientation. If its position, but not orientation is fixed, it may be possible to determine the latter using a simple scan to plot the intensity profile around a circular path. In certain applications, the object may possess obvious physical features, such as holes, that allow the orientation to be determined quickly and easily. (Appendix F) However, none of these fortuitous features is universally present; in those situations where object placement is uncertain, the HT has a pivotal role. The Hough Transform is more general than being just one more method for finding straight lines. It can detect circles and ellipses too. Moreover, it can do so in situations where objects overlap, or for other reasons, there is some occlusion. The ability to detect ellipses may seem to be of no more than academic importance. However, when we realise that viewing a circle obliquely produces an ellipse in the image, we see that this is of considerable practical value. Again, we see that the HT competes with other techniques when there is sufficient application knowledge to be able to predict image appearance. In view of these comments, the Hough Transform should perhaps be regarded as a tool for location, orientation and recognition, rather than verification. The value of the HT is its ability to cope with situations where noise and/or dirt causes other methods to fail.

1.7.1.18 Chapter 19: Morphological Image Processing

The principles of image processing for Machine Vision are described in broad terms in Chap. 14. We turn our attention now to consider in more detail an important class of operations, namely morphology. These provide powerful tools for filtering both grey-scale and binary images, as well as identifying and locating significant features. Noise removal is an obvious first step in many vision tasks and several distinct morphological operators are available for this. We can, for example, eliminate bright spots, or dark spots separately, or together. Alternatively, we can also remove bright and/or dark streaks at specific angles, or at any angle. Noise reduction operators can be applied to the "raw" video (analogue) signal, or after segmentation, to a binary image. To understand the importance and role of morphology in feature detection, consider the task of reading printed text by machine. A naive approach to recognising a capital letter A uses template matching; we place a perfect A over the sample of text and wiggle it around, until we obtain a perfect, or simply a "good," fit. Despite its strong intuitive appeal, this simple procedure does not work very well. It is very sensitive to variations of font, size, orientation, skew (italics), as well as paper and print quality. A more robust approach is to identify smaller features: "components" of the alphanumeric characters. Thus, we might instead look for places where simple patterns, such as

| — / ● ∩ ⊂

fit on the image. Features detected by morphology may lie in the foreground, or background. For example, a printed letter "O" may be located by looking for a thin black circle (figure), or a solid white disc: the "hole" in the middle. Morphology is important for Machine Vision because we can design feature detectors easily and intuitively, to suit the application requirements. This chapter concentrates on the use of morphological operators, while ➋ Chap. 20 discusses how they can be reformulated to operate in hardware or software, to obtain high processing speed. The QT software described in ➋ Chaps. 21 and ➋ 41 facilitates experimentation with morphological operators.

1.7.1.19 Chapter 20: Image Processing Using Finite-State Machines

Morphology has been described in ➋ Chap. 19. It is a popular and versatile method of detecting and measuring features in both grey-scale and binary images. Common sense suggests that the bigger the mask to be fitted (structuring element) the slower the execution in software. This chapter shows why this is not necessarily so. By reformulating the erosion-dilation algorithm, it is possible to obtain an implementation, called SKIPSM, whose execution time is independent of the size of the structuring element. This algorithm lends itself readily to either software or hardware implementation. Therefore, it opens possibilities that would otherwise be impractical. Intelligence is needed to build and apply a SKIPSM machine, because it cannot provide a compact implementation for all structuring elements. However, important shapes, such as open and closed rectangles, diamonds and circles, crosses (and), bars (—, I, \ and /), loops (∩, ∪ and ⊃), and Ls (in all four configurations) are all amenable to this approach. Furthermore, they can be combined to form composite structuring elements, such as

= ^ ∠ ✕ ⊥ 〈 ✱ ⊙ ◉ ● ⊗ ◗ ⊠ ⊡ ▣ ◈ ◈ ◈ △ ▲ ▼

One of the interesting features of SKIPSM is its ability to perform several morphology operations in parallel. For example, it is possible to perform dilation and erosion at the same time. Surprisingly, this does not increase the computation time significantly. It is also able to improve the speed of certain important functions using a generalised SKIPSM approach. These include grass-fire transform, thinning, skeletonisation, condensation (shrinking each distinct blob to a single point), detecting skeleton limb ends and joints. Grey-scale morphology is also discussed and algorithms exist for edge detection, low-pass filtering and median filtering.

Experimenting with morphology is possible using the QT interactive software (Chaps. 21 and 41). A more generalised discussion of algorithm reformulation to ease implementation is to be found in Chap. 17.

1.7.1.20 Chapters 21 and 41: QT – Prototyping Image Processing System

Chapters 21 and 22 describe rapid prototyping packages (QT and NeatVision respectively) that were designed specifically for Machine Vision applications. The essential feature of QT is rapid and simple interaction [2]. The user views a picture on the display screen and types a three-letter mnemonic command and possibly a list of parameters. The image is processed and the result displayed immediately. For most commands, operating on images of reasonable size, the processing time is well under 1 second. In fact, the user sees two on-screen images: one ready to be processed and the input image for the previous operation. This *modus operandi* was developed in the 1970s and has not been superseded, as it is remarkably effective in the hands of an experienced user. On many occasions, the author has entertained industrial visitors for the day. They have brought sample widgets with them to illustrate the requirements for an inspection application. Perhaps for an hour or two, the author experimented with the lighting and camera. When a good image was produced, it was analysed using QT, or one of its several predecessors. Many times, it was possible to develop a prototype image processing algorithm within a few minutes, rarely over an hour and only occasionally not at all. (In the last eventuality, the result was still valuable as it indicated a non-viable project.) The visitors left with a clear picture of the possibilities and limitations of the options available as solutions for that particular application. It must be repeated that, in the author's experience, this has happened numerous times. The power of this approach is only really appreciated when seeing QT in operation. Many of the applications used to illustrate this book were evaluated using QT (In particular, see Chaps. 16, 19, 27, 31, 38). At the time of writing, QT has over 400 functions, written in MATLAB™. These are described and illustrated in Chap. 41. The QT software is available from the publisher's web site http://extras.springer.com/2012/978-1-84996-169-1.

1.7.1.21 Chapter 22: NeatVision: Development Environment for Machine Vision Engineers

NeatVision is another prototyping system for image processing and was designed to be easy to operate, particularly by inexperienced users. Like QT, it has a rich instruction repertoire but employs an entirely different user interface; an image processing program is represented by a network of interconnected modules. Images and parameters derived from them flow between modules, in an obvious and intuitive manner. Each primitive and high-level image processing function is represented visually, by a rectangle with colour-coded inputs and outputs, indicating the corresponding data type. A high-level compound function can be defined by a network incorporating primitive and other compound functions. Once a network has been proven to work satisfactorily, it can be "condensed" into a new module, again represented visually by a rectangular icon. The new module can then be incorporated into other programs, like any primitive function. NeatVision has virtually unlimited capabilities for expanding the command repertoire. While novice users normally prefer NeatVision's visual programming environment, more experienced people are often happier with a command-line interface, such as that provided by QT. In both cases, the user has to learn the function of each module before he becomes an effective user. The advantages of NeatVision are the same as those of any other visual programming environment, being well suited to writing programs that have a rich branching structure. On the other hand, QT and other command-line systems, allow rapid interactive program development, since the command-to-command cycle is shorter. NeatVision was written using JAVA, while QT is based on MATLAB. In both cases, the underlying software is very powerful but rather cumbersome and unsuitable for rapid prototyping. One reason for this is that both Java and MATLAB require the user to remember, and type, the names of image files. Neither NeatVision nor QT do. That may seem to be a small detail, but on such features as this a system is often adopted or forsaken. Although they are very different, the user interfaces provided by NeatVision and QT greatly improve the ease of use and the ability to operate effectively in an interactive manner. Experience has shown repeatedly that this is a key feature when designing algorithms for Machine Vision. Unlike conventional programming, a vision engineer is never quite sure what step to perform next – he must be able to experiment. This is totally alien in normal programming; imagine not being sure what number, or arithmetic operator, to write into a mathematical expression. Developing vision algorithms requires a fundamentally different approach. Choosing a command-line or graphical interface is best left to the vision engineer. Both are effective!

1.7.1.22 Chapter 23: Intelligent Image Processing Using Prolog

Prolog often scares programmers experienced in using standard computer languages, such as C, C++ and Java. Prolog is different! For example, it has no FOR loops and no IF. . .THEN. . .ELSE statements. It does not even allow instructions! It is not particularly good at performing arithmetic, so it would not be sensible to write image processing function, such as image filtering, using Prolog. Despite these points, Prolog has much to offer. Consider the following task: you have lost a book and have asked a friend to find it for you. You would very likely describe the book, indicating its size, colour and subject matter/title. Your friend then goes and looks for the book, without any explicit statement from you about where to look. In this analogy, the description of the book corresponds to the Prolog "program" (properly called an *application*), while your friend operates like a Prolog theorem prover. Another example: suppose you wanted to find a husband/wife for yourself, assuming that there is a vacancy for that role. This time, you would specify your "requirements" in the form of a Prolog application and leave the theorem prover to find a potential candidate. Try doing the same in one of the languages mentioned earlier. General spatial relationships, such as *above*, *left-of*, *inside* and *between* can be expressed very succinctly in Prolog but cannot be represented nearly so readily using a language such as Java, or in MATLAB or QT (➜ Chaps. 21 and ➜ 41). Standard Prolog has no special facilities for handling images. However, a simple extension to Prolog allows it to control a QT system as a slave. It is then possible to embed QT commands in Prolog. The result is a language, called PQT, that combines the image processing capabilities of QT with the expressional power of Prolog. Image processing is not performed in Prolog; it simply diverts image-based operations to QT, which passes the results back to Prolog for interpretation. Now, consider the task of verifying that table-ware has been laid out properly for dinner. A person might well specify what he/she regards as being a good layout, *in English*, using qualitative relationships such as *above*, *beside*, *between*, etc. PQT can readily accept a natural language description and then analyse a complex visual scene, containing many different objects, in order to verify that the table is set correctly. Such a task could be performed in Java or QT but the program would be long and awkward to write and understand. The advantage of PQT over QT is expressional convenience. Java programmers rely on the language, to reduce the effort of expressing complex numerical algorithms. In this respect it is far more convenient than assembly code, or Prolog. However, PQT is superior to Java, MATLAB, or QT for describing and analysing highly variable images. But there is more to PQT than that. The same language can be used to plan the seating at the dinner table, ensure that the meal is nutritionally well balanced, inspect the cutlery to make sure it is clean and examine the food for foreign bodies. Of course, it needs the appropriate sensors and illumination. PQT can control the lighting as well!

1.7.1.23 Chapter 24: Pattern Recognition

Sometimes, the definition of a "*good,*" or "*faulty,*" object cannot be expressed properly, either in natural language, or in a more formal way (e.g., mathematical notation or pseudo-code). For example, it is impossible to write a formula that defines colour classes (e.g., "*yellow*" or "*attractive wood grain*"). Any classification that attempts to assess the aesthetic appearance of highly variable objects necessarily relies on subjective judgement. Human beings are able to grade and inspect natural objects, such as growing plants, fruit, vegetables, etc. using unknown subjective criteria that they have learned but cannot say express adequately. The same its true of food products, such as cakes, loaves, pies and pizzas (see ➲ Chaps. 2, ➲ 36 and ➲ 37). Engineering artifacts that require precise measurements, or clearly defined inspection checks (e.g., "*scratch*"/"*no scratch*"), are not normally suitable for Pattern Recognition methods. However, it should not be supposed that manufacturing processes always attain a high level of order everywhere; even supposedly close-tolerance artifacts may have highly variable parts. A fuel injection nozzle (close tolerance) produces a much more variable spray jet. Sometimes, inspection is possible using heuristic rules, expressed in symbolic terms and which a human inspector has been able to formulate. In this case, declarative, Prolog-style programming is useful (➲ Chap. 23). However, there is another large group of potential applications where the ultimate judge of what is "*good,*" or "*not acceptable,*" is a single trusted person, or a committee of experts, who despite their long experience cannot express their reasoning in any sensible way. In such a situation, we can use one of the self-adaptive Pattern Recognition systems described here. A pattern classifier typically accepts a multi-element vector, measuring a fixed set of image features, and learns, by example, to emulate a human teacher. A set of image measurements might conveniently be generated using morphology (➲ Chap. 19). The teacher is expected to do no more than view each object in turn and return a "*good*" *or* "*faulty*" decision for each one. Introspection is not needed, nor is there any attempt to coerce the inspector to provide any more information than a simple binary decision. Pattern classification rules vary in complexity from simple linear discriminants, to much more powerful techniques, including Neural Networks. Another group of classifiers makes decisions based upon distances from a point in high-dimensional measurement space representing the test sample to multiple stored exemplars. Classifiers based on hyperspace distance measurement include the Nearest Neighbour classifier, Compound Classifier (Supplement to ➲ Chap. 16) and others using Radial Basis Functions. Learning rules for linear classifiers have been known since the 1960s. Those for Neural Networks were developed more recently. The Nearest Neighbour learning rules are proven only by experimentation but have been useful in areas such as colour recognition (➲ Chap. 16). Pattern classifiers should be judged statistically on their performance. They do not always produce the "correct decision," as judged by the teacher. It must be accepted from the outset that Pattern Recognition is not a precise way to make decisions. However, it can cope with difficult situations, particularly where there is little detailed application knowledge. It is also important to realise that self-adaptive learning procedures require a great deal of training data to obtain results that are generalisable to unseen samples. Nevertheless, Pattern Recognition provides a valuable way to proceed in many situations where other methods fail. Once learning is complete, decision making can be performed at high speed in software, or specialist hardware.

1.7.1.24 Chapter 25: Implementing Machine Vision Systems Using FPGAs

It has already been noted that Machine Vision requires two quite different types of image processing system: interactive (➲ Chaps. 21 and ➲ 22) for algorithm design and stand-alone for target systems installed on the factory floor. It is important that the latter be able to match the speed of modern manufacturing machinery. Certainly QT (➲ Chap. 21) and NeatVision (➲ Chap. 22) cannot, except in a very few special cases. General purpose computers are becoming ever more powerful and many tasks that were previously impossibly slow in software are now in commonly implemented in that way. It is clear from the examples cited throughout this book that practical inspection algorithms often require numerous passes through a high-resolution image, thereby presenting a heavy load on a general purpose processor. Sometimes, an inspection algorithm can be reformulated in such a way that it is easier or faster to implement (➲ Chaps. 17 and ➲ 20). Nevertheless, there are still occasions when a general purpose computer is just not fast enough. In such a case, dedicated high-speed electronic hardware is needed. It is difficult to believe that the time will ever arrive when this is not the case, as sophisticated new "processor hungry" algorithms are always waiting to be employed. Real-time robot control by vision is always very demanding and requires the very highest processing speed. However, before we resort to using dedicated electronic hardware, we should always ask the question "*Can we improve the lighting-viewing arrangement to make the processing simpler/faster?*" Let us assume that we have satisfied ourselves that we cannot. So, we are forced, on occasions, to build specialist image processing hardware. Field programmable gate arrays (FPGAs) offer a convenient and flexible platform on which real-time machine vision systems may be implemented. ➲ Chapter 25 discusses how FPGA based design differs from conventional software design for implementing image processing algorithms. Simply porting from software to hardware can give disappointing results. The process of transforming an algorithm for mapping it onto an FPGA is described in detail, showing how a range of low-level image processing operations (➲ Chap. 14) may be efficiently implemented. Interfacing external devices to the FPGA, image capture, image display, and interacting with the user are also discussed, together with debugging and algorithm tuning. Once again, we see that Machine Vision is concerned with numerous interacting systems issues, not just the theory of image processing algorithms.

1.7.2 Applications Case Studies and Practical Considerations

➲ Chapters 26–38 illustrate the general points made earlier, describing a variety of applications case studies. Of particular note is the way that systems considerations impinge on the design of a vision system. Cost, simplicity, user interface, lighting, object variability are the main factors that have influenced the designs discussed here. ➲ Chapter 39 concludes by discussing management, ethical and social issues.

1.7.2.1 Chapter 26: Very Low-Cost In-Process Gauging System

As with any capital investment in manufacturing, cost is always a consideration when designing a Machine Vision system. Recurrent costs are also important but, if they are properly designed, many vision systems require little maintenance, apart from occasional testing, recalibration and routine cleaning of the lamps and optics. Many systems are installed primarily to reduce operating costs. A pay-back period of 2 years is often taken to be the absolute limit, with 6 months much to be preferred. Even when product or process safety is the first consideration, cost is still important. This is a case study of one application where cost and product safety are both critical. Many applications require only simple processing of the digital images but they can still be very challenging, in terms of building a reliable system capable of withstanding hostile factory conditions. A vision system to gauge two types of automotive parts was developed. One of the part types is a power steering connector in which the depth, width and position of a groove and the end of the power steering line are measured. The second type of part was a crimped connector attached to a brake hose. Two diameters of the crimp and the length of the hose inserted into the connector were measured. The hardware to accomplish the gauging tasks consisted of a standard video camera, light source, image digitizer and industrial personal computer. In order to minimize hardware costs, a standard 50 mm C-mount lens and extension tube were used. By modern standards, the computer was rather slow. Nevertheless, every part can be gauged at full production rates. Indeed, the gauging rate so far exceeds the production rate, that with a video multiplexer the system can process data in real time from four measurement stations simultaneously. Any system that is fast, inexpensive, simple to operate and does the job it was designed to do is a complete success; vision engineers must never be seduced by their vanity to seek sophistication.

1.7.2.2 Chapter 27: Automated Handling of Coils with Flying Leads

There is a need to use robot-like devices to coils with loose wires. (The factory that inspired this work makes audio equipment.) Given that a high-contrast image can be obtained, probably using back-lighting (➋ Chaps. 8 and➋ 40), the image processing is easy. Simple thresholding suffices (➋ Chap. 14). However, the interpretation of the resulting binary images is far from straightforward and requires calculations that neither QT nor NeatVision can perform easily. In the example discussed here, it is necessary to employ a minimum of five cameras: one overhead and four others, viewing the sides of the coil. Using the overhead camera it is possible to decide which side view is best. The reasoning needed to make this decision is ideally suited to Prolog but not QT, MATLAB or NeatVision (➋ Chap. 23). The overhead view can be processed to provide coordinates in two axes, [X,Y], in the horizontal plane. A side view can be used to derive one horizontal (X or Y) and the one vertical coordinate (Z). By combining overhead and side views, it is therefore possible to locate a point, such as the end of a wire, in 3-dimensional space. Locating another point close to the end of the wire allows its orientation to be calculated. These two pairs of position parameters are sufficient to guide a robot to grasp the wires. The ambiguity caused by the fact that there are two loose wires can be resolved easily by reasoning in Prolog. The matrix calculations needed to perform the coordinate-axis transformations are well within the capability of MATLAB (QT's host language) or JAVA (NeatVision). Of greater concern is the problem of resolving real or apparently inter-twined wires. The interpretation of pairs of images is again suitable for Prolog. In this application, where there is a high degree of uncertainty due to the flexible nature of the wires, the image processing is trivial but the use of Artificial Intelligence techniques is essential.

1.7.2.3 Chapter 28: A Telecentric Vision System for Broach Verification

Missing machining steps during the manufacture of industrial parts often leads eventually to product failure. Hence, a common requirement in Machine Vision is to build a system that can verify that a product has been properly fabricated or assembled. This chapter describes such a vision system that is able verify that a certain type of internal gear has been processed (broached) properly. With a conventional lens, the large depth of the gear results in a complex image from which it is difficult to extract the desired edge contour. However, a telecentric lens (➲ Chap. 6) greatly simplifies the image, since only those light rays that are nearly parallel to the optical axis of the lens contribute to forming the image. Once a high-contrast image has been created, the gear silhouette can be isolated, by automated thresholding. This makes the system less sensitive to variations in light level than it would be with fixed-level thresholding. This topic is considered in more detail in ➲ Chap. 13 and occurs in many other places in this book. In ➲ Chap. 19, morphology was used in an algorithm for counting the teeth of a gear (➲ Chap. 21 presents a completely different algorithm, in the form of a QT command sequence, for this task.). The simple structuring element used could be implemented using the SKIPSM approach outlined in ➲ Chap. 20. The three most significant features which contribute to the reliability and good performance of the system are the telecentric optics, automated thresholding and morphology. Following a direct design path, towards unadorned simplicity of the target system, was the key to success.

1.7.2.4 Chapter 29: Challenges of Low Angle Metal Surface (Crosshead) Inspection

It was made clear earlier that Machine Vision systems often combine several different technologies: handling of the objects to be inspected, image acquisition hardware, lighting optics, optics, video cameras, image capture hardware, digital processing hardware, image analysis software and user interface. In this application study, a system was built for on-line inspection of a diesel engine component (a crosshead) that relies for its success on the harmonious integration of all of these. The system acquires and examines two images of each part. Both images are captured when a part-in-place signal is received from the handling system. The surface inspection camera and light source are positioned at opposed low angles relative to the surface (➲ Chaps. 8 and ➲ 40). One camera is set to detect surface irregularities, which manifest themselves as shadows on the image of the top surface. These shadows are detected, measured and compared to user specifications. The other camera is placed so that it can detect the presence of foreign bodies in cavities on the lower part of the crosshead. The image contrast is enhanced with circularly polarized lighting and imaging (➲ Chaps. 8 and ➲ 40). A graphical user interface provides easy setup and debugging of the image processing algorithms. A database module collects, archives, and presents inspection statistics to the user. The inspection rate is 60 parts per minute. An automotive parts manufacturer currently uses the system for on-line inspection of four types of crossheads. As a result of this study, the customer wishes to enhance the system by inspecting the surfaces of the cavities. The important features of this study are: careful system integration, lighting-viewing conditions, collection analysis and display of performance statistics, user interface, user acceptance and processing speed (see Chap. 25).

1.7.2.5 Chapter 30: A Machine Vision System for Quality Grading of Painted Slates

Automated surface inspection is a major application area for Machine Vision systems; sheet metal, paper, plastic film, carpet, fabric, DVDs, magnetic recording media, floor and wall tiles are some of the products that have benefited so far. There are numerous other, less obvious applications, where sheet material is cut up, and assembled into products such as electrical connectors, industrial face masks, medical dressings, cakes, biscuits (cookies), clothing, etc. Any product component made by rolling or extrusion might benefit from similar surface inspection techniques. The algorithms needed are usually different from those employed when examining discrete piece parts. Surface inspection is one of the types of application described in Chap. 2 and, as a result, relies on rule-based decision-making (Chap. 23), or Pattern Recognition methods (Chap. 24). Morphology (Chaps. 19 and 20) is also likely to be important for feature identification. Chapter 30 describes an industrial inspection system that is able to identify visual defects on the surfaces of painted slates. The design of a real-time automated slate inspection system is a challenging task. The surface is coated with dark glossy paint and has an undulating form. Material is transported through the inspection area via high-speed conveyors. A customised lighting-viewing arrangement was devised and flexible image-processing procedures written to accommodate the large variety of visual defects that can appear on the slate surface. Vibration generated by the slate-transport system had to be accommodated. The final target system was subjected to a robustness evaluation, aimed at building the customer confidence needed to supplant the manual inspection procedure previously used.

1.7.2.6 Chapters 31–35: Inspecting Glassware

Glassware inspection is, in many ways, an ideal application for demonstrating the philosophy and practice of Machine Vision but the problem has not been fully solved yet. The fact that glass is transparent and has a refractive index that is significantly different from that of air makes the inspection of glassware very difficult, unless we can devise an effective lighting-viewing method (Chaps. 8 and 40). It is virtually impossible to see all of the features of interest on a bottle, or jar properly, without adjusting the lighting at some point. Understanding the nature of light transmission through a glass bottle requires a good level of understanding of optics (Chaps. 5–7) It may even be necessary to simulate the behaviour of a bottle as an optical component by computer simulation. This approach was useful for understanding x-ray images (Chap. 12). Moulded glassware is important commercially, as it is used widely, for packaging food, drinks, pharmaceuticals, cosmetics and toiletries, as well as domestic, scientific and industrial products. It has many attractive properties but two major disadvantages: it is brittle and the edges of broken glass are very sharp and dangerous. Careful inspection is therefore of crucial importance. Human inspectors cannot cope for long with the high production speeds of a modern manufacturing plant. These factors all contribute to motivate the automation of glassware inspection. This was one of the earliest areas of application for Machine Vision systems to be studied. Yet, there is no general or analytical solution; every problem has to be considered individually and analysed experimentally. The factory environment places limitations on what is possible. When they emerge from the mould, bottles and jars are still red hot, emitting a considerable amount of infra-red radiation. There are two choices here: either use the IR self-emission for imaging (➲ Appendix I), or remove it by filtering (➲ Chap. 5) and apply light externally. The camera and its lens must be protected from the fumes and sprays that pervade the factory atmosphere near the moulding machines (➲ Chap. 40). The bottles are transported from the moulding machines, through the annealing tunnel, to final packing along a conveyor belt. This suggests the use of a line-scan camera. Certain critical faults can occur anywhere around the bottle/jar; they have to be rotated to make sure these defects are always detected, whatever the orientation. High quality (i.e., close tolerance) glass products are made for electronic display devices, where they often form the substrate for a complex pattern of thin film electrical conductors. Hence, glass inspection presents not just one "big problem" but a myriad of tasks, each of limited scope. Sometimes quirky solutions are appropriate but serve only a very limited function. In this type of situation, a well equipped design laboratory, with a wide range of lighting equipment, cameras and lenses is essential. It should also possess an interactive image processing facility, to assist in the design and testing of inspection algorithms (➲ Chaps. 21, ➲ 22 and ➲ 41). The algorithms needed for bottle inspection vary in complexity from simple thresholding, for shape analysis (➲ Chap. 14) to morphology (➲ Chaps. 19 and ➲ 20) and may involve Pattern Recognition (➲ Chap. 24) or Artificial Intelligence (➲ Chap. 23). ➲ Chapters 31–35 describe quite different inspection applications involving glass. ➲ Chapters 31 and ➲ 32 demonstrate some convergence of ideas for inspecting moulded glass products. (The authors developed their ideas independently.) In view of their ubiquitous use as containers for food, pharameuticals, toiletries, etc. the safety of bottles, jars, vials, etc. is of paramount importance. Without apology, we repeat that human beings cannot perform repetetive high-speed, inspection reliably, so any improvement through automation is very welcome (➲ *Fig. 1.1*). ➲ Chapter 33 is concerned with analysing how glass panels shatter. The shape and size of the broken glass fragments is an important safety issue, particularly for automobiles. ➲ Chapters 34 and ➲ 35 are concerned with close tolerance glass artifacts. Here, high quality (i.e., close tolerance) glassware is essential for its proper function.

1.7.2.7 Chapter 36: Inspecting Food Products

Food products are usually more variable than engineering components but they are not totally unconstrained (➲ Chap. 2). For example, the height of "good" loaves made on a given production line is unlikely to vary by more than a few percent around the nominal value. Indeed, manufacturers of such products as loaves, cakes, pies, confectionary bars and pizzas are obliged by law to state minimum limits on weight, which in turn defines minimum size parameters. The upper limit is set by the container/wrapping. Aesthetic criteria, economics and customer attitudes may define even tighter restrictions. The application of Machine Vision to many food products is therefore still practical and economically viable. There is, of course, an ever-present need to improve the hygiene, safety and quality of all materials and products that we consume. Stored bulk food materials are prone to attracting insects, birds and rodents, as do growing plants. Infestation is a major issue in food processing and detecting body parts, droppings, nesting materials, etc. in food products or materials is of critical importance. In addition, manufacturers always want their products to appeal visually to the customer. As the sensory medium for Machine Vision, VIS, UV, IR and x-rays, are all valuable and have different capabilities (Chaps. 7–12 and Appendix I). A variety of inspection methods is appropriate for food products, including morphology (Chaps. 19 and 20), Hough Transform (Chap. 18), Prolog-style declarative programming (Chap. 23), colour recognition (Chap. 16) and Pattern Recognition (Chap. 24). Often, naive image analysis techniques will suffice. For example, when inspecting biscuits (cookies), the area of an object silhouette, or a measure of its resemblance to an ellipse, circle, or square, provides a basic level of discrimination. Where greater discerning power is needed, standard image processing methods, such as those described in Chap. 14 and implemented in NeatVision (Chap. 22) and QT (Chap. 21), are useful. Although Chap. 36 does not dwell on practical issues, such as the hygiene requirements for the materials/object transport mechanism, these are essential for a reliable inspection system (Chaps. 12 and 28). Many food products, such as biscuits, are made at very high speed. Achieving the throughput rate needed in a practical inspection system can be a challenge. Fast dedicated hardware is expensive but sometimes unavoidable. The ability to reformulate algorithms to maximise the processing speed in a conventional computer requires ingenuity. Chapters 17 and 20 hint at the way this might be done.

1.7.2.8 Chapter 37: Automatic Produce Grading System

This chapter shows that the technology devised for inspecting industrial products can also be applied successfully to measuring natural materials, in this case asparagus. It is emphasised in Chap. 2 that organic products, such as fruit, and vegetables are usually highly variable, compared to industrial components. Nevertheless, there is an extensive range of potential applications for Machine Vision, in agriculture, horticulture and food processing, particularly where the level of variation is restrained. This can occur naturally, for example as a result of the (statistical) limits of normal plant growth, or artificially, by processes such as trimming before inspection. In any application involving highly variable and/or flexible materials, one of the more difficult issues to resolve is the design of the mechanical handling sub-system. Apart from the obvious requirement that the object under examination has to be held/moved so that it can be illuminated and viewed properly, other demands exist: (a) The inspection system must not be damaged by the product. (For example, the machine must not jam, corrode, or interact chemically with juices exuded by the product.) (b) The machine must not damage the product. (c) The machine must not allow the accumulation of waste that will nurture the growth of micro-organisms. (d) For reasons of hygiene, it must be possible to dismantle and clean a food-handling system in a few minutes. This chapter emphasises that these are not minor issues, simply to be "tidied up," after developing clever image processing algorithms; they are absolutely central to good design. (The same point is made in Chap. 11.) An important feature of Chap. 37 is the use of vision to estimate bulk product properties, in this case volume and hence weight. (X-ray inspection systems provide an alternative approach. See Chap. 12). In this application, it is important to measure and understand the statistics of system performance, since the vision system is being used to estimate bulk properties, rather than delivering parameters for each item individually. While precision measurement of individual objects, is always welcome, it is important that the machine must not bias the statistical distribution of results. At the very least, the mean and variance for each parameter, such as length, diameter and volume, must be known. Better still, the statistical distribution of each measurement should be known. This requires that the system be calibrated carefully and regularly. In many large-volume, and/or high unit-value applications, the cost of installing a vision system can often be justified on economic grounds alone, even if it only achieves a seemingly modest reduction of waste. Significant savings can often be made simply by obtaining more precise and accurate measurements. A small percentage saving on waste, either by better discrimination of defects, or controlling trimming more accurately, can sometimes lead to large financial savings. In some instances, the case for using vision can be quite compelling economically, even if the system does not perform in a way that excites the most sedulous vision engineer. We must never assume without question that precise measurements can be computed at the same time as the product is being examined for damage, rotting, infection, etc; it is very likely that different lighting-viewing methods will be needed. While the inspection of low-variability natural products and semi-controlled manufactured goods, such as loaves, cakes, pies, etc. seems to lie at the fringe of Machine Vision as we describe in the pages of this book, this is clearly an area of major social and economic importance. The most important lesson of ➲ Chap. 37 is that it leaves no doubt that success in Machine Vision requires our adopting a systems approach during the design process.

1.7.2.9 Chapter 38: Analysing the Creasing Properties of Fabric

A large clothing retail store in UK wishes to analyse the creasing properties of the fabrics used in products, such as shirts, blouses, dresses, etc. At the moment, creasing is judged subjectively and inaccurately, by comparing a sample with carefully designed models, photographs, etc. There is a need for a laboratory, rather than a factory, based vision system to automate this task. A sample of the plain unprinted fabric is first subjected to a standard creasing regime. It is then stretched gently and placed on a table. Lighting at a low angle is then applied from one side (➲ Chap. 40). The resulting image has a low contrast but it is sufficient to be able to see the creases. ➲ Chapter 38 presents the results of applying several different (grey-scale) image filters plus thresholding, to produce a binary image (➲ Chap. 14). Several measurements are then taken to describe the texture of this image (➲ Chap. 19). The result is a multi-element vector that can then be used as the input to a pattern classifier (➲ Chap. 24). If necessary, this process can be repeated by applying more than one grey-scale filter. Their pattern vectors are then concatenated. The "teacher" required to train the pattern classifier is the existing human inspector who defines the creasing coefficient. The classifier then learns to predict this coefficient. This is the normal mode for learning by example in a Pattern Recognition system. Similar techniques are suitable for analysing other textured surfaces, such as machined metal, paintwork, decorative marble, wood etc.

1.7.2.10 Chapter 39: Environmental, Social and Ethical Issues

Machine Vision technology has changed considerably over the last 35 years. There have been major improvements in lighting, optics, cameras, camera-computer interfaces, software and hardware for processing images. However, the most significant advances have been in mental attitudes to the way vision systems are used. In the early days of the development of the subject, there was a great deal of scepticism. Nowadays, most people are aware of the possibility of adjusting pictures with a computer, using programs such as Adobe Photoshop™, while visual effects, such as posterising, pseudo-colouring and morphing, are used extensively on television and film. The concept of image processing is familiar now, even though the techniques for doing this are not widely understood. This has had an impact on the willingness of industrial engineers to countenance the use of Machine Vision. However, there is a danger of developing unrealistic, over-optimistic expectations, created by science fiction drama. Vision engineers have also learned a lot since the inception of the subject, particularly about appropriate attitudes and priorities. The following points have been learned, often forgotten and then rediscovered:

- Systems thinking is of paramount importance (➲ Appendices B–D)
- Do not expect to rely on formulae or a list of prescribed steps. (The author has often contemplating trying to condense his knowledge into an expert system but still remains convinced that it is far too difficult. He began working on this book instead!)
- Consider the application requirements (➲ Appendix B)
- Decide exactly what the vision system is supposed to do and do not be deflected from that
- Visit the factory
- Gather plenty of fresh samples of objects to be inspected
- Do not expect the customer to understand or trust the technology, at first (➲ Appendix C)
- Do not expect a vision system to be able to work in uncontrolled natural lighting (➲ Chaps. 8 and ➲ 40).
- Look at the object to be inspected. (This simple advice is often ignored.)
- Everybody is an expert on vision – in his own estimation but not in reality.
- Ask questions (➲ Appendix B contains some typical questions but do not over-rely on this.)
- Select an appropriate camera or scanner (➲ Chaps. 8–10)
- Experiment with the lighting-viewing conditions (➲ Chaps. 8 and ➲ 40)
- Design the optics scientifically (➲ Chap. 5)
- Experiment with the image processing (NeatVision and QT typify the type of software needed. ➲ Chapters 21, ➲ 22, ➲ 41, ➲ Appendix G)
- Demonstrate feasibility at each stage in the design. (This is what QT and NeatVision are intended to do)
- Protect the lights, camera and optics (➲ Chap. 41).
- Remember and apply Occam's Razor: *It is vain to do with more what can be done with less.* (The KISS principle is a more direct way to express the same idea: *Keep it simple, Stupid!*)

➲ Chapter 39 also briefly considers some of the social and ethical issues relating to Machine Vision. This is an area where more serious work is needed. Like all modern technologies, Machine Vision can be used for good or ill. Its power to benefit society lies in its ability to free human beings from tedious boring jobs that people cannot do very well.

The views expressed in ➲ Chap. 39 are those of the author and do not necessarily reflect those of other contributors to this book. Of all the many lectures on Machine Vision that the author has given in his career, the points made in this chapter elicited by far the most enthusiastic response. Even if the reader does not agree, the author hopes that it will trigger discussion and more thought about the important non-technical issues.

2 Inspecting Natural and Other Variable Objects

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_2,

Abstract: This chapter is concerned with the design of artificial vision systems that attempt to emulate one particular human activity: inspecting and manipulating highly variable natural objects and human artifacts. During the last quarter of the twentieth century and the first decade of the twenty-first century, *Machine Vision*, evolved from an exotic technology, created by academics, into one that is of considerable practical and commercial value, and which now provides assistance over a wide area of manufacturing industry. Hitherto, Machine Vision has been applied extensively in industry to tasks such as inspecting close tolerance engineering artefacts, during or shortly, after, manufacture. However, Machine Vision technology can also be applied to those areas of manufacturing where natural materials and other highly variable objects are processed. Our discussion in these pages is aimed at those areas of manufacturing where wide tolerances are encountered, as well as activities, such as agriculture, horticulture, fishing, mining, etc., where similar conditions apply. However, we should not lose sight of the fact that certain so-called high-precision industries are plagued by significant degrees of uncertainty. For example, the electronics industry is renowned for working with high-precision components (integrated circuits, printed circuit boards, etc.). However, it is also concerned with highly variable entities such as solder joints, flexible cables and components with flying-lead connectors (resistors, capacitors, diodes, coils, etc.). This chapter is relevant to applications such as these, as it is to examining fruit, vegetables, animals, fish, etc.

2.1 Introduction

2.1.1 The Problem Domain

We shall concentrate primarily on the inspection of natural materials and products with an ill-defined shape, size, colour or texture. Food manufacturing forms an important area of application but there are applications of this kind in a wide range of industries, including agriculture, fishing, horticulture, mining, catering, pharmaceuticals, clothing, foot-wear, etc. In addition, many tasks in engineering manufacture require the handling and processing of highly variable objects.

Both Machine Vision and Robotics have hitherto achieved their greatest success with close-tolerance products. By broadening the scope of our subject, we are implicitly acknowledging that Machine Vision has reached a certain level of maturity and that it is able to reach into application areas that have hitherto been considered to be too difficult. There are significant commercial and practical benefits to be obtained. For example, there is a strong and continuing demand for new instruments that can improve the quality and safety of all products, especially food and pharmaceuticals items. If we are successful, Machine Vision will bring significant economic, health, safety and social benefits to several areas of industry that have hitherto been inaccessible to it.

When we apply Machine Vision techniques to the inspection and handling of manufactured goods, we know roughly what to expect. This is certainly true for high-precision objects, such as stampings, castings, mouldings, lathe-turned objects, etc. It is also true for many types of mass-produced food items. For example, one loaf of bread, confectionary bar, meat pie or cake, of a given kind, should be "similar to" all other items of the same nominal type. Even live-stock exhibits some similarities but these may be harder to define objectively. Most pigs of a certain breed will have "similar" colouring patterns. More generally, natural products of a given class usually possess some degree of "similarity" to each other. Indeed, this helps us to define the concept of a "class". More recently, Machine Vision, and the allied subjects of Pattern Recognition and Artificial Intelligence, have all developed to the point where we can broaden the concept of "similarity".

2.1.2 Applications Classified by Task

The potential for applying Machine Vision technology in food industry, agriculture and horticulture is huge, although the penetration of these markets to date has been somewhat less than in manufacturing. Present and projected applications of Machine Vision to natural products may be classified conveniently according to the function they perform. No particular commercial importance is implied by the order of the following list:

- *Analysing the content* of a mixture (e.g., count how many sweets of each kind are put in a box; estimate the lean-to-fat ratio of a batch of butchered meat; check the mixing of granulated materials)
- *Analysing the shape* of whole products as a prelude to processing them using robotic manipulators (e.g., fruit, vegetables, animal carcasses, etc., might be trimmed and packed by a visually guided robot)
- *Analysing texture* (e.g., bread, cork floor tiles, wood panels, etc.)
- *Assembling food products* (e.g., pizza, quiche, meat pies, etc.)
- *Checking aesthetic appearance* (e.g., loaves, cakes, quiches, trifles, wood veneer, marble tiles, etc.)
- *Cleaning* (e.g., selective washing of cauliflower, broccoli, leeks, lettuce, cabbage, etc.)
- *Coating* (e.g., chocolate coating of confectionary bars, icing (frosting) on cakes)
- *Counting* (e.g., counting cherries on the surface of a cake, counting bubbles on top of a trifle, estimating the number of healthy leaves on a growing plant)
- *Decorating* (e.g., cakes, chocolates, trifles, pies, etc.)
- *Detecting foreign bodies* (These may be “natural” and intrinsic to the product (e.g., seeds, nut shells, twigs, etc.), or truly “foreign” (e.g., stones, rodent remains, broken machine parts, contact lenses, false teeth, etc.))
- *Detecting surface contamination* (e.g., mildew, mud, bird excrement, etc.)
- *Estimating the size or volume* (e.g., fruit, fish, animal, poultry carcasses, meat fillets, etc.)
- *Grading* (e.g., identifying premier-quality fruit and vegetables)
- *Harvesting* (there is a huge variety of tasks of this type)
- *Identifying loss of integrity* (e.g., rotting of fruit or vegetables, withering due to disease or lack of moisture, bird pecks, insect holes,)
- *Measuring linear dimension* (e.g., fruit, vegetables, animal carcasses)
- *Packaging* (e.g., fragile or variable products, cream cakes, meringues, etc.)
- *Sorting* (e.g., fruit from leaves; fish by size / species on a trawler)
- *Spraying* (e.g., selective spraying of insecticides and fertiliser)
- *Stacking / packing* (e.g., carrots, oranges, frozen chickens, boxes, jars, bottles, cans or tubs, flexible bags)
- *Trimming and cutting* (Fish and vegetables all require robotic cutting. Butchery and automated shearing of sheep are also included in this category)

This does not include the multitude of tasks that can arise in manufacturing, where low-tolerance features occur, and giving rise to highly variable images to be processed. The following list gives a hint of the wide variety of inspection tasks of this kind that exists:

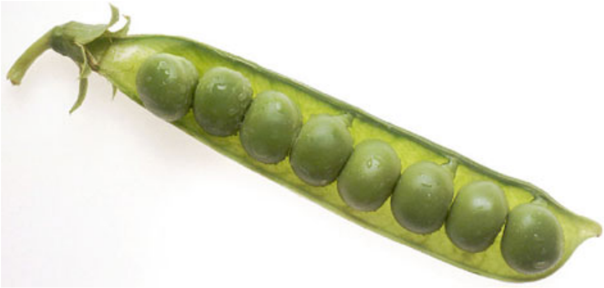
- Adhesive strings and drops
- Complex assemblies of components
- Electrical coils that have flying wires attached

- Feed stock for automatic machining
- Flexible pipes
- Gobs of semi-molten glass (prior to forming jars, bottles, etc.)
- Moulds loaded with powders, granulated or semi-fluid material
- Material-feed hoppers
- Powdered material prior to melting, sintering, etc.
- Rubber or plastic gaskets, water and oil seals, etc.
- Solder joints
- Spray cones, flames and smoke plumes
- Sprue, swarf, remnant material (for example, after punching)
- Unfired ceramics, including tiles, table-ware, etc.
- Welds
- Wiring looms

The fact is that even so-called high-precision manufacturing is not as tidy and well controlled as we would like. The main reason is that raw materials are unpredictable in shape, size, and colour. Another important factor is that it is sometimes expedient, or necessary, to apply a low-tolerance manufacturing technique (e.g., applying adhesive) to high-precision parts. The engineer's skill is manifest in doing this in such a way that the "untidy" parts are not apparent to the customer.

2.2 Product Variability

In British English it is common to say that two similar objects are "as alike as two peas in a pod". Yet, peas in a pod can be very different from one another (➲ *Fig. 2.1*). They can differ very considerably in size, shape, colour and surface texture. Some peas are likely to be bright green, while others have a brown or yellow tinge, or be nearly white. Their skins can be split and some peas have insect holes. They can also differ in shape; some peas are almost square, having been squashed by their neighbours in the pod. Most peas are nearly spherical, while others may be ovoid. Natural objects, like peas, frequently vary from one another in many different ways. In the light of these remarks, it may seem that by stating that "objects A and B are as alike as two



◘ Fig. 2.1

Peas are not alike in shape, colour or surface texture (Photograph Renee Comet, http://visualsonline.cancer.gov/details.cfm?imageid=2612, accessed 6th October 2008)

peas in a pod", we are not making a very strong statement about their similarity. In fact, we need to revise our concept of similarity, since all of the peas growing in a given pod are genetically identical; they all contain the same macromolecules and they have very nearly the same taste and nutritional value. Natural variations in physical size, colour, shape and texture all have to be *tolerated* by an inspection system. Peas are never more than 15 mm in diameter. They are never blue, striped or hairy. They do not have a sponge-like surface, nor do they move of their own volition. This is the nature of their similarity, which is fundamentally different from that relating two cars of the same model, or two bottles made in the same mould.

2.2.1 Linear Dimensions

We need to define a measure of variability. Let X be some conveniently measured linear dimension, such as the diameter of an apple, the length of a banana, or the circumference of an orange. Let X_0 be the average value of X, for a certain class of objects, C. Furthermore, let δX be the maximum observed deviation from X_0. (Hence, all estimates of X for objects in class C lie in the range $X_0 \pm \delta X$.) The degree of variation of objects in class C is defined as V_C where

$$V_C = \log_{10}(X_0/\delta X) \tag{2.1}$$

Statisticians would, no doubt, argue that we should instead relate V_C to the standard deviation of X, rather than the total range of this variable. However, the logarithm in the definition of V_C makes this change relatively unimportant. Furthermore, as far as both manufacturers and customers are concerned, the range of variation ($X_0 \pm \delta X$) is often more important than statistical measures. If an object, such as a loaf, is too large, it will not fit into its packaging. On the other hand, if it is too small, the customer will not buy it! The present measure of variability (V_C) is conceptually simpler than one based on statistical parameters and is perfectly satisfactory for our present purposes.

We shall see that V_C is large for high-tolerance (engineering) products and small for highly variable objects (e.g., food and natural products). In the following discussion, remember that almost all of the successful applications of Machine Vision to date have been based on products for which $V_C \geq 2$ (➲ *Fig. 2.2*).

Among the very highest precision objects made in industry are mirrors and other optical components. A good-quality plane mirror has a surface ground to about $\pm\lambda/10$, where λ is the working wavelength. Suppose a mirror has a diameter of 50 mm and is expected to reflect green light ($\lambda = 0.5$ μm). Then, $V_C = 5$. (It is more meaningful to compute V_C in this way than to compare to the thickness of the mirror substrate.)

Electronic circuit boards combine high precision components (semiconductor chips) and low precision features (e.g., resistor placement and solder joints). Integrated circuit chips with a conductor width of 2 m (i.e., $X \approx 0.2$ m) and a diameter of 8 mm have a variability score $V_C = 4.6$.

A "typical" engine part for an automobile engine might be 10 mm long and have a tolerance of 10 m. Then, $V_C = 3$.

A bottle or jar has a slightly greater degree of variability. A wine bottle is about 300 mm tall and its variation in height is roughly 1 mm. (Although it is made in a mould, the bottle is liable to sag under its own weight, before the glass cools to become "solid".) Hence, $V_C = 2.4$.

Now, consider more variable items. A jam doughnut is about 150 mm in diameter and its variation in diameter can be as much as 10 mm. (It is not truly round either.) Hence, $V_C = 1.18$. Baked goods, formed by cooking semi-fluid dollops of dough on a plain tray, can vary by even

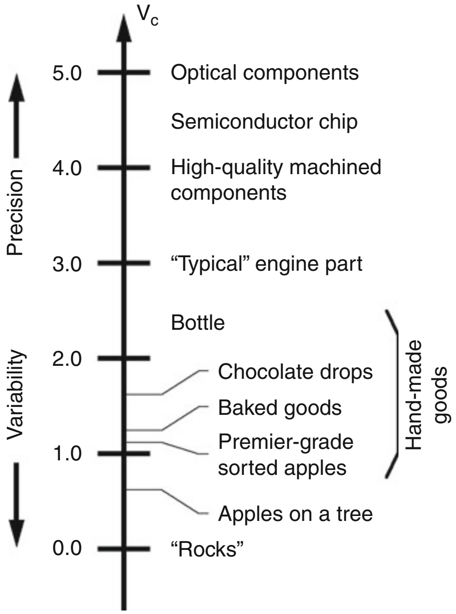


Fig. 2.2
The measurement of variability in human artefacts and natural products. All values of Vc are approximate. Hitherto, almost all applications have been based on products for which Vc > 2.0

more than this. The baking process, combined with the ill-defined size of a "dollop" can produce values of V_C less than 1.0. The author measured two packets of chocolate drops, of different sizes, yielding measurements of V_C equal to 1.54 and 1.56. Bread rolls, croissants and many other baked goods and items of confectionary are highly variable, giving values of V_C equal to 1.0 or even less.

Natural products, such as apples, of a given variety, typically vary by a large amount, giving values of V_C as small as 0.4–0.5. Modern supermarkets tend to avoid selling apples of highly variable size, by the simple expedient of grading them before they are put on sale. (Grading apples represents a potential application for Machine Vision.) In a series of measurements of premier-quality graded apples, a value of $V_C = 1.10$ was recorded.

Agriculture, as distinct from food processing, is concerned with very high degrees of variability, since growing animals and plants can differ greatly in size. A farmer cannot properly control the size of fruit on a tree; he or she must pick whatever happens to be there. Hence, V_C is likely to be very small, possibly under 0.5. Of course, farm animals also vary in size. For adult pigs of a given breed, $V_C = 0.5$.

There is another important class of objects that we have not mentioned yet but which deserves attention: hand-made goods. Consider a hand-thrown pot, such as a jug, or vase. No two vessels, even of the same nominal type are exactly alike in size and shape and we might expect V_C to be about 1.3–1.9. Hand-carved and painted artefacts produce a roughly similar range of variation, as do hand-cut and engraved glass-ware. Exceptionally, human beings can make objects for which V_C is as large as 2.3.

There is another even worse situation in mining and quarrying, where it is almost impossible to define the size of a "typical lump" of rock. Here, it is meaningless to quote typical values for our measure of variability, V_C. Let it suffice to say that gravel, lumps of rocks and coal, etc., are very variable ($V_C \leq 0.3$) and therefore require non-specific handling techniques.

2.2.2 Shape

The so-called *shape factor* is one such shape descriptor that is popular among vision engineers. The *shape factor* of a blob-like object is defined as 0.079577 (1/[4π]) times the ratio of its area to the square of its perimeter. This has a maximum value of 1.00 for a circle and has low values for spider-like objects. For example, a hair comb gave a value of 0.01532. Five ivy leaves (➋ Appendix G) produced values of shape factor varying from 0.425 to 0.546. Similarly, five chicken "butterflies" (➋ Chap. 12) gave values between 0.421 and 0.597. On the other hand, a croissant produced a very similar value (0.633) to that obtained from a slice of bread (non-lidded tin loaf, 0.631). The fact that intra-class variability is comparable to and may even exceed inter-class variability merely indicates that shape factor is not a particularly good measurement of shape. Other shape measurements may be more sensitive to the particular types of shape variation that are important in a given application.

Despite the differences that exist among objects like ivy leaves, human beings are readily able to classify them as belonging to the same general class. Of course this merely confirms that human beings are well suited to recognising natural objects, despite their highly variable shapes. This is just one example of the general principle that tasks that a person finds easy may be quite difficult for a machine (and vice versa).

When designing Machine Vision systems, we have to assume that the shapes of both natural products (e.g., fruit, vegetables, nuts, individual leaves, decorative domestic plants, etc.) and certain manufactured items (baked goods, confectionary, meat pies, joints of meat, etc.) will vary considerably. We have only to pick up a handful of fallen leaves, or buy a kilogramme of carrots or potatoes, to observe the high level of variation of shape that a vision system must tolerate. Of course, while shape variation is usually manifest in three dimensions, it is only observed in two dimensions, assuming that we employ a single video camera. A stereoscopic vision system or 3-D scanner may see the full effects of shape changes but we do not need either of these to understand the nature of the problem that shape variation causes. It must be understood that conventional (i.e., geometric) concepts of shape are totally meaningless in this context. For example, "round" fruit is not truly circular, in the mathematical sense. Furthermore, straight lines, right-angle corners, rectangles parallelograms, ellipses and other geometric figures do not exist in nature, except in the special case of crystalline structures.

The unpredictable shape of certain natural objects creates severe problems for an automated mechanical-handling system. Fixed tooling is out of the question for tasks such as trimming lettuce, shearing sheep, or automated butchery. Alternatively, multi-axis robots require complicated multi-sensor feed-back control techniques to cope with highly variable object shapes. Even seemingly simple vision-based tasks relating to natural objects can require the use of complex equipment. For example, removing spot-like surface defects on nominally round fruit or vegetables (e.g., "eyes" on potatoes) requires the use of a 4-axis (X,Y,Z,θ) visually-guided robot. Trimming rhubarb requires a 3-axis robot (X,Y,θ), while placing decorative features on top of a cake requires 4 degrees of freedom, (X,Y,Z,θ). Everyday tasks, such as removing the leaves from carrots, or trimming leaks, are often quite difficult when we try to automate them. We should bear in mind too that in many cases we must treat natural products with great care, to avoid damaging them. By clever user of guide rails, shaped conveyors, etc., it is sometimes possible to reduce the complexity of a robot handling highly variable products. For example, a single-axis robot could be used to trim the ends of carrots that have already been aligned, perhaps using a slotted conveyor. Nevertheless, the complexity of the handling equipment is usually higher than it is for high-precision objects. The general rule is that, if we know what an object is and where it is, simple handling techniques are possible, even desirable. Variations in shape make this prerequisite difficult to achieve.

Many shape-analysis techniques that work satisfactorily on one example of a given type of object may not work with other samples of the same product kind. In other applications, ill-defined shapes are present that are amenable to only the simplest and most robust methods of analysis. In some situations, we may even have to change the method of analysis as the shape changes. A child's toy illustrates this point (Appendix F). Organic materials and objects frequently change shape as they grow. Hence, we must be prepared for a similar situation to occur, when we are working with natural products.

2.2.3 Why Physical Tolerances Matter

There are several reasons why physical dimensions matter:

(a) Objects to be inspected must be fed through the inspection machine, whatever their size and shape. The mechanical handling system must accommodate all variations of these parameters without jamming. Clearly, this is much more difficult if these objects are of uncertain size and shape.

(b) In view of the preceding point, the system for mechanical handling of highly variable objects must either be very intelligent, or very simple, such as a plain-top conveyor belt. Of course, a conveyor belt is far simpler and cheaper than a multi-axis robot but has one serious drawback: it is unable to hold the object in any particular pose before the camera. The design of robust mechanical handling systems for highly variable objects, especially plants with flexible foliage, requires considerable skill and ingenuity.

(c) The camera may not be able to see certain features. Certain objects (e.g., bread rolls and some cakes) are actually made on a conveyor. It is therefore quite difficult to examine their bases. Certain objects will always fall into the same pose, if dropped haphazardly onto a flat surface (e.g., a plain conveyor belt). Other objects may have two or three stable states, while objects such as apples have one or more quasi-stable states. As a result, measurements of certain parameters, such as apple diameters, may show statistical bias, unless care is taken to orientate the objects first. The conveyor itself may obscure some features. It is common practice to use shaped (e.g., cupped) conveyors to stop delicate objects such as eggs, fruit, etc., from banging into one another. Inevitably, this causes some restriction on viewing angles.

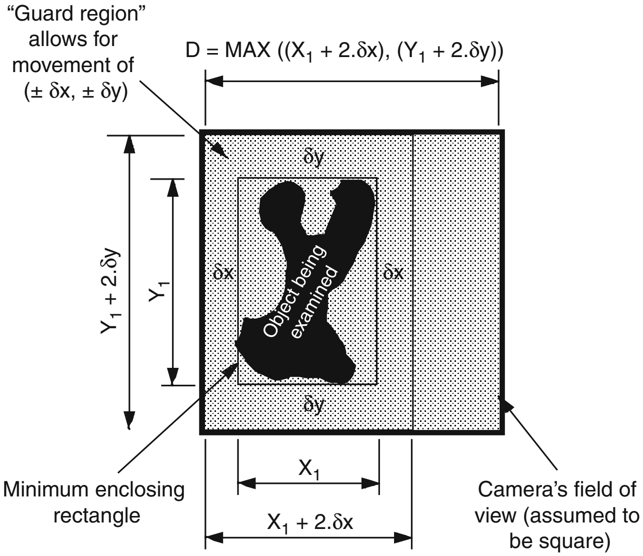
(d) Varying shape presents problems by obstructing illumination, or viewing. At its simplest, this means that certain features are obscured, either by being out of the camera's line of sight, or by being in a shadow. The latter can *always* be solved by coaxial illumination and viewing but this may not yield sufficient contrast to be of practical use. Obtaining images from the unpredictable form of untrained foliage presents a particular challenge and a high level of intelligence is needed to perform operations such as pruning, picking fruit, selective spraying, etc. In general, the lighting arrangement needed for highly variable products is problematical, since the optimal illumination configuration for one sample may be far from ideal for another. The problem is made worse by the fact that samples of the same type of object may lie in different poses. The range of options for maximising image contrast by good lighting is rather smaller than that available for well-defined, high tolerance products. The use of intelligent lighting is another possibility for coping with high levels of product variability but has, as yet, received scant attention.

(e) When object size and/or shape is highly variable, choosing the most appropriate lens can present problems. The field of view must be large enough to accommodate the biggest objects of a given class. Yet, this may mean that the smallest examples may not be seen easily. The problem is worse than we might imagine at first, because natural products tend to be delivered haphazardly for inspection. It is impossible to predict how they will fall to rest, since they roll, fall into a quasi-stable pose, or even change shape as thy come to rest (e.g., soft-heart lettuces, certain types of cut flowers). All of these produce an uncertainty of position that must be accommodated by increasing the size of the camera's field of view (➋ *Fig. 2.3*).

(f) Changes in object size alters the contrast in x-ray images. The thicker the sample, the denser an object is to x-rays and the lower the contrast on small foreign bodies of fixed size and material will be.

(g) Finally, the image processing operations needed to inspect natural and other highly variable objects (Vc $\leq$ 2) often differ fundamentally from those used for high-tolerance parts. (Vc $\geq$ 2). The former have to be more intelligent, since they have to cope with greater levels of uncertainty about all aspects of the object's appearance: size, shape, pose, position, texture and colour.

Perhaps the most significant problem of all is the lack of a clear objective criterion for what is an acceptable product. Bakers have devised heuristic rules for identifying malformed loaves



"Guard region" allows for movement of (± δx, ± δy)

■ Fig. 2.3

Uncertainties in the position of the object being examined require that the camera's field of view be larger than the object itself. If the object orientation is not controlled, the field of view must be even larger. (Also see ➋ Chap. 40 [Methods 8 and 9] and ➋ Chap. 41 [QT function fov].)

or cakes. These are used principally to train inspection personnel and were derived by bakers, trying to predict what their customers want. The best practice is, of course, to ask a large number of customers what they will accept. Although this is expensive, it does not necessarily give a perfect picture of what constitutes a "good" product, since customers cannot always vocalise their preferences. Precision in such an exercise is notoriously difficult to achieve, because there is no such thing as a "typical" customer. Judgements are made sub-consciously, based upon a large variety of factors, such as packaging, cost, and even location on a supermarket shelf. In some companies, opinion about what is acceptable may even come from casual remarks made by the CEO's wife! However, the final decision about what constitutes an acceptable loaf or cake is based on purely subjective criteria by individual customers in a supermarket. Strict rules do exist for grading and classifying fruit and vegetables. (Indeed, these are fundamental to the international trade agreements.) These include but are not restricted to specification of shape, size and colour. Criteria for grading living plants, and animals are almost inevitably expressed by heuristic rules, derived by nursery-men, farmers, whole-salers, retailers, etc., who try to anticipate what the end-customer wants. Aesthetic judgement about decorative items, such as wood panelling and marble tiles is difficult to automate but criteria based on experience probably represent the best explicit statements that we can achieve. To a software engineer, this suggests the use rule-based decision-making techniques and expert systems. Self-adaptive Pattern Recognition techniques, including Artificial Neural Networks, are appropriate when a human inspector can only say that an object is either "good" or "faulty".

2.2.4 Flexible and Articulated Objects

Many natural and fabricated products are totally or partially flexible and present considerable problems for the designer of a vision system. The mechanical handling sub-system and image processing algorithms have to be designed with particular care.

Tasks involving the manipulation of simple articulated objects may be far more difficult than we might imagine. Even a simple pair of scissors alters its topology as it is opened and shut (Appendix F). A chain of linked levers is even more difficult to inspect and may require that we flex the assembly to examine it properly. This may well require sophisticated sensing (vision and force feed-back) and manipulation (robotics), as well as a high-level of intelligence and knowledge about the application. The posture of an articulated object may become unstable, causing it to fall over, as is it (un)folded. Certain features may become invisible, for example when an articulated arm is folded. Flexible objects and articulated mechanical systems are often fragile and therefore require special care in handling. Non-contact opto-electronic sensing is, of course, ideal, provided that the inherent difficulties of working with flexible or articulated systems can be overcome. Unfortunately, we are not yet able to build an effective "multi-purpose" handling system for flexible and articulated objects; each application has to be considered separately.

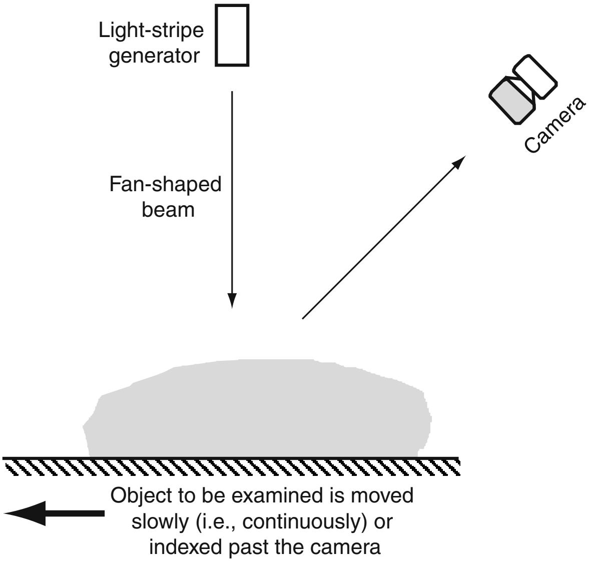
It is fairly easy to design a mechanism to transport carrots, once their leaves have been removed but they do not oblige us by growing according to our whims! Vegetables and fruit may well be delivered to an inspection system with their leaves and stalks still attached. Of course, it is likely to make the design task easier for the vision engineer, if they have been removed beforehand. Many types of fruit and vegetable can be handled successfully by cleverly-designed mechanical systems but these are expensive, prone to jamming and damaging the product. In addition, food-trimming machines require frequent cleaning and may be quite wasteful by removing too much "good" material. It would be better, therefore, if we could use vision to minimise the physical contact between the machine and the product that it is processing.

Gardening and horticulture present some interesting but very challenging applications, including pruning, grafting, taking cuttings, replanting seedlings, etc. These are difficult tasks for a machine and consequently require intelligent image analysis techniques and careful design of the robot and its end-effectors. Micropropagation is a well-constrained task of this type and offers immediate financial and social benefits. (Human beings have to wear face masks, hair nets and overalls to avoid infecting the tiny plants, as they are working.)

Broadly similar problems occur in engineering industry, for example, when handling objects that have trailing tubes, wires or cables (➲ Chap. 27). Industrial parts-handling applications create a wide spectrum of difficulties.

Some objects such as certain cuts of meat and fish, foliage, leather, cloth, etc., are, of course, flexible. Sometimes a vision system is required specifically to guide a robot to handle and process such materials. This type of task still presents a formidable challenge to both vision engineers and robot designers. Hence, on many occasions, we still have to rely on human beings to deliver flexible materials to an inspection station. (The chicken-breast "butterflies" illustrated in ➲ Chap. 12 are fed to the x-ray system in this way.)

Once again, it may be impossible to achieve optimal lighting everywhere. At first sight, structured lighting (➲ *Fig. 2.4*) seems to provides a possible way to acquire detailed information about the 3-dimensional structure for certain applications. However, there are considerable problems, due principally to glinting, occlusion, and the limited working speed. of light-stripe triangulation techniques.



Light-stripe generator
Camera
Fan-shaped beam
Object to be examined is moved slowly (i.e., continuously) or indexed past the camera

Fig. 2.4
Structured lighting to measure 3-d shape. The light-stripe generator may be as simple as a diode laser fitted with a cylindrical lens. If the positions of the laser and camera are reversed, the data is more difficult to analyse

2.2.5 Soft and Semi-Fluid Objects

Machine Vision has an important role to play in inspecting soft and semi-fluid materials, such as uncooked dough, pastry and cake mixture, minced meat, whipped cream, jam, various gels and pastes used in the food and pharmaceutical industries, etc. Many industrial artefacts contain materials that are semi-fluid at some time during the manufacturing process. Examples are uncured foams, molten solder, globs of adhesive, gobs of molten glass, etc. These all require special handling techniques, as we must not disturb a semi-fluid dollop unnecessarily, simply to suit the whim of a vision engineer.

A characteristic that is peculiar to this class of materials is that their composition can be changed very easily and quickly. To avoid drying and curing semi-fluid material, infra-red and ultra-violet should be removed from the illuminating radiation, using standard optical filters. Sometimes in particularly dirty factory environments, an air purge is used to maintain clean optical surfaces. In this situation, we must ensure that it does not blow dust or moisture onto the damp surface. An ill-directed air purge can cool the surface too quickly and blow dirt onto it.

However, if care is taken to avoid the problems just mentioned, Machine Vision is ideal for inspecting semi-fluid materials, as no physical contact is needed. Thus, the shape of a lump of unbaked dough, or a dollop of whipped cream, is not altered by the inspection system. Furthermore, there is no possibility of introducing micro-organism contamination to food or pharmaceutical products. These facts provide powerful motivation for using Machine Vision in these industries. However, there is one fundamental problem: *What does a "good" lump of dough look like?* How do we define an acceptable range of shapes for dollops of cream on a cake or trifle? This the classical "ground truth" problem encountered when designing Pattern Recognition systems.

2.2.6 Colour Variations

2.2.6.1 Colour Variations in Natural Products

One of the greatest challenges encountered when applying Machine Vision to natural objects lies in the recognition of colour. Natural objects tend to display very subtle variations of colour, which usually changes continuously across an object's surface. While sharp colour gradients sometimes occur in nature, they are usually less common and less pronounced than those found in industrial products with highly variable coloration. Natural objects of the same nominal type may differ from one another, with significant changes in colour. On the other hand, damage or disease in plant or animal material may be manifest by very subtle colour changes. Sometimes infra-red and ultra-violet illumination help to improve image contrast; IR is particularly sensitive to detecting bruising in fruit.

2.2.6.2 Colour Variations in Manufactured Products

Subtle colour changes occur on the surfaces of many industrial artefacts as a result of processes such as drying, oxidation, rust formation, chemical corrosion, micro-organism attack, etc. Detecting these conditions can be just as difficult for a Machine Vision system as any task involving natural products. Highly sensitive sensors have been developed for industries such as textiles and automobiles, where high colour fidelity is essential. However, these usually measure the colour either at a single point, or averaged over a region. To date, the use of a video camera for monitoring subtle colour variations across a large area, such as a complete car body, has not been very successful, to date.

2.2.6.3 Pseudo-Natural Colour Recognition Task

Many engineering artefacts are either monochrome, or polychrome with colours that are distinct in both space and hue. The most notable exception to this is to be found in high-fidelity colour printing, which attempts to emulate natural colouration. For this reason, we should regard colour printing as a "natural" scene, although two important difference exist:

- We know very precisely what colours to expect at each point in a printed colour image. In principle, this allows direct, point-by-point comparison to be made between two samples of colour printing. However, this approach is not possible as a basis for inspecting true natural products.
- Colour printing uses very few pigments, perhaps only three or four, to approximate continuous colour variations. It is necessary therefore to view the printing at an appropriate resolution; if we wish to see individual dots of coloured ink, we need a very high resolution. To view printing in approximately the same way that we do, we must use a much lower resolution to obtain a degree of spatial integration.

2.2.6.4 Traditional Colour Theory

A common practice in books and papers on Colour Theory is to annotate the standard CIE Chromaticity Diagram by placing a spot to indicate the colour of, say, a ripe tomato, lemon or lettuce. Unfortunately, this excessively naïve view is unhelpful for our purposes and can be misleading. In reality, a ripe tomato should be represented by a large diffuse cluster, not a single point, as there is likely to be a considerable variation in colour across its surface. In theory, the ripening process of a tomato could be mapped onto the Chromaticity Diagram by drawing a thick arc, starting at green, travelling through yellow, to orange and then red (➲ *Fig. 2.5*). However, the standard treatment of colour is inadequate to represent the subtlety of natural phenomena, such as tomatoes ripening. The difficulty lies not, so much in the representation of colour, as the analysis of the data. No general theoretical model yet exists. Instead colour recognition can be approached using Pattern Recognition learning methods (➲ Chap. 24), or the Programmable Colour Filter described in ➲ Chap. 16.

2.2.6.5 Problems in the Naming of Colours

The core of the colour recognition problem lies in the fact that we do not know what a label such as "yellow" really means. Of course, you "know" what "yellow" is, because you were taught from an early age to associate that word with a certain class of visual stimuli. Since then, you have had your mental concept of "yellow" fine-tuned by years of exposure to other people, even though each has a slightly different idea. The people who taught you what "yellow" means did not teach me, so my concept of "yellow" is slightly different from yours. Proving this is easy: simply ask

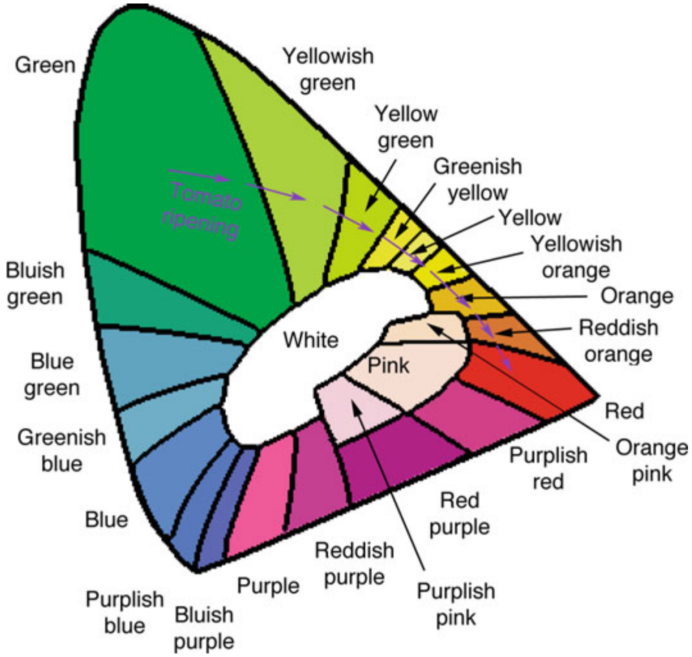


Fig. 2.5
To reduce the cost of printing, the CIE Chromaticity Diagram is often published in monochrome form, with labelled "cells" added as an aid to understanding. Sometimes each "cell" is assigned a uniform colour, as shown here, but this merely illustrates what labels such as "reddish orange", "red", "purplish red", etc., typically represent. These "cells" create the false impression that it is possible to discriminate accurately between colours; they do not provide the basis for universally agreed colour identification. Furthermore, the diagram makes no contribution towards the recognition of commercially important colour categories, such as "butter yellow", "leaf green", or "well cooked cake". Notice that colour labels apply to sets not points on this diagram. Hence, the process of ripening in a tomato should be represented diagrammatically by a broad band, not a single point locus

a few people to draw limits of what they perceive to be "yellow" on the spectrum, or any other rainbow-like pattern. (➋ Chap. 16 presents the results of one simple study of this kind.) Why are there such wide differences in the definitions of colours? We all agree on certain "core" colours being given names such as "yellow", "red", "turquoise", etc. However, we differ in our naming of those colours at the boundaries between these classes. There are certain reasons for this:

(a) Different languages name colours in different ways. ➋ *Figure 2.6* explains the differences in the naming of certain colours in Welsh and English. (These two languages have been juxtaposed for over a thousand years.) There are even significant differences in the use of colour names between Welsh speakers from North and South Wales. The English word "yellow" cannot be translated exactly into French. It is less surprising that major differences exist between English and Japanese, as well as between English and Chinese.

(b) Certain diseases, brain injury, ageing and drugs can all cause changes in colour perception.

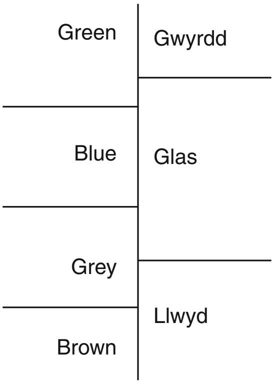

Fig. 2.6
Differences in the naming of certain colours in Welsh and English. A Welsh speaker will refer to the colour of grass and blue sky using the same word. Despite this, many Welsh speakers insist that the translation of "blue" is "glas".

(c) Specialist occupations, such as printing, weaving, etc., lead to refinement of previously learned colour concepts.
(d) Ambient lighting. The grey skies of northern Europe and the subsequent heavy reliance upon electric lighting provides a very different visual environment from that encountered by people living in the tropics. It is well known that lighting alters our perception and naming of colours.

Since the naming of colours is so subjective, we must build Machine Vision systems so that they are able to learn what colours to expect in a given application. This where Pattern Recognition comes into its own.

2.2.6.6 Colour Sensors

By themselves, most video cameras are incapable of discriminating reliably between healthy and diseased tissue, or providing a reliable basis for deciding when fruit on the tree is ready for picking. However, more accurate instruments for measuring the spectral composition of light (from a point source) are available and can be used to calibrate a video camera. Assuming that we have given proper consideration to calibrating the camera, guaranteeing that the light source is stable and sufficiently bright over the visible spectrum and cleaning all optical surfaces, there is no reason why a low-noise solid-state camera cannot be used for colour analysis. The major problem for colour recognition lies elsewhere.

2.2.6.7 RGB Representation

A colour video camera measures the so-called RGB components of the light falling at each point in its retina. It does this by placing monochrome photo-sensors behind three differently coloured filters. These selectively attenuate different parts of the spectrum. R, G and B have traditionally been associated with detecting "red", "green" and "blue" although this idea must not be carried too far. A camera that outputs an HSI video signal (measuring Hue, Saturation and Intensity) uses an RGB sensor and performs the RGB-HSI transformation within its internal electronics.

Let [r(i,j), g(i,j), b(i,j)] denote the measured RGB values at the point (i,j) in a digital image. The set of colours in the image can be represented by S_3 where

$$S_3 = \{[r(i,j),\ g(i,j),\ b(i,j)]/1 \le i,j \le N\} \tag{2.2}$$

By mapping the image into this particular 3-dimensional measurement space (called RGB-space), we forsake all knowledge of the position within the image for each colour vector. However, by extending this definition slightly, we can preserve this information. The set of points

$$S_5 = \{[r(i,j),\ g(i,j),\ b(i,j),\ i,\ j]/1 \le i,\ j \le N\} \tag{2.3}$$

lies in a 5-dimensional space and preserves both position and colour information. For most purposes, S_5 is usually too cumbersome to be useful in practice. The representation embodied in S_3 is normally preferred, when we want to recognise colours independently of where they lie within an image.

We can combine the output of a colour recogniser with the spatial co-ordinates, (i,j), to obtain essentially the same information as is implicit in S_5. The following is a hybrid representation which combines colour labelling (not "raw" RGB values) with geometric position (i,j) within an image.

$$S_{\text{hybrid}} = \{[\text{colour\_name},\ i,\ j]/1 \le i,\ j \le N\} \tag{2.4}$$

This representation is more economical than S_5 yet contains more information than S_3. Moreover, S_{hybrid} can be stored and processed as a monochrome image, in which "intensity" (i.e., an integer) represents symbolic colour names, i.e., a palette. (The result is an image like that used when "painting by numbers".) It is often convenient to display such an image in pseudo-colour, since similar values of the integers defining the values of *colour_name* may represent quite different physical colours. The design and use of a colour recogniser will be explained in ➋ Chap. 16, which also emphasises the innate differences between colour variation in natural products and human artefacts.

2.2.7 Transient Phenomena

The following story was told by a colleague, who is a highly experienced and well-respected vision systems designer. He was commissioned to design a machine to detect patches of mould on the surface of (edible) nuts. The customer supplied him with a large bag of nuts, enabling him to study the problem in detail. He conducted a detailed feasibility study, then designed and built an inspection system. Of course, this took him several weeks. Then, he contacted the client, to arrange a demonstration, prior, to delivering and installing the system in a food-processing factory. A person from the client company arrived for the demonstration, carrying another large bag of nuts. Following good engineering practice, both parties wanted to test the inspection system on previously unseen samples. However, it did not respond well in these tests and failed to satisfy the client's expectations. There was a very simple reason for this disappointment: the new sample of nuts had fresh mould which was *green*, whereas the original samples had older *brown* mould. The client had omitted to tell the vision engineer that the green mould quickly changes colour to brown. This fact was so obvious to the client that he had not thought it important enough to tell the vision engineer. Since brown and green mould patches can be identified by eye, it was "obvious" to the client that both could be detected easily by a Machine Vision system. It is a universal truth that, whenever a client tries to tell the vision engineer how to do his/her job, trouble will follow.

The lesson for us is that materials of biological origin change with time. The surfaces of industrial artifacts can also change their appearance as a result of oxidation, drying, as well as other chemical, physical and biological processes. The visible changes in biological materials can at times be very significant, yet in certain situations they can be very subtle. Dehydration will cause foliage to change shape quickly as it wilts, but early stages of decay are manifest as very slight changes of colour. It is essential that Machine Vision systems be designed on exactly the same type of product/material samples as will be seen by the final, ("target") system. This seemingly obvious principle is not always obeyed!

Transient phenomena occur in a wide variety of applications, particularly in the food and pharmaceutical industries, agriculture and horticulture. On-line data capture is essential whenever the appearance is susceptible to significant changes. In this event, we must build an image-acquisition rig over the production line, even for a feasibility study; off-line analysis will not suffice.

2.2.8 Very Complex Objects

It is nonsensical to search for optimal lighting methods for very complicated objects, because features that are enhanced by one lighting method may be obscured by another, and vice versa. Few objects can match the complexity and unpredictability of form of a living plant. Imagine that we want to view its leaves, perhaps searching for spots indicating fungal disease. Lighting from the sides inevitably casts shadows, leaving "internal" features poorly illuminated. Even omni-directional lighting will fail to produce good images within a dense thicket (➋ *Fig. 2.7*). Coaxial illumination and viewing produces no shadows whatsoever but is prone to creating highlights, due to glinting (➋ *Fig. 2.8*). This can be problematical, if the object surface is shiny, perhaps through it being wet or greasy. Some relief can be provided using a circular polariser (➋ *Fig. 2.9*), or crossed linear polarisers (➋ *Fig. 2.10*). In many applications, however, one standard lighting method can be used, even though it is not optimal for any particular task. Such an arrangement is used in a wide variety of applications where the shape of an object is too complicated to allow optimal lighting methods to be devised.

Machine Vision has the potential to do something that natural vision finds impossible: combine several views of the same object or scene, taken under different lighting conditions. So far, this exciting idea has not been exploited to its full potential. Intelligent lighting, perhaps generating different colours from the same set of "point" sources (multi-colour LEDs) is now a real possibility. Imagine a lighting rig, consisting of an array of multi-colour LEDs, each one individually controlled. By switching the LEDs and combining the images that result, a variety of interesting effects can be achieved that have no counterpart in human vision. Although this has very real potential for inspecting objects that have a highly complicated structure, much more fundamental research needs to be done.

2.2.9 Uncooperative Objects

By definition, inanimate objects are neutral in neither co-operating nor obstructing visual examination. On the other hand, animals such as pigs, chickens and fish will avoid strange and

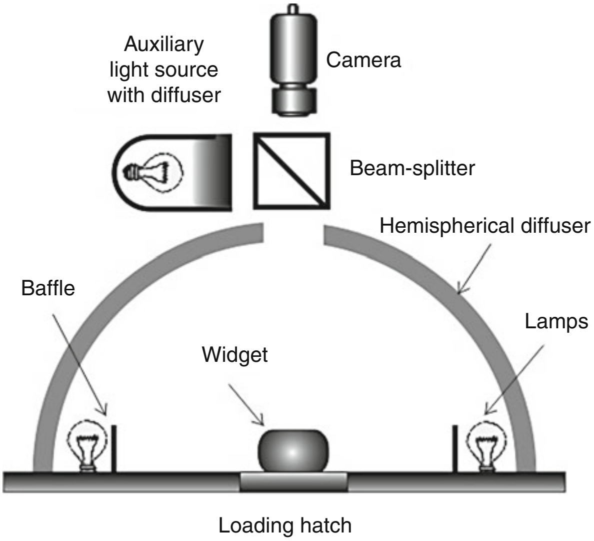

Fig. 2.7
Omni-directional lighting. The auxiliary light source and beam-splitter are used to compensate for the hole cut in the hemi-spherical diffuser

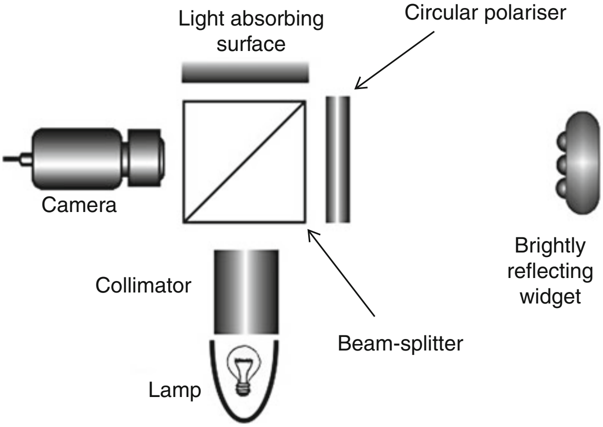

Fig. 2.8
Coaxial illumination and viewing

seemingly threatening equipment, particularly if it makes an unusual noise, has a strange smell, brightly coloured or flashing lights or even superficially resembles the animal's natural predator. These can be major obstacles to gaining an animal's acceptance of a vision system. Moreover, it must be borne in mind that an animal does not see the world as we do. It may be sensitive to a different part of the electro-magnetic spectrum. It may perceive two LEDs as being the eyes of a potential predator. Animals can sometimes be encouraged to move past a camera in a semi-controlled manner by the judicious use of guide rails (pigs, sheep, etc.), or glass panels or tubes

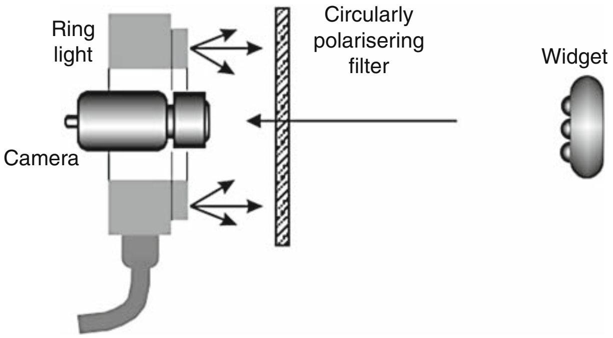

Fig. 2.9
Circular polariser used to reduce the effects of specular reflection

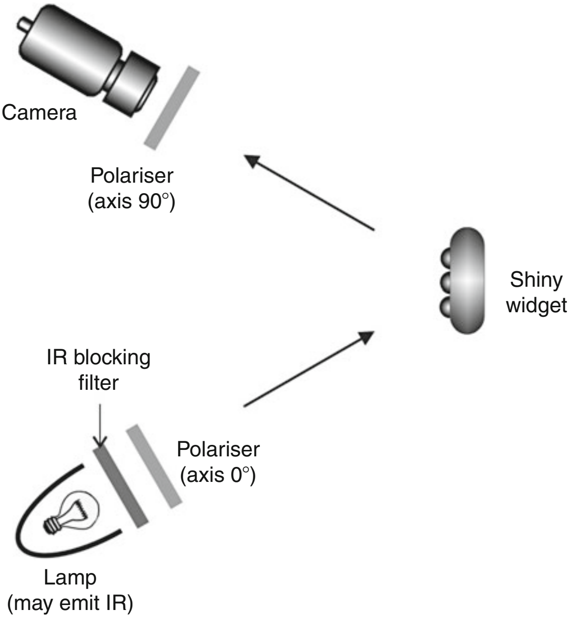

Fig. 2.10
Crossed linear polarisers used to reduce the effects of specular reflection

(insects, fish, etc.). Some animals may also need encouragement, in the form of some prospect of a reward (food), to move at all.

Needless to say, the inspection equipment must be very robust to work safely in close proximity to animals and it must be able to continue working unattended for long periods in extremely dirty working conditions. Designing a suitable image acquisition system for this type of application is far removed from a vision engineer's normal experience, developing algorithms, writing software and designing hardware.. However, it is just as important. Failure to pay attention to these matters will significantly alter the vision system's prospects of success.

2.2.10 Texture

Texture is one of the most difficult areas for Machine Vision engineers, because there is no clear objective definition of what it actually is. Moreover, it is often extremely difficult to collect samples of "good" and "bad" textures, particularly in those situations where texture is merely an indicator of another more significant parameter. For example, the texture of the cut surface of a loaf is known to be related to the "in mouth" feel of the bread. The nature of the texture varies across the slice. (Indeed, bakers often deliberately cause this to happen, by rolling the dough to maximise the surface brightness of white bread when it is cut in the normal manner.) The sensation of biting an apple can be predicted, to some extent, by the cellular-level texture, although the exact nature of the relationship is unclear. The adhesion of paint to a steel surface is known to be affected by the surface texture of the metal. The texture of a coated surface is an indication of its weathering and wear properties. The surface texture of many types of engineering products, most notably cars, white goods, woven fabrics and knitwear, is critical to customer acceptance.

It is not difficult to derive a multitude of measures for representing texture. However, analysing the data causes a severe problem, because we do not know how to interpret the numbers that we obtain. Apart from a few exceptions, texture analysis remains an elusive and enigmatic problem that continues to challenge vision engineers.

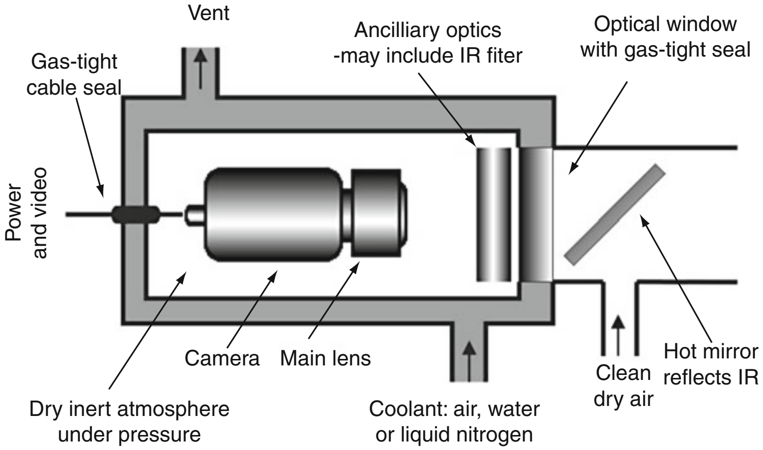
2.3 Systems Issues

We conclude this brief introduction to our subject by making some pertinent remarks about the practical issues that must be considered to ensure that an inspection system works properly and reliably over a long period of time. The most important points to remember are:

- Natural products are not all alike; they vary very considerably.
- It is important that the inspection system does not damage, pollute or infect the object being examined.
- It is important the object being examined does not damage the inspection system.
- A series of general principles relating to the design of industrial vision systems summarised in Appendix C and guided the design of the questionnaire in Appendix B. Nearly all of these apply with equal validity to systems for examining natural products.

The criteria by which an inspection system is judged are the same, whether it is applied to natural products or engineering artefacts:

- It must be easy to use; a PhD in Engineering or Computer Science should not be necessary to operate it.
- The system must be acceptable to the work-force. This requires careful attention to a wide variety of factors, including the user interface and other points in this list.
- It must perform at the speed required. (For example, it must be able to keep up with production in a food-processing plant.)



Vent
Gas-tight cable seal
Ancilliary optics -may include IR fiter
Optical window with gas-tight seal
Power and video
Camera
Main lens
Hot mirror reflects IR
Clean dry air
Dry inert atmosphere under pressure
Coolant: air, water or liquid nitrogen

Fig. 2.11
Protecting the camera

- It must perform the necessary function, with a minimum of human intervention. Stringent tests are required to ensure that the system functions properly. Judgement will be made on a statistical basis, against previously agreed criteria, as set out in the specification.
- As far as possible, it should be possible to reuse the system to inspect new product lines.
- The system must be robust and reliable.
- Since cost is always of great importance, the system should be able to pay for itself in a few months. The food industry is notable for operating on very low profit margins, so this is often difficult to achieve.
- The system must be safe and hygienic. Since hygiene is critical in the food and pharmaceutical industries, we deal with this point separately.

Animals are likely to cause particular problems for a vision system, because they create a lot of pollution. They are liable to create a considerable amount of air-borne pollution in the form of droplets, when they urinate, defæcate, sneeze, cough or simply bellow. They also increase the amount of dust in the atmosphere by kicking up straw or feed-stuff, as well as by shedding hair. Animals may even lick a lamp or camera if it is within reach. Making sure that the vision system is protected from pollution of this kind is vitally important, if it is to have a long and useful working life. There are many techniques for doing this, some of which are summarised in ➲ *Fig. 2.11*. Of course, for safety's sake, the animal must also be protected from the vision system. Animal pens are hostile places for vision systems, so protection for both livestock and machine is essential.

Of course, inanimate objects also cause pollution, which can render a vision system useless. Biological materials are even worse than most standard engineering materials in causing air-borne pollution. Flour and other fine powders abound in many food factories, as do mists, fumes, smoke, occasional splashes, etc. All of these can settle on lenses, mirrors, lamp surfaces, and other optical components, causing malfunction of an inspection system.

One of the biggest hazards for a vision system in a food, toiletry, or pharmaceutical factory is *hygiene*. The need to keep all factory equipment scrupulously clean, including all exposed components of the vision system, means that equipment will be washed down on a regular basis. Not only must the optical-lighting-camera sub-system survive being hosed down, it must be easy for factory personnel to dismantle it, so that any traps where debris could accumulate are cleaned.

3 Human and Animal Vision

Jonathan T. Erichsen · J. Margaret Woodhouse
Cardiff University, Cardiff, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_3,

Abstract: Since this is a book about artificial vision, it may seem strange that we include an essay on vision in the natural world. The reason is simple: we need to convince the reader that there is no single model for vision that is ideal for all circumstances. Our own visual system, sophisticated though it is, would not suit a housefly, eagle, owl, chameleon, or even a horse. Each of these animals has managed to thrive within a specific type of environment, for far longer than human beings have walked on two legs. Even though it is very limited in its visual capability compared to human beings, a frog has a vision system that has served it well for many millions of years. In many instances, an industrial Machine Vision system is like a frog: both can do certain well-defined tasks, without attempting to achieve the subtlety of discrimination and the high level of intelligent scene analysis that a human being can accomplish. In nature, there are four scenes that nearly every organism has to recognise: food, threat, mate, and shelter. This is not so very different from an inspection system that is merely intended to distinguish between 'good' and 'faulty' products. Animals do, however, have to cope with highly variable environments and cannot change the viewing conditions as a vision engineer can do to make his/her creation cheaper, faster, or more reliable. So, our task is usually simpler than designing a machine as complex as a frog. We must never make the mistake of thinking that only we see the world as it really is. We are only sensitive to a narrow range of optical wavelengths. We cannot sense polarisation, whereas bees and appropriately designed machines can. We cannot sense very low light levels that some animals have to use. Why should we want to replicate a system like ours that is confused by numerous visual illusions? The natural world has produced many different models for vision. For example, there are over 40 different types of eye. The compound eye of the insects and our own eye are obviously very different. Even the eye of a relatively close relation, the cat, is significantly different from our own, having a vertical pupil in bright light. Some animal eyes move the lens to focus on objects that are moving along the line of sight, rather than alter the shape of the lens, as our own eyes do. There is nothing particularly special about our colour vision either. Mantis shrimps, for example, have 12 different colour pigments in their eyes. Spiders are not content with just two eyes as we are; they have eight! This variety does more than present us with a collection of interesting curiosities; it provides inspiration! Vision engineers can benefit from learning about non-human vision systems. Perhaps the most important point of all is that vision engineers should have the confidence to be different; we should not be constrained always to try and emulate human vision. Nature isn't! Although it is immensely powerful, human vision is sometimes ineffective, and in other cases grossly over-sophisticated, for the humble tasks required of industrial vision systems. It is always vain to do with more what can be done with less. So, if frog vision works, use it!

Vision is pervasive in the animal kingdom and is a sensory capability that is variously relied upon to find reproductive mates, suitable food, and/or shelter while avoiding predators or other dangers. The receptor organs (e.g., eyes) and associated visual system not only provide the basis for visual perception of the surrounding environment but also drive and guide the visuomotor responses (e.g., locomotion, eye movements, reaching to grasp, etc.) in reaction to changes or objects of interest in the world. Although animal vision has intrinsic limits that vary from species to species as well as different properties (e.g., colour vision) that may arise for specific purposes in the course of evolution, its main characteristic is that it represents a generalised adaptation that can deal with a diverse range of problems and challenges. In contrast, machine vision is narrowly designed for a particular purpose or function and its related systems are normally highly constrained. This chapter offers a broad summary of human and animal vision, with an emphasis on vertebrates, paying particular attention not only to its basic design properties and limitations but also the sheer diversity of biological solutions to the problem of perceiving the world and responding appropriately. The hope is that such an examination of vision from a variety of perspectives will inform and inspire the future design and engineering of machine vision.

3.1 Introduction

The capacity for vision, ranging from a crude sensitivity to light through to an acute appreciation of form, movement, and colour is found in nearly all living creatures. It is the dominant sense in many animals, and arguably reaches it highest level in primates and birds, whereas in those relatively few animals without sight, there is evidence that vision has only been lost in the course of evolution rather than having always been absent. The pervasiveness of vision may not always have been the case. Andrew Parker in his eloquent book, *In the Blink of an Eye*, argues that, prior to the Cambrian era, all animal life was blind. Indeed, he argues that it was the appearance of a sensitivity to light (➋ *Fig. 3.1*) that heralded a veritable explosion in the diversity of life forms as well as in the wide range of methods for achieving visual perception.

The evolutionary history of vision since that time is characterised by two major themes. In a given line of animals, vision is guided and at times perhaps constrained by the structural and physiological approach taken (e.g., compound eyes of insects, the 'inverted' retina of vertebrates, etc.). On the other hand, the existence of numerous convergent structures (e.g., vertebrate and squid eyes, the same types of visually guided movement found in insects and mammals, etc.) strongly suggests that they are solutions necessitated by general problems in vision that must be solved by all animals that need to achieve visually guided motion. The structural and optical constraints, as well as the sheer diversity of these biological solutions, affords the opportunity to examine vision from a variety of perspectives, and such analyses have the potential to inspire the design and engineering of machine vision.

In the present chapter, we will begin with an overview of the design characteristics of various vertebrate eyes and properties of visual systems. Then, after a brief consideration of the basic aspects of machine vision, we will turn our attention to human vision, such as the reader will be familiar with from his/her own experience. Finally we will examine the similarities and differences that arise amongst diverse animal species. Such an approach will allow us to highlight the instances of convergence in structure to achieve a particular function. Moreover, we can identify illustrative examples of the way in which constraints (e.g., purpose or environment) have moulded the design of visual systems.

3.2 Overview

Vision begins with the organ that is sensitive to light. In vertebrates, the eye has a common fundamental plan (➋ *Fig. 3.2*). At the front of the eye is a transparent refracting surface (the cornea) and at the back lies a layer of neural tissue (the retina) with light-sensitive elements (the photoreceptors). In between, there is a variable aperture (the pupil) and behind that a second refracting element (the lens). The lens affords the possibility of changing the focal length or power (accommodation) to adjust for the distance of an object of interest. The ability to accommodate varies considerably between animals and even in the same animal with age.

Fig. 3.1

The light wavelengths that are visible to humans. Visible light is only a small portion of the electromagnetic radiation spectrum

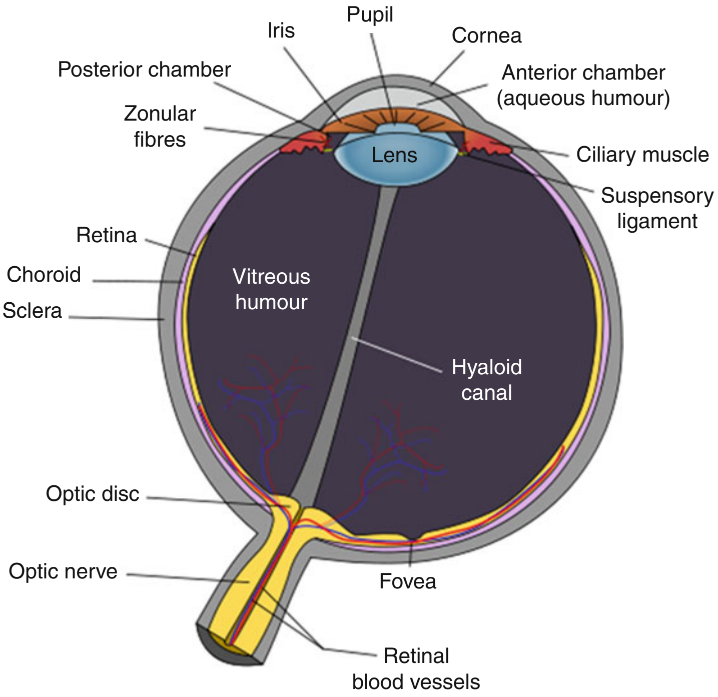

Fig. 3.2
The human eye

3.2.1 Eye Orientation

Every vertebrate has two eyes, but the orientation of the eyes in the head has a dramatic impact on the overall field of view, quite apart from any differences in optical design within the eye. Humans and owls, for example, have frontally placed eyes and, for that reason, must move their eyes or head in order to sweep a wide field. In contrast, a horse's or pigeon's eyes are angled away from each other and therefore provide an almost panoramic view of the world (*Fig. 3.3*).

3.2.2 Visual Performance

The quality of vision (e.g., resolution) is not uniform across the retina (or the field of view). Most animals have a central area in each eye that provides higher resolution and is normally used for fixating and inspecting an object of interest. This area is located centrally in the retina in order to take advantage of the better quality image along the optical axis of the refracting surfaces. In some species (e.g., humans and birds), there is an additional specialisation in this central area that takes the form of a depression in the retina itself (the fovea) (*Fig. 3.4*). The fovea varies in shape and depth across animals, but its function is to maximise the quality of the image reaching the photoreceptors by the displacement of some of the overlying retinal tissue. This retinal adaptation is another example of maximising the quality of the optical image. Whether or not there is a fovea, the density of photoreceptors is usually higher in the central

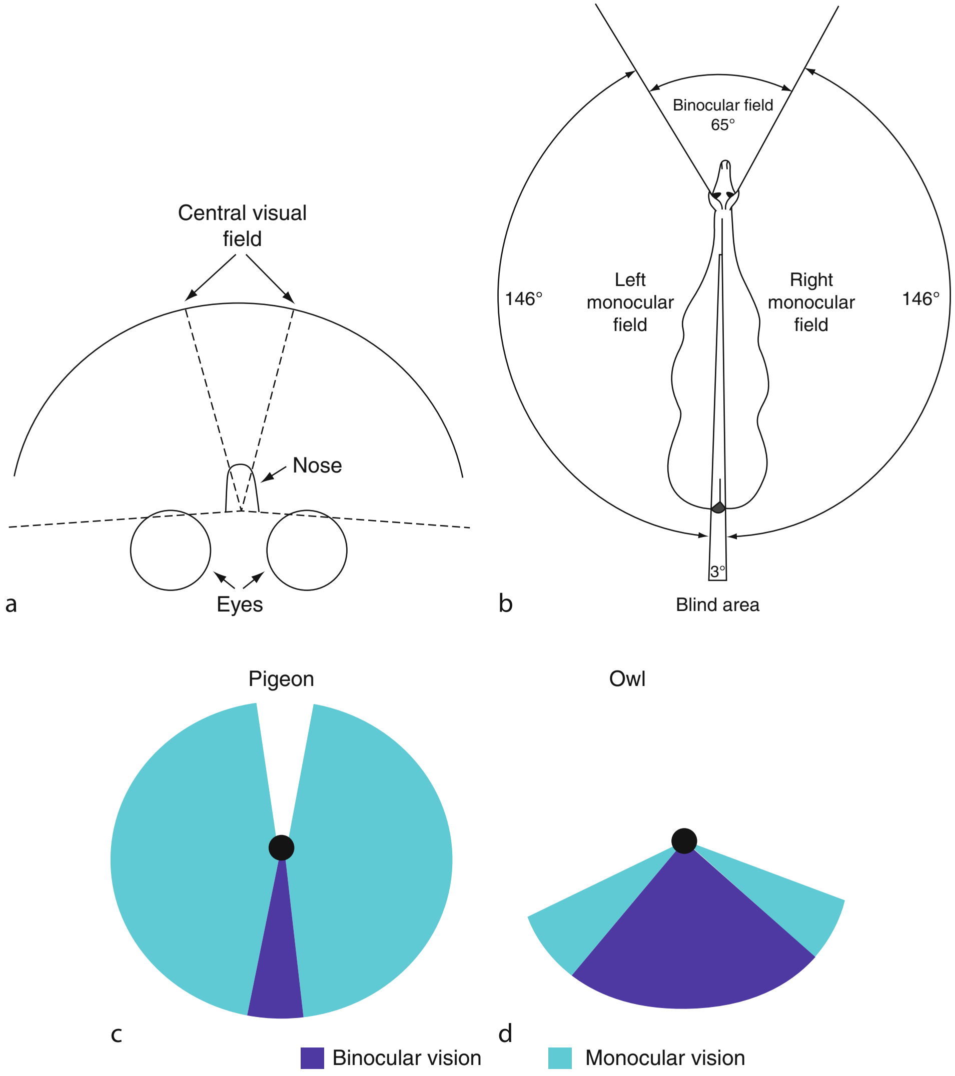

Fig. 3.3

The very different fields of view of a: (a) human (b) horse (c) pigeon (d) owl

area than in any other part of the retina. Taken together with the quality of the image reaching the photoreceptors, this provides the basis for the high acuity vision possible at the central retinal location and explains why it is preferentially used for visual fixation.

In order to obtain the most information from the visual world, there are many aspects of vision that must be optimised. These include resolution, contrast sensitivity, motion perception and, for many species, colour discrimination. Resolution is the ability to discriminate detail, for example, the ability in humans to distinguish correctly between different letters on an optometrist's eye chart. Contrast sensitivity is the ability to perceive an object against a background, in terms of brightness difference. In its simplest form, motion sensitivity is

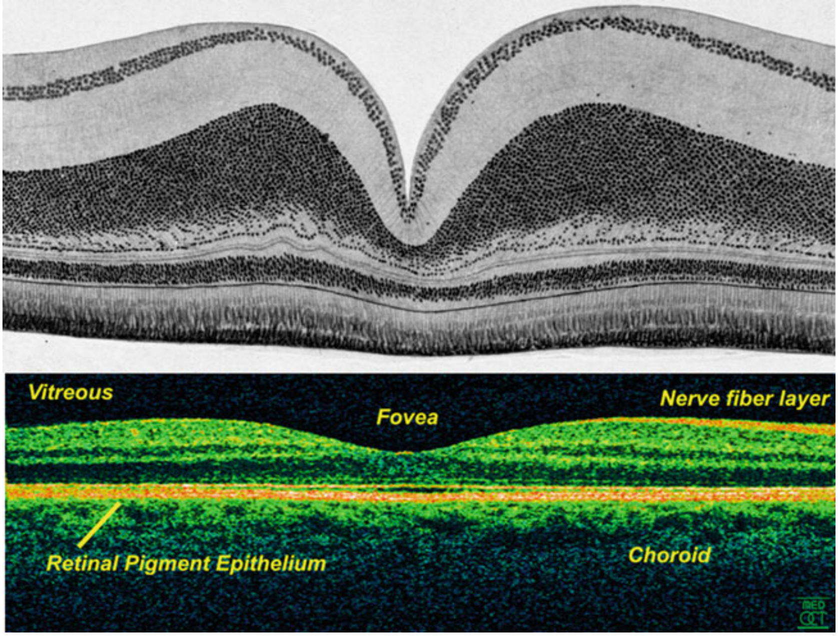

Fig. 3.4
Cross-sectional view of the central retina, including the fovea of a bird (*Sterna minuta*) (*upper figure*) and a human eye (*lower figure*)

the ability to perceive changes in any visual stimulus over time. Finally, colour discrimination, which is not found in all animals, is dependent on the discrimination of wavelength difference made possible by the absorbance properties of different visual pigments in the photoreceptors.

3.2.3 Visual Processing and Eye Design

When light reaches the photoreceptor pigments, the energy is transformed into cellular electrical signals in a process known as *transduction*. These signals are then propagated to other retinal cells, which perform a degree of image processing. However, ultimately the retina must send these resultant signals to the visual processing centres in the brain. This is accomplished by the exit of nerve fibres from the eye at the optic nerve head or disc. At this stage, various properties of the visual image (e.g., fine detail, colour, motion, etc.) have already been segregated into separate parallel channels that progress through several stages of processing before finally coming together in the highest visual areas of the brain to produce a coherent visual percept of the outside world (see ❯ Sect. 3.5.1).

The structures of the eye are often compared with some justification to the various components in a simple camera. Using this analogy, one can understand, for example, why a larger eye, which has a longer focal length and a correspondingly magnified image size, can produce a better resolution (i.e., higher quality) image. Similarly, a change in aperture size alters the intensity of light that falls on the light-sensitive surface (i.e., the retina), which is analogous to the light-sensitive array of a digital camera, in order to compensate for changes in

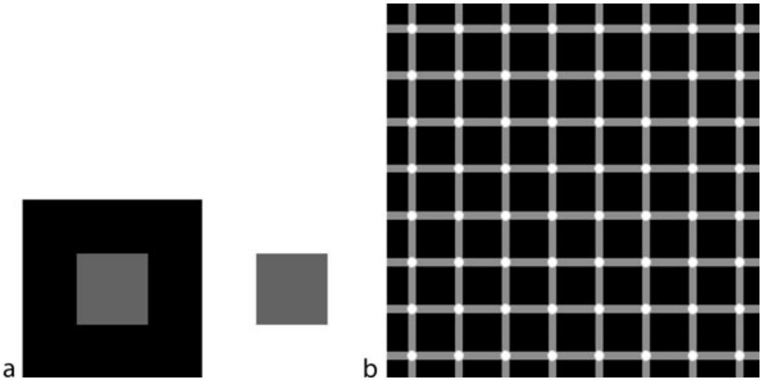

Fig. 3.5

Examples of visual illusions: (a) Simultaneous contrast. The central grey square has the same brightness, but appears different depending on the background. The reader can test this by masking the surrounds and comparing only the central grey areas. (b) The Hermann Grid. The observer sees illusory black dots at each of the intersections, other than the one directly fixated

light levels. However, this way of considering vision fails to take account of the need to *interpret* the image of the outside world. The simplest illustration of this is that the optical elements of the eye produce an inverted image, and yet we perceive the world as upright. This straightforward transposition is accomplished within the brain. At a higher level of complexity (but a lot more fun!), visual illusions clearly demonstrate the extent to which processing by the eye and/or the visual brain influences what we see (➜ *Fig. 3.5*).

No individual animal (including humans) has a limitless capacity for all aspects of vision. As with other parts of the body, there are always evolutionary and energetic constraints that influence the extant design and properties of the visual system. For example, a frontal eyed animal (like humans) has overlapping fields of view for the two eyes, thus providing the basis for binocular summation (i.e., improved light sensitivity) and depth perception (i.e., stereopsis). However, the disadvantage of frontal eyes is a more limited total field of view, thus making an animal more vulnerable to the approach of predators than are animals with more laterally directed eyes. Another example concerns wavelength sensitivity or colour vision, which is characteristic of diurnal animals that live under bright light conditions. One of the possible advantages of colour vision is to enhance the visibility of certain objects against their background (e.g., ripe red fruit hanging in a dark green tree). In contrast, nocturnal animals generally place a priority on light sensitivity rather than the ability to discriminate wavelength.

One of the interesting features of parallel processing in the visual system is that each property of the image is analysed by its own computing module. Presumably, such an arrangement is an efficient and rapid way of dealing with complicated stimuli; the greater the number and sophistication of these modules, the more comprehensive the visual perception. In some animals, aspects of the visual system can be tightly constrained to deal with a highly specific visual task or perception. One extreme example can be found in the toad's differential response to a short line stimulus, depending on its orientation with respect to its direction of motion. When such a stimulus is horizontal and moves, say, from left to right, the toad behaves as if the line were a worm, i.e., the frog approaches and tries to bite the object. However, when the same stimulus is vertical and moves left to right, the toad now reacts as if the line were a threat, i.e., the toad crouches down and puffs up its body. This response is completely hardwired and does not depend on experience. Yet, it clearly involves perception of different aspects of the stimulus, i.e., its orientation.

The toad's stereotypical response to certain visual stimuli is the exception rather than the rule. Most animals (e.g., many reptiles, birds and mammals) have a much more generalised visual perception which leads to visuomotor responses that are modifiable by experience. That is, the animal's vision is adaptable to a variety of different situations.

3.3 Machine Vision

Unlike animal vision, the major characteristic of machine vision is that it is not generalised, but rather is narrowly designed for a particular purpose or function. That purpose can be highly specific and may include, for example, the detection of flaws in a manufactured item, verification of various specifications (e.g., shape, colour, etc.), or controlling dynamic processes in production (e.g., filling a receptacle). Therefore, the design of the machine vision system will typically be highly constrained such that the parameters are narrowly tailored to the particular task in hand. The various functions, properties, and constraints of machine vision are covered in detail in the other chapters of this book.

3.4 Human Vision: Low Level Processing

3.4.1 Visual Acuity

In specifying the quality of vision, one of the most common descriptors is visual acuity: defined as the resolution of the visual system to discriminate fine detail. It is traditionally described in angular terms, i.e., the angular subtense of the detail just perceptible in the object. The precise value varies with the task. For example, for a normally sighted young adult discriminating the bars of a grating, the acuity limit is the gap between adjacent bars and is around 0.5 min of arc, whereas when discriminating and identifying a letter, the acuity limit is around 0.66 min of arc. At the level of the retina, the acuity will be dependent on the separation of photoreceptors, and as already described, this is at its minimum in the fovea (➋ *Fig. 3.6*).

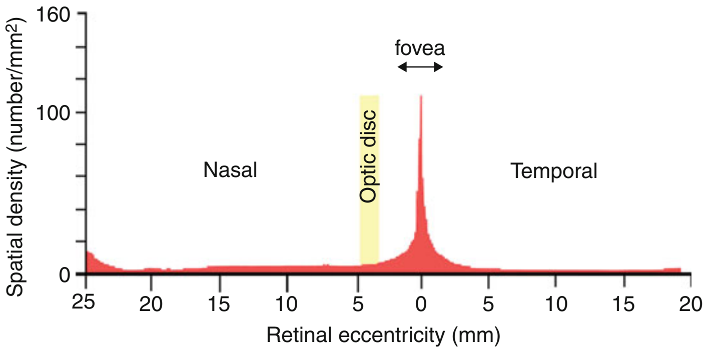

Fig. 3.6
The concentration of cone photoreceptors (in thousands) across the human retina

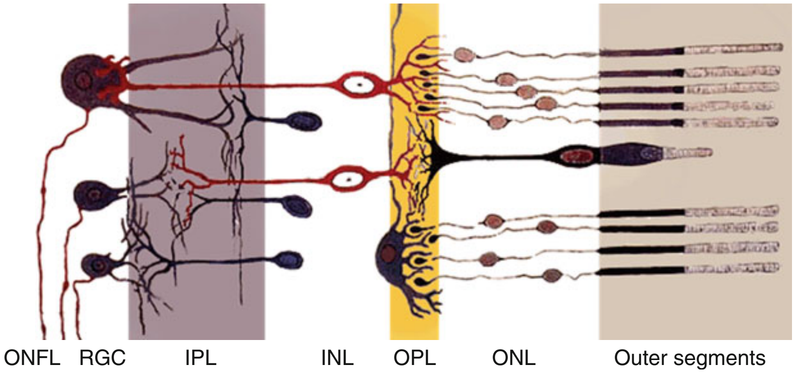

Fig. 3.7
Diagrammatic representation of cells within the retina and their linkages, including the outer segments of the rods and cones, the outer nuclear layer (ONL), the outer plexiform layer (OPL), the horizontal cells, amacrine cells and bipolar cells of the inner nuclear layer (INL), the inner plexiform layer (IPL) and the retinal ganglion cells (RGC) and their axons in the optic nerve fibre layer (ONFL)

In the fovea of the human eye, the separation of the photoreceptors (called cones from their cellular shape) is, on average, 0.5 µm and their width 1.5 µm. A calculation of resolution for receptors with this spacing yields 0.85 min of arc. This is similar to the average visual acuity measured in a young healthy adult, demonstrating that cone density is the primary factor determining visual acuity.

However, visual perception does not arise in the retina, and considerable processing takes place both within the retina and, more significantly, between the retina and higher brain centres. In particular, over most of the retina, there is not a one-to-one transmission of information, but pooling of signals from many photoreceptors to each output cell (a retinal ganglion cell) by virtue of connections amongst other cells within the retinal layers (➲ *Fig. 3.7*).

When the signals from several photoreceptors are pooled in this way, the critical factor at the retinal surface is not the receptor spacing *per se* but the extent of aggregation of receptors, which is referred to as the receptive field of the retinal ganglion cell. The larger the receptive field, the poorer the system's ability to distinguish adjacent images, i.e., the poorer the acuity. However, pooling information gives rise to larger overall signals and therefore to greater sensitivity to low light levels. This may also smooth out any 'noise' intrinsic to low light levels.

The trade-off between sensitivity and acuity is amply illustrated by the distribution of the two types of photoreceptors across the retina (cones and rods). Cones are used at bright light levels and their distribution mirrors the variation in acuity across the retina. The fact that resolution calculated from cone spacing matches measured acuity suggests that there is indeed one-to-one transmission from each cone to a single ganglion cell in the fovea, and this proves to be the case. On the other hand, rods are used at low light levels and have a distinctly different distribution across the retina.

There are no rods at the fovea (➲ *Fig. 3.8*). The reader can verify this, for his/her own eyes, by noting what vision is like at very low light levels (such as indoors at night with no lighting). If one looks directly at a small object (a number on a watch face, for example), the image will fall on the rod-free fovea and will disappear because cones do not function at this light level.

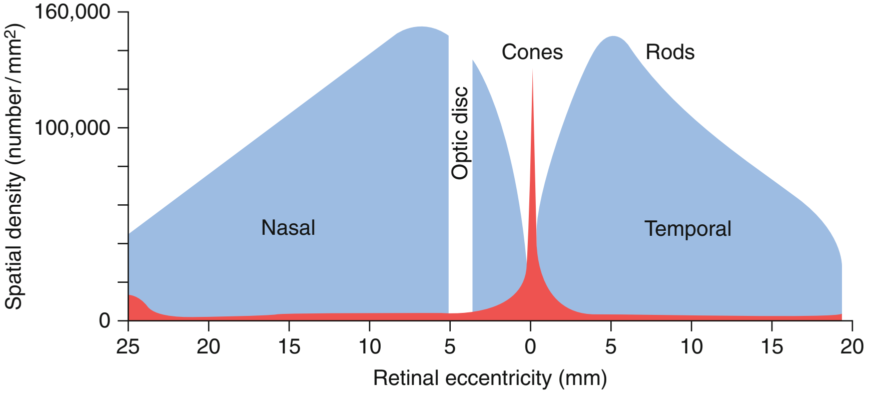

Fig. 3.8
The density of both rods and cones across the human retina

However, adjacent objects are still visible 'out of the corner of one's eye' because the retina adjacent to the fovea has a high density of rods.

As *Fig. 3.8* shows, the density of rods a few degrees away from the fovea is even higher than the density of cones at the fovea. If the only factor determining acuity were the receptor density, then our vision at or near the fovea would be much better at night than our foveal vision during the day. Yet, manifestly, it is not. Rods are connected together in very large numbers to a single output cell in order to increase the overall signal and therefore maximise sensitivity. In dim lighting, when rods dominate, visual acuity is sacrificed for sensitivity. In bright light, sensitivity is not an issue since there is ample light for the now dominant cones to operate, and the system can concentrate on maximising acuity.

3.4.2 Sensitivity and Adaptation

The human (and animal) visual system is more adaptable than the above description suggests. Rather than a simple two-state system, utilising cones and rods, the visual system is capable of operating over a very wide (10^{10} fold) range of light levels. (This is above the dynamic range of current imaging technologies.) The receptive fields can vary in size for differing light intensities, by virtue of the interconnections within the retinal layers. The brighter the light, the smaller the receptive fields (acuity winning over sensitivity) and the lower the light, the larger the receptive fields (sensitivity dominating over acuity). Thus, the vertebrate visual system can operate continuously over a very wide range of light levels.

The process of vision is initiated by the biochemical changes in pigment within the photoreceptor that generate the electrical response. All of the pigments found in the different photoreceptors, when extracted and viewed under dim lighting, are coloured. The rod pigment, for example, is sometimes called 'visual purple'. When activated by light, pigments become colourless. The process of pigment activation is therefore referred to as *bleaching*. In order for transduction to electrical energy to happen again, the pigment must return to its former state, or *regenerate*. After exposure to light, regeneration takes a finite time, and explains why the visual system, although capable of operating under widely different lighting levels, needs time to adapt when light intensity changes. When leaving a brightly lit foyer and entering a dark cinema, at first it is a struggle to find one's seat. Immediately after the sudden drop in light intensity, the retina is very insensitive, and vision is correspondingly poor. The pupil immediately dilates to allow more light in and, more slowly, the pigments regenerate. The interconnections within the retina become more active and sensitivity increases. These processes all contribute to dark adaptation. In time, the cinema auditorium appears more easily negotiable. The reverse process, light adaptation, is much quicker, involving pigment bleaching rather than regeneration. On leaving the cinema and entering daylight, the very sensitive rod-based system briefly gives discomfort, but after a few moments, sensitivity lowers. Pupillary constriction helps as well by reducing the light reaching the retina.

3.4.3 Spatial Contrast

Visual life is not all about detail. Indeed, so few tasks in the human daily round are conducted at or even near the acuity limit that a measurement of visual acuity can arguably be said to be irrelevant to establishing quality of vision. Of much greater significance is the ability to detect contrasts in the visual scene. This is the difference in brightness between objects or between figure and ground, leaving aside colour contrasts for the time being. This ability is called *contrast sensitivity* and is formally recorded as the contrast between adjacent bars of a sinusoidal grating that can just be discriminated, across a wide range of bar widths or spatial frequencies (➋ *Fig. 3.9*).

The illustration below (➋ *Fig. 3.10*) shows that sensitivity is maximal for gratings of medium frequency. The plot of contrast sensitivity against spatial frequency (*the contrast sensitivity function*) reveals that, in humans, maximum contrast sensitivity occurs at a frequency of 2–5 cycles per degree. This corresponds to a single bar width of 15–6 min of arc. As the frequency increases (i.e., bars become narrower), contrast sensitivity falls, and thus higher contrast is needed. The narrowest bar (highest frequency) detected at 100% contrast corresponds to visual acuity. The contrast sensitivity function (the shaded area in ➋ *Fig. 3.10*) thus represents the 'window on the world' as it encompasses the size and contrast of all objects that are visible. Objects outside this window are too small or too low in contrast to be seen.

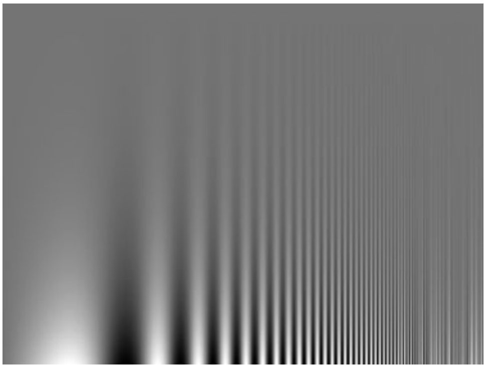

Fig. 3.9
Variation in contrast and grating width demonstrates the reader's own contrast sensitivity function

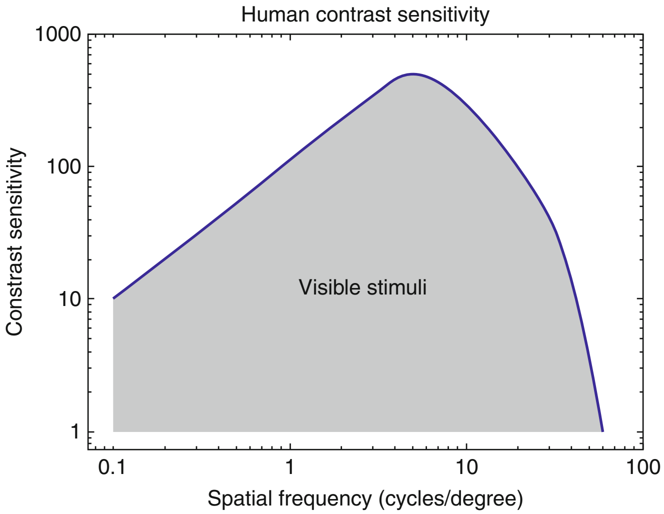

Fig. 3.10
Average human contrast sensitivity function

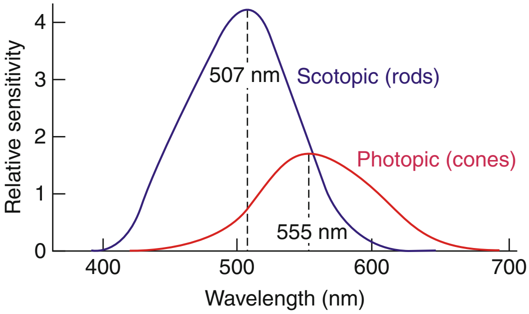

Fig. 3.11
Sensitivity to different wavelengths for both rods and cones in the human eye

3.4.4 Spectral Response

Just as there are constraints on the human visual system in terms of size and contrast of objects, so there are limits in terms of the wavelength of light to which the visual system can respond. The visible spectrum is so called because it encompasses wavelengths that are visible to the human eye (➋ *Fig. 3.1*). Many insects and some birds are sensitive to wavelengths, particularly in the ultraviolet, that are completely invisible to the human eye; thus, the visible spectrum of a bee or a bird can be quite different to that of a human.

Light that lies beyond the visible spectrum of a given animal does not evoke a response in either its rods or cones and therefore, does not initiate vision. Further, the visual system is not equally sensitive to all wavelengths within the spectrum. As ➋ *Fig. 3.11* illustrates in the human eye, the overall cone response (under bright lighting or photopic conditions) is

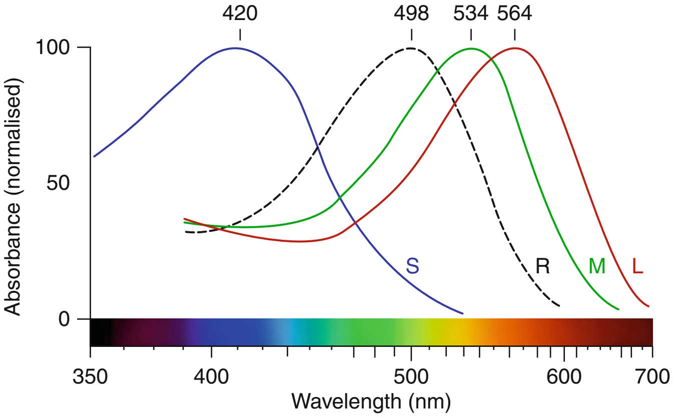

Fig. 3.12

Sensitivity to different wavelengths for rods and the three types of cones in the human eye (S = short [*blue*], M = medium [*green*], L = long [*red*] wavelength, R = rods)

maximal to light around 550 nm. Rods, which operate under dim illumination or scotopic conditions, have their peak sensitivity at 500 nm. Thus, the apparent brightness of a light source or an object is not simply a function of the intensity of light reaching the eye from the object, but also of its wavelength. For example, when cones are operating, yellow light (or light reflected from a yellow object) will appear much brighter to a person than red light of equal intensity.

The difference in peak wavelength sensitivity between cones and rods can be appreciated by an apparent colour shift when light is dimming. The reader can verify this by sitting in a flower garden as the light dims at twilight and noting the apparent blueness of the flowers becoming exaggerated. This occurs because rods are more sensitive to the short (blue) wavelengths than are cones.

Colour discrimination, or the ability to detect differences in wavelengths of light, is a property only of cone vision. It is possible in humans by virtue of the retina containing three distinct types of cones: cones maximally sensitive to long, medium, and short wavelengths, often referred to as ‘red’, ‘green’ and ‘blue’ cones, respectively (➋ *Fig. 3.12*).

The responses of the three cone types are kept separate as they are transmitted in parallel through the visual system. Differences in wavelength are ultimately processed in the brain by comparing the responses of the three (relatively) independent colour systems. Thus, for example, a wavelength of 625 nm initiates a particular ratio of response in long and medium wavelength cones that ultimately gives rise to a sensation that we normally call ‘yellow’. The sensation of ‘white’ arises when responses from all three cone types are approximately equal. Humans, however, possess only one type of rod, and therefore, wavelength discrimination or colour vision is not possible under scotopic conditions.

3.4.5 Accommodation

The values given thus far in specifying human vision (e.g., visual acuity limit of 0.8 min of arc) are dependent on a good quality image in focus on the retina. The main refractive component of the eye is the transparent cornea, but its focussing power is fixed. An active focusing

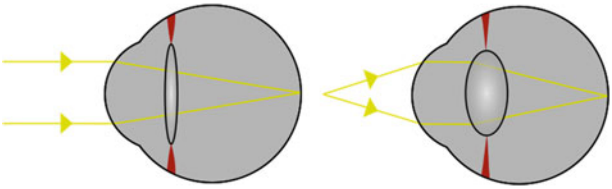

Fig. 3.13

Changes in the shape, and therefore power, of the lens allow the human eye to change focus for objects at different distances

mechanism within the eye is essential for maintaining a good quality image when the object of regard changes distance from the observer. In humans and many other vertebrates, this is attained by virtue of the flexible crystalline lens, which under the action of intra-ocular muscles changes shape and therefore its refractive power to adjust focus (➋ *Fig. 3.13*). This is the process of *accommodation*. For a distant object to be focused on the retina, the lens must adopt minimum power (i.e., its thinnest or least convex shape). Conversely, for a close object to be focused, the lens must adopt maximum power (i.e., its thickest or most convex shape).

The range of accommodation in a young adult human is about 8 cm to infinity. In fact, the ability to focus on close objects is highly dependent on age and begins to deteriorate almost from birth. A young child can focus on objects at 5 cm from the eyes, whereas a 40-year old will struggle to focus at 20 cm. This deterioration, known as *presbyopia*, is due to increasing rigidity of the lens, which becomes completely inflexible in old age. This is the reason why middle age is typically accompanied by the need to wear reading glasses or bifocals.

In order to obtain maximum visual information about any object (in daylight conditions), the fovea is normally used for fixating and inspecting. In addition to acuity and optical quality, good vision depends on the ability to maintain a stable gaze. To achieve this, head and/or eye movements must often be employed to direct the fovea as required. There are several types of these visuomotor movements and the kind used depends on the situation. For example, looking around at different stationary objects, e.g., reading a line of text, employs jerky eye movements (*saccades*) that are extremely rapid and precise, whereas visually tracking a slowly moving object requires fine continuous control of position as the eye smoothly changes its orientation to match the position of the object. The purpose of such ‘pursuit’ is to keep the object’s image stable and on the fovea at all times. In addition, as the head and body move through an environment (or the environment moves by), optomotor reflexes of the eyes are used to compensate for this movement, in order to maintain a stable view of the visual scene. All of these movements involve the two eyes moving together in the same direction. However, as the distance to an object changes, the eyes will alter their orientation, often in different directions, to minimise the binocular disparity of the image. This is called *convergence*. The brain exploits the remaining, inescapable disparity (due to the separation of the two eyes) to calculate the distance to a reasonably near object, while at the same time providing binocular depth awareness.

3.5 Human Vision: Higher Level Processing

The eye’s output fibres that form the optic nerve (➋ *Fig. 3.14*) eventually project to a relay nucleus in the brain where the different types of visual information are passed along for their

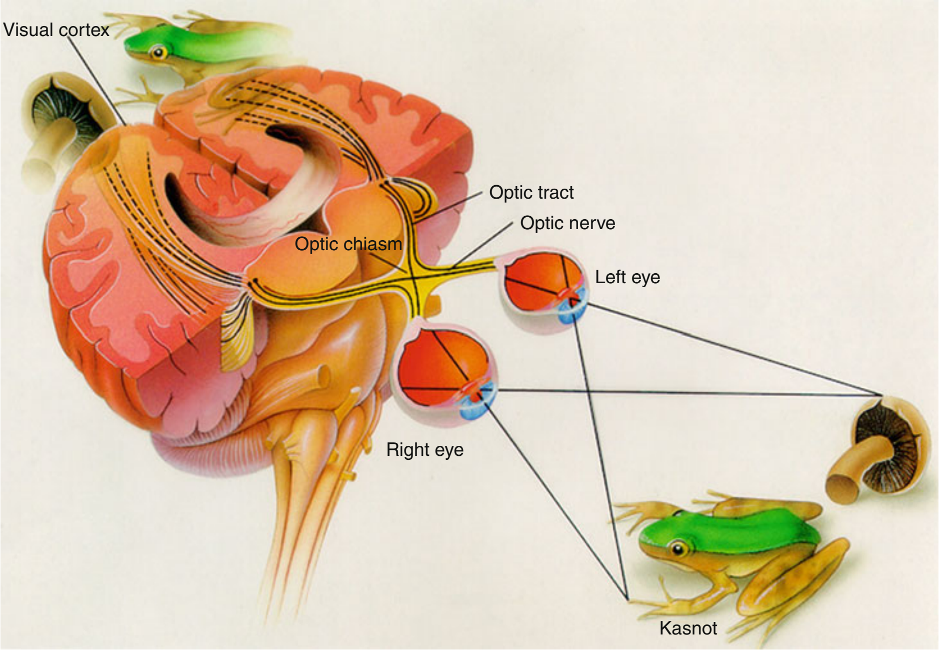

Fig. 3.14
The visual pathways in the human brain

initial processing in the primary visual cortex. At this point, the visual information from the right and left visual fields (hemifields) is proceeding to the left and right sides of the brain, respectively.

3.5.1 Parallel Processing

As already described for colour vision, numerous properties of the visual image are transmitted separately, and in parallel, to the primary visual cortex where certain basic features (e.g., orientation, size and contrast) are now extracted. As the information leaves the primary visual cortex, this parallel organisation of visual information is maintained, but now each type of information is sent to a different, largely independent higher cortical centre. Thus, the visual system at this level has not only a parallel but also a modular organisation. For example, there are separate higher cortical areas concerned with motion, colour, or object recognition rather than the visual image as a whole. One of the intriguing consequences of this modular arrangement is that, if a person suffers localised damage to the brain, involving one of the higher visual centres, the deficit can be very specific in nature. Neurological case studies of individual patients describe, for example, the inability to perceive either motion or colour. Other patients may be unable to recognise familiar objects, or even more specifically, faces. In many of these patients, all other aspects of their visual perception appear to be normal.

Conscious perception of a visual scene with all of the various properties reintegrated only occurs later, at higher levels of the visual system (➜ *Fig. 3.15*). At that stage, the various

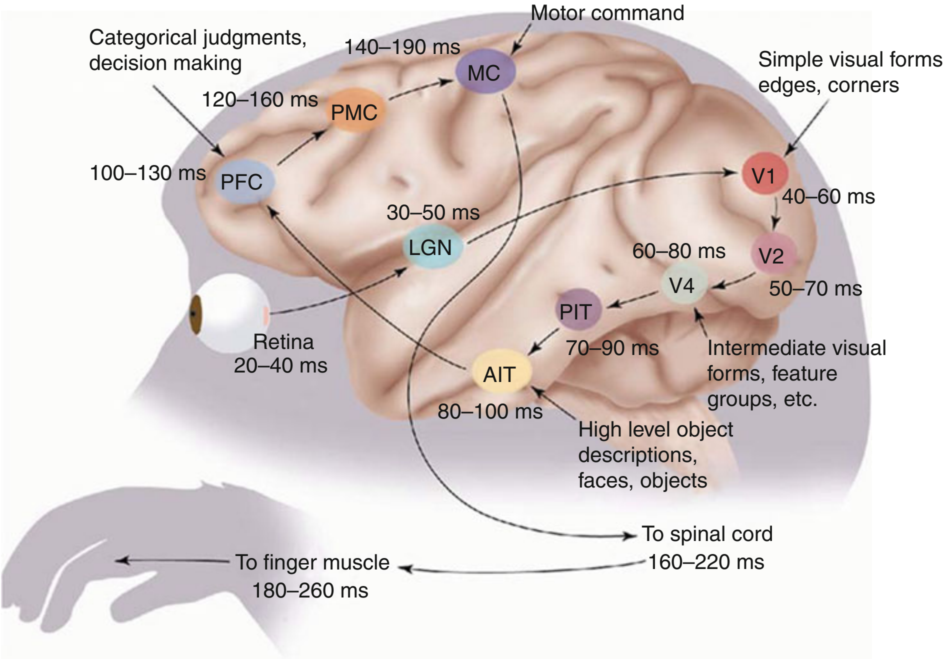

Fig. 3.15
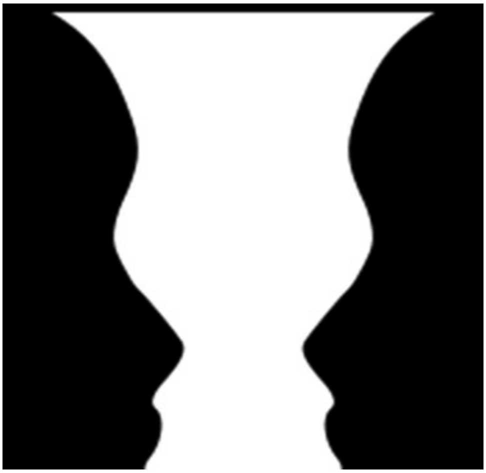
The visual and motor pathways in the human brain that allow object recognition and control motor responses. Light-induced signals travel from the retina in the eye to the lateral geniculate nucleus (LGN) and then via the primary visual cortex (V1) on to higher visual centres (V2, V4, etc.). Recognition of the object of interest occurs in areas of the inferotemporal cortex (PIT and AIT). A motor response originates in prefrontal cortex (PFC) and is then transmitted via premotor cortex (PMC) to the primary motor cortex (MC), which produces the response in skeletal muscles via the spinal cord

components of the scene, each with their attendant characteristics of form, colour etc., are recognised and understood. A complete interpretation of the visual world involves not only identifying different objects and their spatial relationship to each other but also their significance. This can relate to the need to navigate through the world, whether there is a threat, the availability of food and so on. The context in which an object is viewed can affect the meaning assigned to it. Thus, an apple can be aesthetically attractive, evoke feelings of hunger or cause one to consider Newtonian equations of gravity. This demonstrates that visual perception is, by and large, not hard-wired and illustrates the inherent flexibility of the visual system.

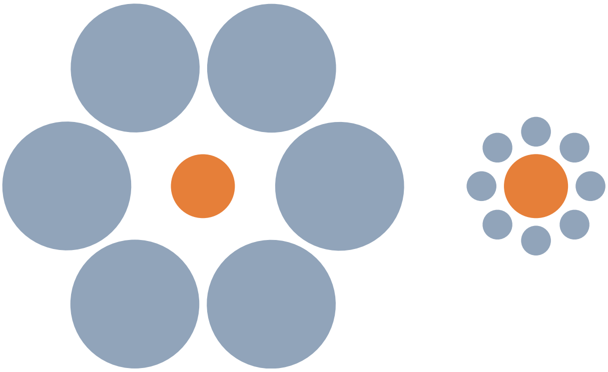
3.5.2 Visual Illusions

However, there are clear manifestations of the visual system making, in essence, assumptions about the world and this can lead to characteristic misinterpretations of visual scenes, i.e., visual illusions. Some of these illusions depend on ambiguity (see *Fig. 3.16*) whereas others appear to suggest that the brain has built-in models, spatial or otherwise, of how the world works (*Figs. 3.17* and *3.18*).



■ Fig. 3.16

An example of an ambiguous figure. Is it a *white* vase against a *black* background or two *black* faces against a *white* background?



■ Fig. 3.17

An illusion of size. The central *orange circles* are equal in size, but their different surrounds create apparent differences in size

In either case, the inability to overcome or ignore a visual illusion strongly suggests that at least some of the visual system has hard-wired circuitry that is analogous to the frog's differential response to horizontal and vertical line stimuli. Interestingly, many animals fall victim to the same visual illusions indicating that the built-in models within the visual system operate similarly across species.

3.6 Animal Vision

Presumably all animals, including humans, must face and solve the same challenges in viewing the world. Rather than limiting one's analysis to human vision alone, it is instructive to

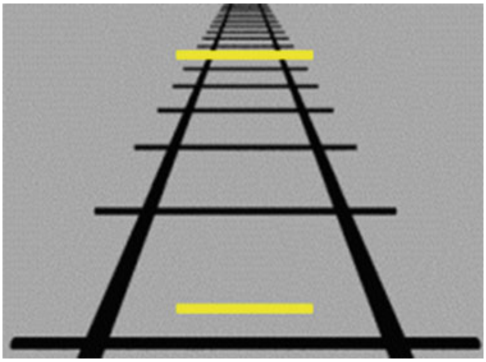


Fig. 3.18

An example of an illusion based on perspective. Both *yellow lines* are of the same length but the apparent distances in the drawing, created by perspective, distort their apparent size

consider the alternative solutions that evolution has produced in other species as well as those approaches that are held in common. Potentially, this knowledge tells us a great deal about the structure and functions of the visual system and may offer strategies for designing machine vision systems.

3.6.1 Visual Acuity

When one considers the range of animals living today, the importance of vision in their everyday lives varies considerably. Indeed, in many species, vision is not the dominant sense for perceiving the world; for example, many animals depend instead on an acute sense of smell or hearing. As a consequence, the ability to resolve detail (visual acuity) can range from a crude distinction between light and dark (e.g., the mole) all the way to acuities that exceed that found in the human eye (e.g., the eagle). Presumably, this relates to the requirements of an animal's lifestyle, and depends ultimately on the evolutionary history that led to the current species. The level of visual acuity is the product of both the quality of the eye's optics and the 'grain' of the photoreceptor system. In the case of a low acuity retina, the photoreceptors may either be more widely separated or may pool their signals into a single output cell rather than having their own dedicated channel to the brain. As mentioned when discussing the density of rods in the human retina, this has the consequence of increasing sensitivity at the expense of resolution.

In the human eye, the fovea represents an adaptation to enhance the quality of the image that reaches the photoreceptors in a region of the retina where the cone density is at its maximum. This region is used preferentially for the fixation and detailed examination of objects of interest. The concentration of photoreceptors does not remain constant across the retina; there is a precipitous decline in the density of cones as one moves away from the fovea (➜ *Fig. 3.6*). One obvious question that arises is why don't the eyes of animals, including humans, maintain a constant high photoreceptor density across the entire retina and thus allow good acuity vision in all parts of the visual field? Presumably, this reflects genuine energetic and structural constraints. These can include a limit on the diameter of the optic nerve that penetrates the retina and emerges from the back of the eye. A larger optic nerve would produce a correspondingly larger blind spot (i.e., absence of photoreceptors). In addition, higher cell

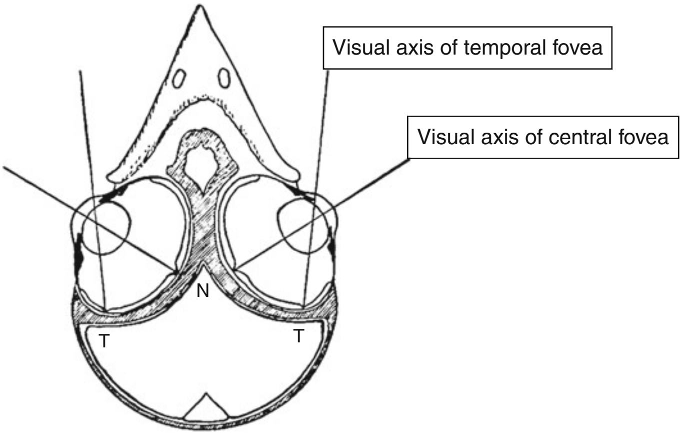

Fig. 3.19

Cross-section of a bird's eyes showing the line of sight of both foveas in each eye

density would increase the demand for attendant neural circuitry within both the eye and the brain.

Some animals have neither an apparent fovea, nor even a differential distribution of photoreceptors, and possess a relatively low acuity (e.g., rabbit), whereas others exhibit a relatively high density area in the central retina, with no foveal depression (e.g., cat and dog). Other than primates, foveas are not found in mammals but they are quite widespread in reptiles and birds. Indeed the central fovea in these species is extremely well defined (➔ *Fig. 3.4*), and in a number of birds the eyes have two foveas (➔ *Fig. 3.19*). Moreover, in most species of bird, the retina is dominated by cones, and interestingly, their density does not decline away from the fovea to the same degree as in human. This suggests that their peripheral acuity is correspondingly higher. Presumably this reflects the overwhelmingly diurnal (daytime) nature of most birds and therefore results in a relative scarcity of rods. Nocturnal birds, such as owls, have a higher proportion of rods to increase sensitivity to low light levels.

3.6.2 Light and Wavelength Sensitivity

The relative preponderance of cones and rods generally relates to an animal's lifestyle. Thus, the retina of a diurnal species that lives in a photopic environment has a relatively high proportion of cones (e.g., reptiles and birds), or even exclusively cones (e.g., ground squirrel). By contrast, the retina of a nocturnal species (e.g., rat), which is largely confined to a scotopic environment, will be dominated by rods. Those animals that live in both light regimes (e.g., humans) or those that are active primarily during dawn and dusk (e.g., fox) have mixed cone-rod retinae. One interesting consequence of having a mixed retina is that there are unavoidable time delays when moving from photopic to scotopic light levels to achieve dark adaptation. Another involves changes in the size and shape of the eye's aperture or pupil. In fact, whereas the pupil in humans and many other animals is circular, or nearly so, many species have quite different shapes. These appear in many cases to be adaptations to the different light conditions in which they live. The most familiar example of this is the cat's pupil, which is clearly a vertical slit in bright light conditions but much more rounded in the dark. Although outside the scope of this chapter, the reader is encouraged to look at the sheer diversity of shapes, sizes and orientations of animal pupils as this has intriguing implications for the design of optical systems.

As mentioned earlier, the visible spectrum for different animals can vary significantly. This, too, reflects the ecological environment as well as lifestyle requirements. On the one hand, two species living in the same place may have very different wavelength sensitivity. For example, the honeybee is sensitive to the ultraviolet patterning of flowers (but, interestingly, is relatively insensitive to the colour red) whereas the visible spectrum of most diurnal mammals does not extend into the UV. Their lenses filter out UV light, presumably to protect the retina against damage. Some nocturnal mammals (e.g., bats, rats) can perceive UV light, and their lenses are transparent to UV, as this protection is not required.

Moreover, marked differences in the environment are correlated with equally dramatic alterations in the wavelength sensitivity in closely related animals. Fish that live deeper in the ocean have a visible spectrum that is shifted toward short wavelengths (blue) when compared with more shallow living fish. Within the lifespan of a single animal, changes in the environment can result in an adaptive change to their visual system in response. This is illustrated by changes to the photopigment found in the eye of the European eel, which undergoes several metamorphoses involving a change in lifestyle from river dwelling to swimming in the depths of the sea. The significant difference in the characteristics of the light experienced at each stage brings about a shift in the properties of the pigments and therefore in the visible spectrum for this animal.

For all animals, wavelength sensitivity ultimately depends on the absorbance properties of the visual pigments in the photoreceptors. Colour vision, on the other hand, requires the interaction between two or more cone pigments in the retina. Many mammals have only two cone pigments (dichromats); primates often have a trichromatic system, and many birds have an additional UV or near-UV sensitive pigment (➋ *Fig. 3.20*). In the extreme case, the mantis

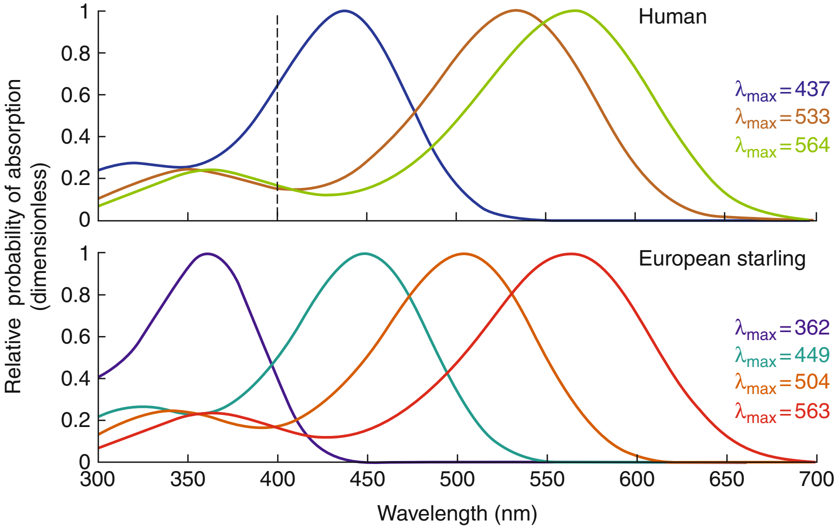

Fig. 3.20

Colour vision in humans is mediated by three pigments (trichromatic vision) and in many birds by four (tetachromatic vision)

shrimp has 12 distinct cone pigments. Colour vision based on a discrete number of pigments can involve the perception of not only primary colours, but also intermediate hues. For example, colour vision of bees appears in that sense to be similar to that in humans. On the other hand, in some animals, highly specific behaviour can be triggered by particular wavelengths only. For example, certain species of moth have feeding and egg-laying behaviours in response to quite precise wavelengths of light.

Presumably, the larger the number of pigments, the better the ability to distinguish subtle changes in hue. Measuring colour vision in an animal like the shrimp presents its own special challenges! The precise location of the absorbance peak of each pigment and the separation between these peaks will have significant consequences for the quality of colour vision. This has interesting implications for visual perception. For example, the 'blue' pigment of one animal may be sensitive to a different wavelength from the corresponding pigment of another animal. It is perhaps impossible to know whether two such animals will see any given visual scene in the same way. Predicting exactly how the separation between the absorbance peaks of various pigments will affect colour vision is equally problematic. It is interesting to note that the difference between the 'green' and the 'red' peaks in birds is much larger than that found in humans.

Finally, it is worth considering the functional significance, or adaptive advantage, of colour vision. Colour vision can be defined as the capacity to distinguish different wavelengths of light irrespective of their intensity. Current opinion suggests that a major purpose of colour vision is to enhance the contrast of certain objects against the predominant colour of their surroundings. Thus, primates, which originated in arboreal environments, have a green-centred colour system, in order to help distinguish objects of interest against the prevailing background. A second important function is to provide information to help in identification of objects (e.g., recognising specific fruits and/or their degree of ripeness).

3.6.3 Vision at Different Distances

One obvious property of the visual world is that objects lie at different distances from the eye. Therefore, for consistently good vision, the eye must have the ability to alter its refractive state so as to accurately focus the image on the retina, whatever the distance to the object. As pointed out earlier, the lens is the component of the eye used to achieve this change in focal length. In humans and many other animals, the mechanism of accommodation involves a change in shape and thus, radius of curvature of the lens. However, some animals take a very different approach. For example, instead of changing its shape, the lens may move toward or away from the cornea, in a manner analogous to a zoom camera lens. This is a common mechanism in teleost fish (e.g., mackerel or bass), but is also found in amphibians. One advantage of this focusing mechanism is that, because the shape of the lens does not change, there is no increase in spherical aberration during accommodation (e.g., a camera telephoto lens). In diving birds, the normal corneal refractive power is all but lost when the eyes are underwater, and therefore, the lens must be used to compensate while diving. In the cormorant, for example, the accommodating lens thickens and is actually pressed against the back of the iris. The middle portion has even been reported to protrude through the pupil, producing a much smaller radius of curvature in the central lens and a correspondingly greater focussing power. Although one normally thinks of the cornea as a static refracting surface, there are some reports that a number of bird species (e.g., chicken, pigeon) actually change the curvature of their corneas when focussing on near objects. The relative contribution of such a mechanism, compared to that of the lens, remains to be determined. As opposed to using dynamic changes in refracting surfaces like the cornea and lens, other solutions to the problem of viewing objects at different distances are also possible. For example, analogous to humans wearing varifocal spectacle lenses, some ground foraging birds possess an eye that simultaneously focuses distant objects on to the central retina and nearby objects (on the ground) on the upper retina. This so-called lower visual field myopia appears to be a fixed (possibly corneal) adaptation. In the same way that the visual spectrum can vary across species, the range of accommodation amplitude can also differ. This presumably relates to the visual requirements of the animal's lifestyle.

3.6.4 Visuomotor Behaviour

As mentioned previously, the main functions of eye and head movements in humans are to direct the central retina to objects of interest and/or to stabilise gaze to compensate for movements of the body or objects in the visual world. Interestingly, all of the same types of eye movements (i.e.,, saccades, pursuit, vergence, optomotor reflexes, etc.) are found in virtually every animal, not just vertebrates. In this context, 'eye movements' are not restricted to movements of the eyes in the head, but also encompass redirections of gaze accomplished by head and/or body movements. At one extreme, the eyes of the housefly cannot move, so the head or entire body is used to accomplish these optomotor movements. In a given animal, the extent to which the eyes can move in the head will presumably depend on a variety of evolutionary and/or ecological factors. For example, in the case of birds, the eyes are disproportionately large (outweighing the brain in many species), and eye movements are relatively restricted. This results in the characteristic rapid head movements that can be readily observed in birds.

3.6.5 Eye Orientation

When considering the issue of the number of eyes possessed by animals, it is intriguing to consider why, in almost all species, there is a minimum of two. One obvious advantage of two eyes is the possibility of stereopsis, or 3D vision. However, this capability is actually quite rare in the animal kingdom, suggesting that stereopsis is a possible adaptation arising from, but not a cause of, having two eyes. Perhaps, more simply, the occurrence of two eyes is the result of an imperative for symmetry in development. Whatever the reason, the orientation of the two eyes in the head varies considerably in vertebrates. There are frontal eyed animals (e.g., owls), lateral eyed animals (e.g., rabbits), and animals with the two eyes on the top of the head (e.g., alligators) or even with both eyes on the same side of the head (e.g., plaice or flounder). The resting orientation of the two eyes defines the overall visual field of the animal. So, for example, binocular animals have a relatively small total visual field with a large 'blind area' behind. Animals like the rabbit or pigeon, however, have extensive fields with little overlap between the two eyes that enable them to keep watching almost all the way around them (see ➋ *Fig. 3.3*). On the one hand, eye and/or head movements can be used to extend the world visible to the animal. In humans and many other vertebrates, the eyes move together, but in the case of some animals, the eyes are also capable being moved independently of one another. A particularly striking example of this can be found in the chameleon. On the other hand, eye movements like convergence can change the extent of the overlap between the visual fields of the two eyes. Although one normally thinks of convergence in connection with fine-tuning binocular disparity to provide for depth perception, many animals do not appear to have stereopsis. Another possible advantage of a greater overlap between the monocular visual fields is that combining the input from both eyes improves visual acuity and contrast sensitivity as well as increases light sensitivity. This improvement in vision is known as *binocular summation.*

A number of the issues we have already considered can interact in ways that provide further insight into the organisation of the visual system as well the specific behaviours of animals. An interesting example can be found in the rather comical head bobbing made by pigeons and other birds as they walk along the ground. This appears to result from the interaction of eye orientation in the head, the requirement for a stable gaze when viewing the world, and a curious higher order feature of the visual system known as *saccadic suppression*, which turns out to occur in virtually all vertebrates, including humans (see below). Pigeons have eyes that are orientated very laterally in the head. This necessarily means that, when a pigeon walks forward, its largely monocular view of the world lurches backward. Without some sort of compensation for this movement, this would result in 'smearing' of the image across the retina. This is similar to what happens when a video camera pans too quickly across a scene. There is no straightforward eye movement that can cancel this unwanted effect (➋ *Fig. 3.21*). Instead, the bird temporarily adopts a stationary head position while walking so that it can have a stable view of the world, until the head must 'bob' forward to a new steady position to catch up with its body. Interestingly, during the head bob, the pigeon actually sees little or nothing because of saccadic suppression. When the eye makes a saccadic movement (either by itself or as a result of

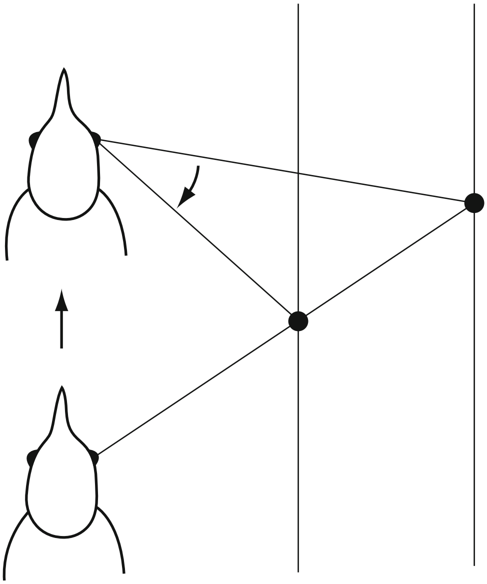

Fig. 3.21

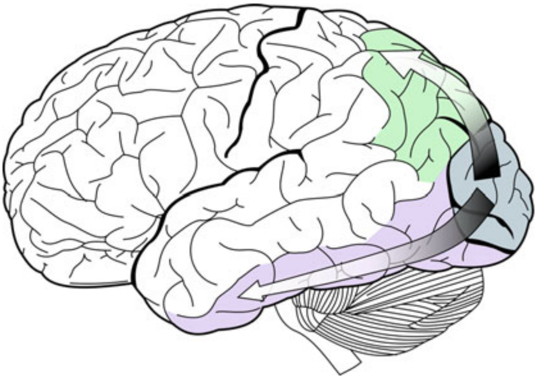
Forward translation of an animal with lateral eyes leads to different shifts in the retinal position of objects at different distances

a saccadic movement of the head), the visual system actually 'turns off' or suppresses the input from the retina to the higher visual centres in the brain. Demonstrate this to yourself by simply looking into a mirror and trying to see your eyes move without moving your head. Thus, the pigeon, while walking (i.e., a saccadic motion), must periodically stabilise its head in order to see anything at all. This sort of visual sampling is not necessary for humans while walking because our frontal eyes allow us to keep our gaze steadily on the world in front of us, thus avoiding any smearing of the central retinal image. However, when making saccadic eye movements, e.g., during reading, humans must also in effect 'sample' the visual world.

3.6.6 Visual Pathways

In all vertebrates, the basic design of the retina is reasonably similar. The transduced signals are then transmitted to higher centres in the brain. However, the pathways used for processing this visual information vary considerably across species, with different characteristic plans being found in each class (i.e., mammals, birds, reptiles, etc.). Although the exact details of brain anatomy are outside the scope of this chapter, a brief consideration of certain principles underlying the organisation of these pathways is relevant. The principal characteristic of visual processing in humans and other primates is the separation of different aspects of the visual stimulus into discrete parallel streams. For example, visual processing in higher brain centres divides into a dorsal stream largely concerned with motion and location and a ventral stream that deals with object recognition and colour (➋ *Fig. 3.22*). As described in ➋ Sect. 3.5.1, isolated brain lesions in humans can sometimes lead to highly specific visual deficits. The extent to which this degree of parallel and/or modular processing also exists in other animals is far from clear and remains to be determined.

All vertebrates that are capable of visual processes, such as recognising objects or assigning significance to what is being seen, must ultimately depend on more complex brain circuitry. Looking beyond reflexive stimulus–response actions, such as that described earlier for the frog, a good example of higher visual processing is the perception (or is it misperception?) of visual



◘ Fig. 3.22
Schematic illustration of the dorsal (*green*: motion and location) and ventral (*purple*: detail, colour and object recognition) streams of visual processing in the cerebral cortex

illusions. The fact that, like humans, some animals experience visual illusions is certainly evidence for a degree of pre-programming or hard-wired assumptions made by the brain. Moreover, the evidence that some illusions are perceived in the same way suggests further that this circuitry has a similar organisation. This would seem to be a fruitful approach for further investigation of higher visual processing in different animals.

3.7 Comparing Animal and Machine Vision

Inevitably, this brief stroll through the properties of human and animal vision can only highlight some of the basic principles of eye morphology, brain organisation, visuomotor behaviour, and perception. At first glance, one is struck by the enormous diversity encountered in all aspects of biological vision, including – but not limited to – eye shape and size, retinal properties, eye orientation in the head, etc. Almost certainly, this diversity reflects an underlying variation in the environments within which each of these animals is trying to survive. In this limited sense, animal and machine vision can share a common goal: the development of the 'equipment' necessary to solve a particular visual problem or task. As different animals often face very different challenges to which they must adapt, the solutions that arise in the course of evolution vary considerably. A careful examination of such adaptations may well provide further valuable insights for future work by computer vision scientists, which eventually benefits machine vision. The corollary of this view is that at least some aspects of animal vision either get their start or are subsequently shaped by the need to achieve quite specific, often relatively simple goals, just as occurs in some machine vision applications. In addition, constraints and limitations, including cost-effectiveness or efficiency, are just as important for animal vision as for machine vision. For example, in the course of evolution, evolution will presumably only 'invest' in the processing power that animals require for the purpose.

However, this is clearly not the whole picture, as survival for animals rarely depends on the ability to deal with a single problem: survival is a multi-function task! This fact alone will account for the higher complexity of animal vision, which in turn produces its arguably most important feature: *emergent properties*, which can be thought of as incidental benefits. Vision, perhaps originally designed for one, or just a few limited tasks, can lead to new abilities and opportunities simply because of the additional perception that is made possible. A good example of this is the advent of colour vision in some animals. Many have argued that wavelength sensitivity arose in primates originally to allow them to detect riper fruits against a different colour background. However, chromatic sensitivity leads to the solution of many other perceptual problems. In turn, species with colour vision can then exploit colour in their social communication, as evidenced in the colourful plumage of many birds.

One last thing to consider is the nature of perception itself. In the context of machine vision, the equipment is carefully designed to register certain objects or scenes and then make one or more discriminations. In contrast, animals generally must have a much more flexible visual system, possessing the ability to make many kinds of discriminations in a range of environmental and lighting conditions. Nonetheless, just as a machine can only take in the visual stimuli it is designed to receive, humans and animals do not actually 'see' the real world; we perceive what each of our visual systems allows us to experience. Animals may have just as valid a percept as we do, but it can be very different. Similarly, machines may 'see' the world differently from the way we do, but we must not suppose that our view is necessarily 'right' or indeed 'better'.

4.1 Introduction

The sensation of colour arises as a result of the brain's response to variations in the wavelength of light received by the eye. It provides the brain with signals representing four different views of a scene. (Rod cells and three different types of cone cells provide these signals in the eye.) Hence, we can regard the eye-brain complex as a system that generates four precisely aligned images. These are then compared/combined with each other within the brain but the way in which this is done remains enigmatic. There are many subtle features of human colour vision but we shall argue that many of them need not concern us, as our objectives in Machine Vision are quite specific.

The scientific study of colour (*Colour Science*) is a complex subject; it is concerned with the perception of colour by the human/animal eye, the origin of colour in materials, colour in art and fashion, photography, printing and video, as well as the physics of light. Colour Science encompasses many technical disciplines, including physiology, anatomy, psychology, philosophy, chemistry, optics, materials science and many aspects of engineering. The subject is complicated by the fact that human perception of colour is influenced by many factors: physical and mental illness, ageing, physical injury, surroundings, motion, alcohol drugs, past experience (e.g., working in the printing industry) and even language and culture. Much of Colour Science was developed by the need to reproduce colours accurately, for printing, photography and video displays. This does not have much relevance to our immediate need, as we shall show later. In this essay, we shall concentrate on those aspects of the subject that relate directly to Machine Vision, taking a pragmatic approach and ignoring those areas of Colour Science that do not contribute directly to the design of practical inspection, measurement or guidance systems.

As so often happens in Machine Vision, we are interested in verifying that a manufacturing process is running properly. Hence, we know what to expect from a "good" sample. Any significant deviation from the norm is an error that must be detected by the inspection system. Moreover, we are limited by the sensors that we can use. Colour video cameras provide us with just three channels, usually referred to as *R*, *G* and *B*. While Colour Science suggests that other representations (such as hue, saturation and intensity, *HSI*) may be better for certain tasks, we have to base all of our processing on the RGB signals from a camera. If a colour recognition task is impossible using the RGB signals, it is also impossible with HSI as well. (*H*, *S* and *I* can be calculated from *R*, *G* and *B* and vice versa.) On some tasks, it may be more convenient in practice to use HSI rather than RGB but we gain no theoretical advantage in doing so. It must be understood that no representation (called a *Colour Model*), however attractive theoretically, provides any direct advantage to us, since we can only buy cameras that supply RGB signals. The RGB system for video cameras was devised on the assumption that human beings have trichromatic vision. There is good evidence for this; cinema and video image reproduction are based on this idea. If it were not so, we would have to tolerate poor colour reproduction when watching television and films.

4.1.1 Why Is a Banana Yellow?

First, let us consider the physics involved in this question. The visible part of the electromagnetic (EM) spectrum comprises wavelengths between about 0.38 and 0.74 μm (➋ *Fig. 4.1*). A light signal containing components with a non-uniform mixture of wavelengths will appear to be coloured to a human observer. If the energy spectrum is nearly constant for all

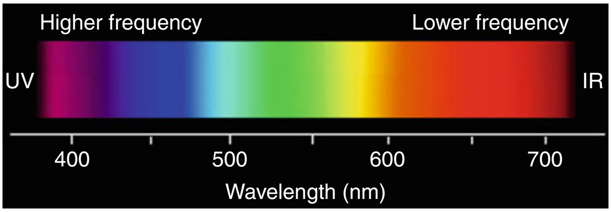

Fig. 4.1
The electromagnetic spectrum and colours within the visible (VIS waveband)

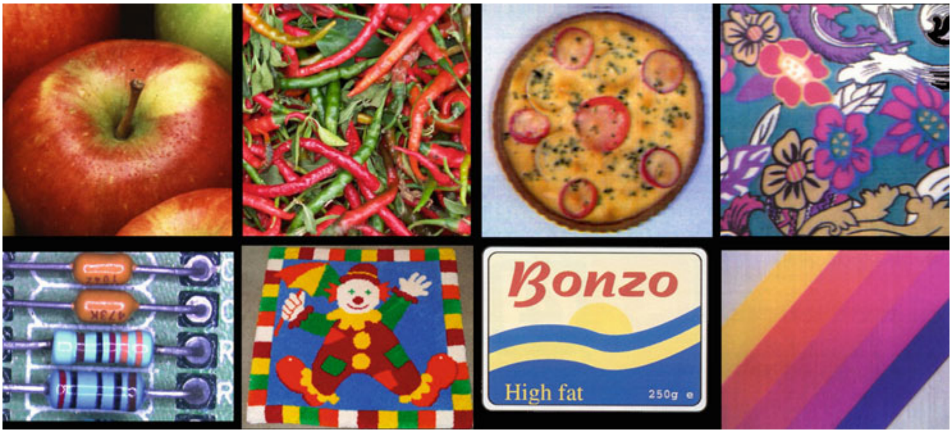
wavelengths in this range, the observer will perceive white light. The (non-uniform) spectrum of light reaching the eye of a human observer from a banana leads the brain to call it "yellow." A similar but slightly different spectrum of light might emanate from a canary, or lemon. The seemingly trivial question at the head of this section has a deeper meaning than we might at first think. When faced with this question, many people begin by thinking about Newton's demonstration of the multiple-wave composition of white light and the fact that bananas reflect light within a certain range of wavelengths, while absorbing others. Curiously, most people, even non-scientists, attempt to answer this question with reference to the *physics* of light absorption and reflection. However, light rays are not actually coloured. So-called "yellow light," reflected from a banana, simply appears to us to be coloured yellow, because the human brain is stimulated in a certain way that is different from the way that it is when the eye received light from an orange or tomato. This stimulus results in the brain responding with the colour label "yellow."

In fact, a banana is yellow because a lot of people collectively decided to call it "yellow." As young children, we are taught by our parents to associate the sensation of looking at lemons, butter, bananas and canaries (and many other yellow things) with the word *"yellow."* At that age, we do not know anything about the physics of differential light absorption. Of course, we do not need to do so, even as adults. A ripe banana *"is yellow"* because a lot of other people persistently call it *"yellow"* and we have simply learned to do the same. There is no other reason than that! In particular, the physics of light has got nothing whatsoever to do with the *naming* of a colour. Physics can only explain how the particular mixture of wavelengths that we have learned to associate with *"yellow"* is generated.

4.1.2 Defining Our Objectives

We can best define our area of interest by example, with specific reference to some of the industrial inspection and control tasks that we might want to perform (➜ *Fig. 4.2*). Broadly speaking, our objective is to provide *coarse* colour recognition facilities. We make no apologies for using the word "coarse," since it is a fair description of what we need to do! Here are a few more examples of tasks that fall within this category:

- Grading and sorting fruit and vegetables. This is important for quality control and for checking bulk delivery consignments against the details of the product actually ordered.
- Inspecting food products. A certain cake that is popular in Britain is called a Bakewell tart and consists of a small pastry cup, filled with frangipan, is covered in white icing (frosting) and has a cherry placed at its centre (➜ Chap. 23)



■ **Fig. 4.2**

Typical products for which coarse colour recognition is appropriate. (a) Grading/inspecting fruit. (b) Sorting vegetables. (c) Quality control of manufactured food products. (d) Inspecting dress fabric. (e) Reading colour codes of electronic components. (f) Inspecting carpet (hand-knotted rug). (g) Inspecting packaging (simulated image of butter-substitute container). (i) Identifying packaging (Feature. The colour bands identify the product type)

- Checking that fabric has been dyed, woven, knitted, or printed correctly.
- Checking that each carton of sweets (candies) contains a certain proportion of orange ones. What could be worse than not having any orange M&Ms in a packet? (➲ Chap. 16)
- Checking labels on boxes, bottles, jars, cans and other containers. In the pharmaceutical industry, there are serious concerns about the safety of mis-printed boxes. In other industries, carton inspection is important for two reasons. The customer sees the box first and the most popular "product" of all is containers!
- Reading component colour codes for the electronics industry.

More examples of coarse colour recognition will be encountered as we proceed through this chapter. Another example of coarse colour recognition is shown in ➲ *Fig. 4.3*.

4.2 Physics of Colour

Visible light is electro-magnetic (EM) radiation within a narrow wave-band and is usually characterised by its spectrum (➲ *Figs. 4.1* and ➲ *4.8*). This may be expressed as the *intensity* (i.e., number of photons/s), measured as a function of wavelength *(λ)* or frequency (*f*). These are related by the equation:

$$v = f.\lambda$$

where v is the velocity of light in whatever medium the light is traversing. In air, the velocity of light is close to that within a vacuum: 2.998×10^8 ms^{-1}. EM radiation with a wavelength inside the band 0.38–0.74 μm is visible to the human eye and is therefore known as visible light (VIS). Within this band, different wavelengths produce different sensations of colour to an observer. In practice, there is a multitude of wavelengths in the light reflected from a surface, or emitted

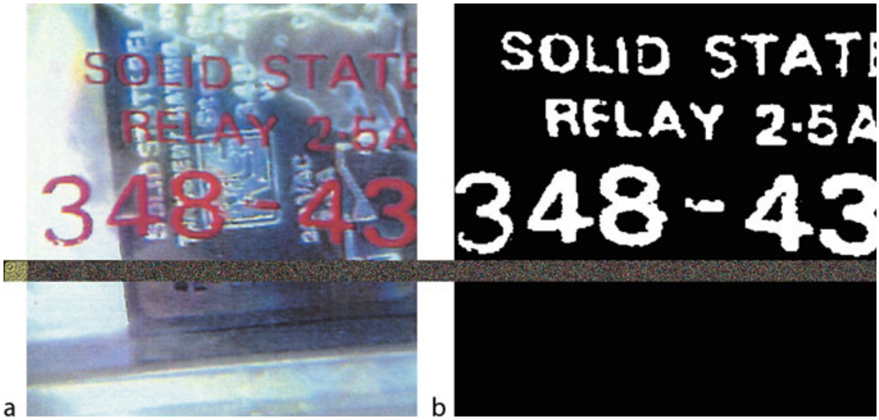


Fig. 4.3
Coarse colour recognition. (a) Original image: black electronic component with silver printing, enclosed in a plastic bag. The latter has the red text printed on it. (b) Output of the programmable colour filter described later in this chapter

by standard ambient lighting. (Lasers and LEDs provide notable exceptions to this.) Notwithstanding the remarks made later, the spectrum is the principal factor in determining the perceived colour of light.

4.2.1 Interaction of Light and Matter

When light strikes a surface, it can be reflected, absorbed, scattered, or re-emitted at longer wavelengths (fluorescence). Several different optical effects can take place simultaneously and combine to form an emergent beam with a spectrum that quite different from that created by any one of them. Some of these effects are orientation specific and hence the combined beam might well produce quite different colour sensations in the observer, depending on the illumination and viewing angles (➋ *Fig. 4.4*). A surface that diffusely reflects all wavelengths in equal measure is seen as being grey or white. A surface that totally absorbs all wavelengths is perceived as black.

In English, it is common practice to refer to the rainbow as having seven colours: violet, mauve, blue, green, yellow, orange and red but, in reality, there is an infinity of “colours.” Subdividing the spectrum like this is an artefact of language, created out of the need to give names to colours and has no physical significance or biological basis. In some languages, fewer colour terms are applied to the rainbow but there are seldom more than seven [10]. The rainbow contains all of those colours that can be formed by visible light of a single wavelength. These are known as *spectral colours* and can be generated optically, using a prism or grating. By selecting light from a very narrow region of a “rainbow,” it is possible to build a *monochromator*. The arrangement shown in ➋ *Fig. 4.5* can be used to select any desired spectral colour from a panchromatic source, or for spectral analysis of the light reflected from a surface.

Interference occurs when a surface has a microscopically repeating structure, where the spatial period is comparable to the wavelength of VIS light. It occurs in nature, on butterfly and beetle wings, and is seen on CDs, DVDs and hologram wrapping paper (➋ *Fig. 4.6*). The brilliant colours it generates are well known and are dependent on the angles of illumination

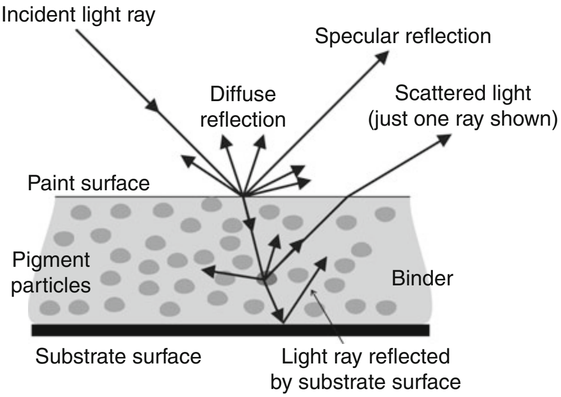

Fig. 4.4

When light falls on a painted/lacquered surface, its spectrum can be altered in several ways. Paint consists of numerous tiny pigment particles suspended in a clear binder. Reflection at the surface of the paint, transmission through the binder, reflection/scattering from the pigment particles and reflection from the substrate all contribute to changes in the colour of the emergent light. If the pigment particles are elongated and aligned in one direction, the apparent colour of the surface is highly directional

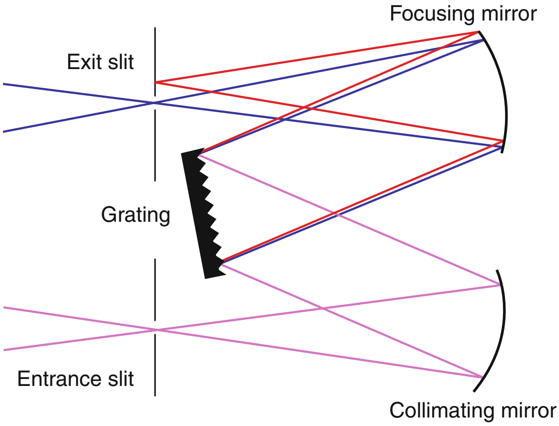

Fig. 4.5

Czerny-Turner monochromator. White light is focussed onto the entrance slit, is collimated by a curved mirror and is then projected onto a grating. The dispersed beam is re-focussed by a second mirror, onto the exit slit. Each wavelength is projected to a different position at the exit slit; the wavelength that is transmitted through it depends on the angular position of the grating

and viewing. Holograms also produce colour by optical interference and the techniques that we shall discuss later in this chapter could be used to verify the authenticity of holograms, such as those found on credit cards (➋ *Fig. 4.6c*). Iridescence is an optical effect in which the colour of a surface varies with viewing angle. It is caused by interference, when multiple reflections occur in thin multi-layered, semi-transparent surfaces. Iridescence is seen on pearls, soap bubbles and

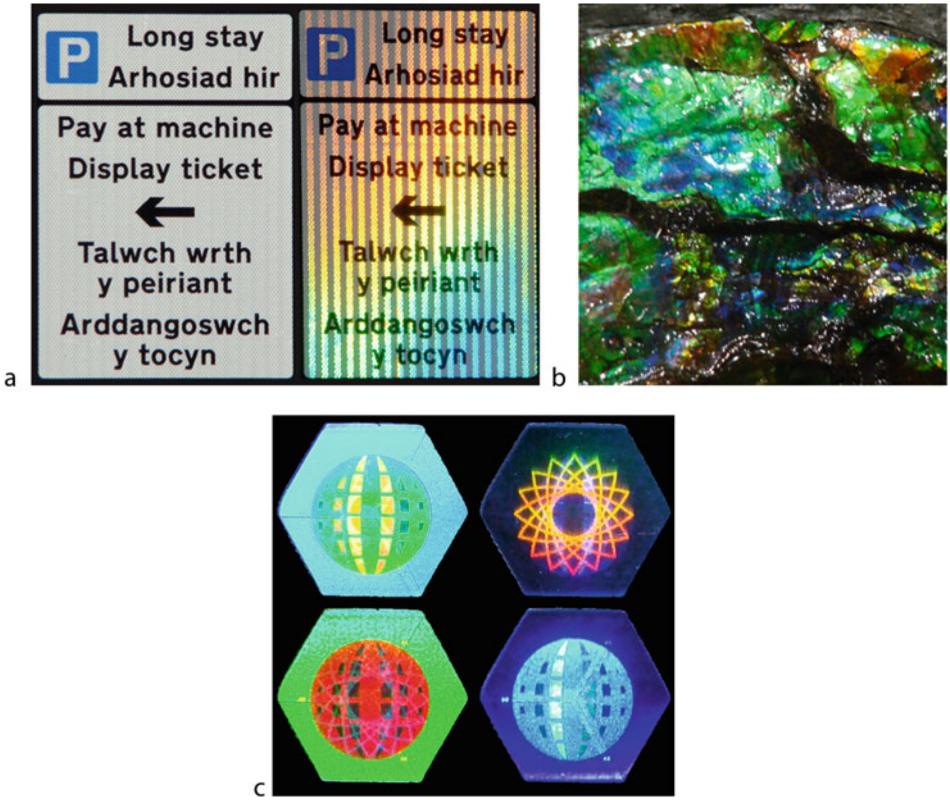

Fig. 4.6

Structural colour. (a) Street sign, variable lighting. (b) Ammolite. (Fossiled ammonite shell) (c) Hologram on a credit card, variable lighting

optical coatings. Dichroic mirrors, such as those used on the integral reflectors on projector lamps show the same effect. Iridescence is sometimes exploited for decorative effects on the packaging of goods such as cosmetics and on jewellery (➋ *Fig. 4.6b*).

Most light sources encountered in everyday life, including the sun, incandescant filament and fluorescent lamps, do not emit pure spectral radiation; we most commonly experience light containing a mixture of wavelengths (➋ *Fig. 4.8*). Sometimes, light sources with quite different spectra may be perceived by the eye in the same way as each other and the same as a pure spectral colour. For instance, a computer screen displaying an "orange" feature does not emit pure spectral light. Instead, the screen emits a mixture of "red" and "green" light, with an intensity ratio of about 2:1. There is little, or no, blue component. To produce the same sensation, pure spectral light of about 0.6 μm would be needed. For sources that emit across a broad spectrum, it is often convenient to refer its *dominant wavelength*. This is the wavelength of pure spectral light that produces the same perceptual sensation as the mixed (i.e., non-spectral) source. The dominant wavelength effectively determines the *hue* of the light.

It is important to note that many colours cannot be represented in this way, using a single pure spectral colour. For example, purple, which is a mixture of red and violet light cannot. The *achromatic colours* (i.e., black, grey and white), pink, brown and magenta do not produce the same visual sensation as any one spectral colour.

4.2.2 Image Acquisition Sub-system

The spectrum of light reaching the retina (of the eye or a camera) is given by the following product:

$$L(\lambda)R(\lambda)O_1(\lambda)O_2(\lambda)...O_N(\lambda)$$

where

L(λ) is the spectrum of the light emitted by the primary source

R(λ) is the reflection characteristic of the surface being viewed

$O_1(\lambda)$, $O_2(\lambda)$,...,$O_N(\lambda)$ are the spectral transmission characteristics of the various components in the optical path. This includes the reflector on the luminaire, the air path, lenses, filters, optical window on the camera.

The most significant elements determining the spectral characteristic of the optical system are normally the light source and any filters that are deliberately introduced to modify the spectrum.

4.2.2.1 Light Sources

Lighting can greatly influence the visual appearance of coloured surfaces and the signals generated by a video camera. ➲ *Figure 4.7* illustrates this by showing the same scene illuminated in five different ways [12]. Notice that, in two cases (➲ *Fig. 4.7c and e*), there is no obvious relationship to the colours that a person would observe when viewing the same scene in natural light. In the other three cases, the "real" colours are identifiable, although there are still clear differences due to the lighting. ➲ *Figure 4.7* was prepared using a camera and the colour changes due to alterations in the lighting are obvious. However, a person viewing the same scene directly would, under certain conditions, observe far smaller changes. This is due to the phenomenon called *colour constancy* and in which the human visual system compensates, in part, for variations in ambient lighting. Neither a photographic nor video camera makes adjustments like this. Hence, in some cases, a human observer's perception of colour changes under varying different lighting conditions is much smaller than a Machine Vision system would experience. The choice of appropriate lighting is therefore of great importance for machine recognition of colour; there are two critical conditions:

(a) The lamp must emit strongly in all relevant parts of the spectrum. (What is relevant depends, of course, on how the surface reflectance function varies with wavelength.)
(b) The lamp emission spectrum must be stable, both in the short and long term.

Lamps differ considerably in their spectral characteristics (➲ *Fig. 4.8*). Daylight has a smooth wide spectrum spanning the whole visible waveband. An incandescent filament lamp has a lower shortwave output than daylight and hence oranges and reds appear to be more prominent than in daylight. Many lamps are based on the emission of light from excited ions of sodium or mercury. These lamps tend to have prominent well-defined peaks in their spectra, due to electron transition from one energy level to another. Strong, spiked spectral peaks can cause problems in certain situations. Since the peaks occur at well-defined

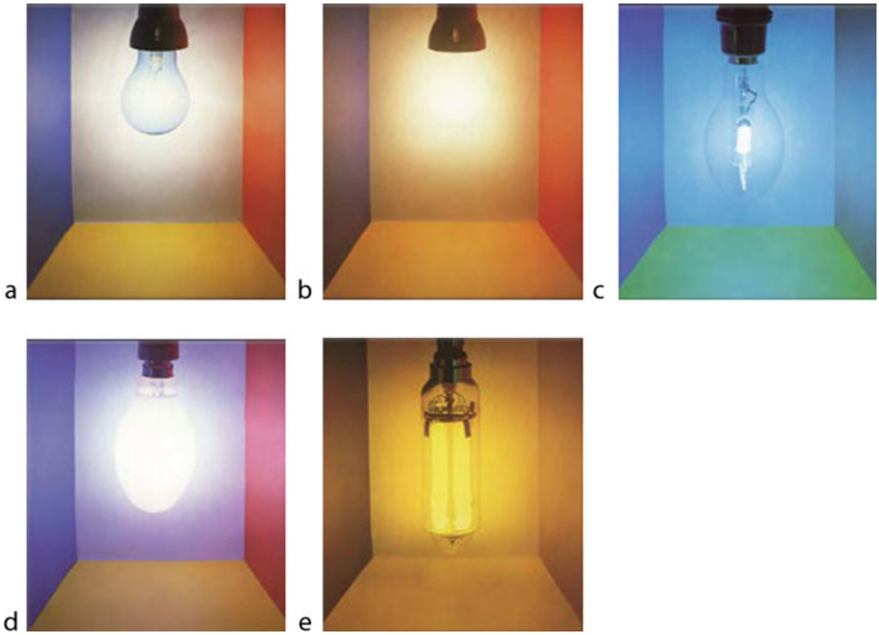

Fig. 4.7
Effects of lighting on the appearance of coloured surfaces. (a) Artificial day-light lamp. (Has a similar spectrum to a cloudy northern sky at mid-day, Northern hemisphere). (b) Household incandescent filament lamp. (c) Mercury lamp. (d) High-pressure sodium lamp. (e) Low pressure sodium lamp (nearly monochromatic). (Reproduced from [12], used with permission)

wavelengths, they can be exploited to good effect in some applications. Some lamps have been designed to match the spectral characteristics of daylight and are widely used in photography and video recording. When lamps have been in use for a long time, the light output usually falls but the spectrum does not normally change much, as this is defined by atomic behaviour. However, there is a special situation that should be borne in mind when using filament lamps, with feedback applied to stabilise the light output. There is a temptation to use the feedback signal to adjust the current through the lamp. However, this alters the filament temperature and hence the spectrum; as the lamp current increases, the filament gets hotter and emits more strongly at shorter wavelengths. To stabilise the light output without altering the colour, it is better to use a variable-size optical aperture, rather than adjusting the lamp current.

4.2.2.2 Adjusting the Spectrum

It is possible to adjust the spectrum of the light projected onto a widget at will, using a liquid crystal light valve. (Lighting-viewing method number 44, ➲ Chap. 40) This is an expensive option but virtually any arbitrary spectrum can be created under software control. A cheaper alternative exists, using a series of LEDs to generate light at different wavelengths. In ➲ Sect. 4.3.4, we show how the contrast between two surfaces of seemingly similar colour

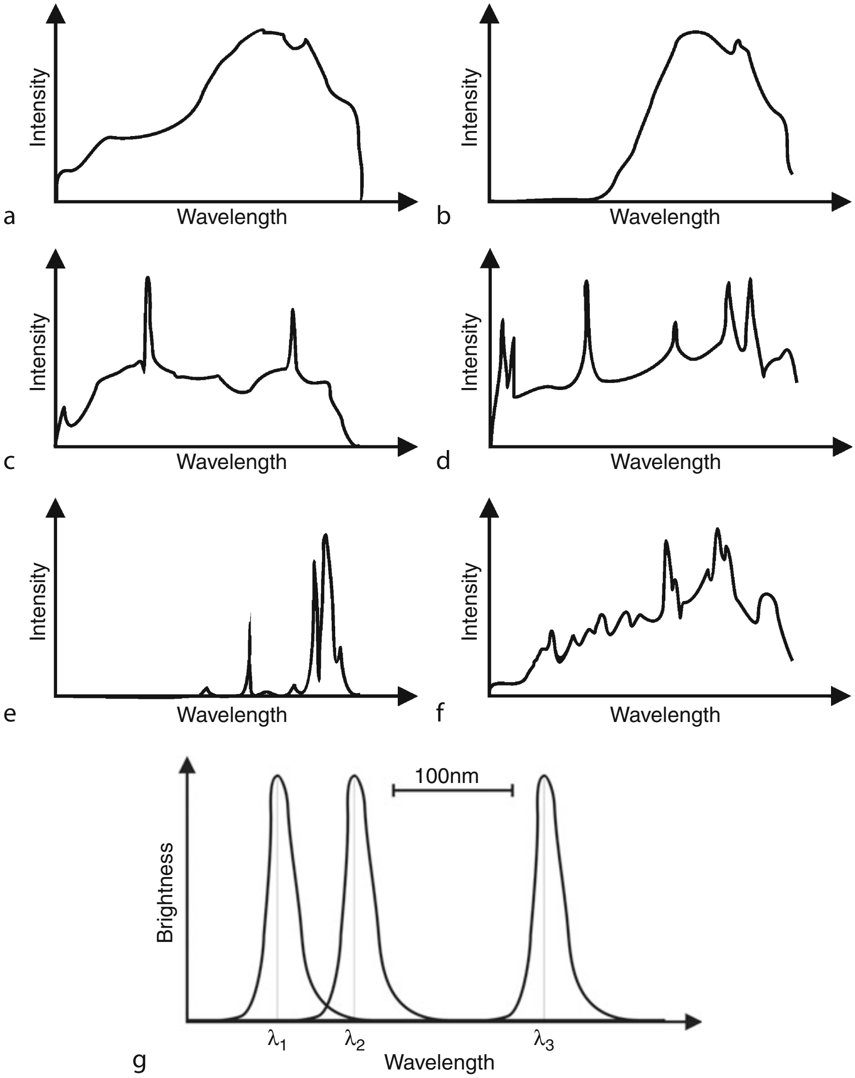

Fig. 4.8

Spectra of common light sources. (a) Daylight. (b) Incandescent filament lamp (c) Fluorescent. (d) Low pressure mercury. This is a strong UV emitter. (UV spectrum not plotted). (e) Low pressure sodium. (f) Xenon flash. (g) LED spectra. A single LED emits light over a narrow band of wavelengths. LEDs can be ordered with spectral peaks at any specified position within the VIS waveband. Hence, illuminants may be built that combine the outputs from several LEDs of different colours. In this illustration, the light from three LEDs, whose peak wavelengths are λ_1, λ_2 and λ_3, is mixed. A tunable light source with a spectrum that consists of a series of spikes can be useful for improving contrast in scenes containing metamers. Individual LEDs can be strobed in sequence, to generate multiple colour-separated images, or always switched ON to obtain a single composite image. Their drive currents can be adjusted individually to alter the balance of their contributions to the spectrum of the mixed beam

(metamers, see ➲ *Fig. 4.18*) can be maximised by using LEDs to generate light with several peaks at appropriate points in the VIS waveband. Using only "off the shelf" LEDs, it is possible to match a given wavelength quite accurately (error less than ±10 nm). Hence, a light source with a multi-peak spectrum can be built using LEDs (➲ *Fig. 4.8*). Moreover, any predefined set of LEDs within an assembly can be strobed. This enables spectral sampling and results in a series of "colour separation" images. Clearly, this is only feasible for illuminating small-medium size objects. Image acquisition is slow, taking several video frame periods.

4.2.2.3 Filters

Another way to modify the spectral characteristic of the image acquisition system is to use filters. These are available to perform of the following functions (➲ *Fig. 4.9*):

- Block short wavelengths (long-pass filter)
- Block long wavelengths (short-pass filter)
- Block all but a very narrow spectral band (band-pass filters)
- Block only a very narrow band (band-stop filter)
- Block ultra-violet and pass VIS light, or vice versa
- Block infra-red and pass VIS light, or vice versa

Interference filters have very sharp cut-off characteristics and can be "tuned" slightly, by adjusting the angle relative the light path (➲ *Fig. 4.10*). Filters can be concatenated. For example, a long-pass filter and a short-pass filter can be combined to select a wide band within the VIS spectrum. Two or more band-stop filters can be used to suppress multiple peaks, for example, in the spectrum of a mercury lamp.

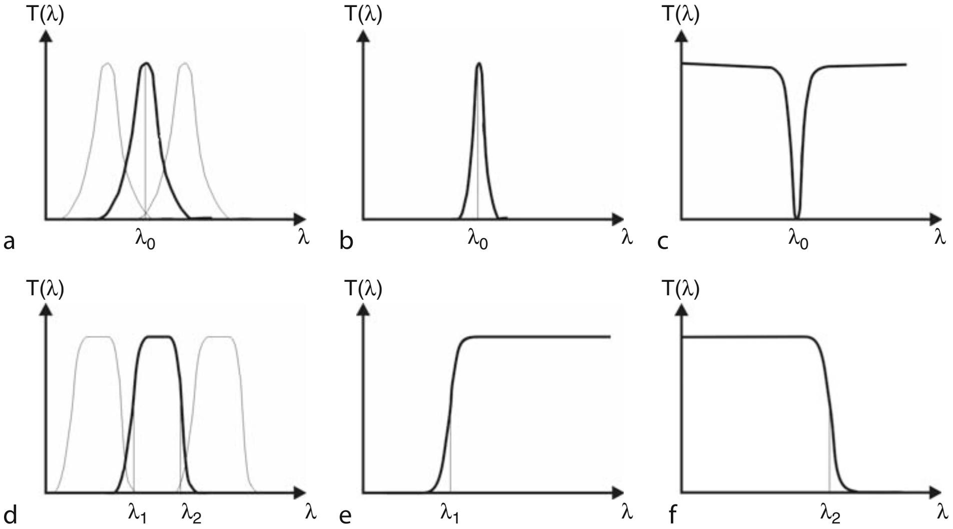

Fig. 4.9
Optical filters. Filters are available for near-UV, VIS and near-IR. (a) Narrow band-pass filter. (b) Very narrow band-pass filter. (c) Very narrow band-stop filter (d) Wide band-pass filter. (e) Long-pass filter. (f) Short-pass filter

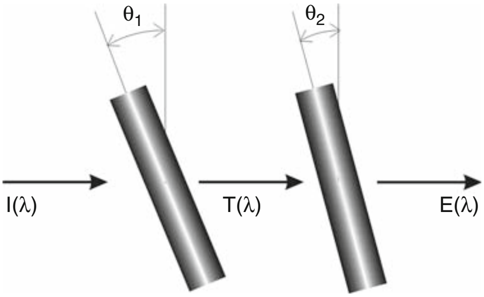

Fig. 4.10
Cascading optical filters. The incident beam (I(λ)) is short-pass filtered to produce beam T(λ). This is, in turn, long-pass filtered to produce the emergent beam E(λ). The exact cut-off wavelengths of the filters can be adjusted by altering the tilt angles θ_1 and θ_2

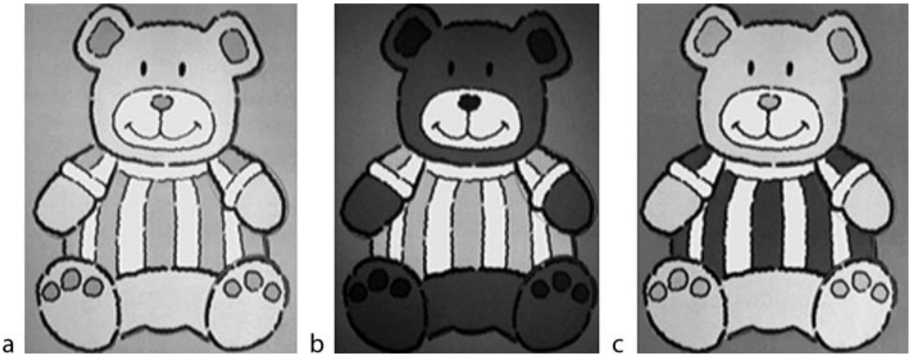

Fig. 4.11
Interference filters have a sharp cut-off and can greatly increase image contrast. (a) Child's toy printed on card. No filter, monochrome CCD sensor. (b) Short-pass filter ($\lambda_{\text{cut-off}} = 0.55\ \mu$m). (c) Long-pass filter ($\lambda_{\text{cut-off}} = 0.55\ \mu$m)

Where the function is to be switched automatically, perhaps to enable a factory-floor inspection system to accommodate a different product line, several filters can be mounted on an indexed wheel. Commercial filter wheels are operated by software, via a low-speed interface (RS232) (Lighting-viewing method 75).

Using interference filters, large increases in image contrast can often be achieved (➲ *Fig. 4.11*).

Filters can be mounted immediately in front of the lamp. However, it is usually better to place them between the object being viewed and the camera's main lens: smaller filters are needed and are not heated by the lamps. Once a filter has been purchased and mounted for a given application, there are no "running" costs. Optical filters are much faster and more reliable than software. The disadvantage is, of course, that the filter function is fixed.

Colour filters can be used, with separate sensors in cascade, to create a multi-spectral image series (➲ *Fig. 4.12*).

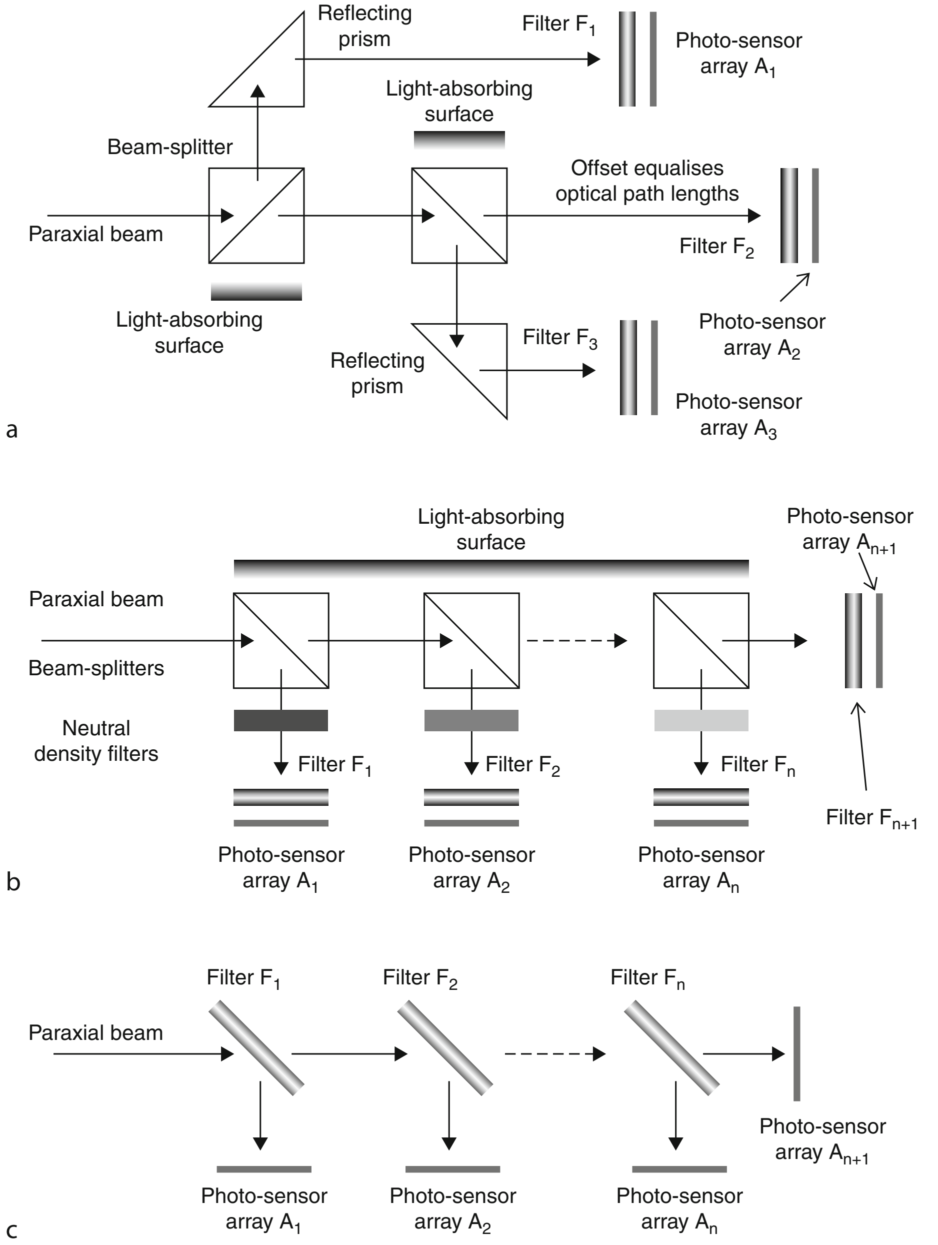

Fig. 4.12

Optical arrangements for multi-spectral imaging. The photo-sensor arrays are capable of detecting light over wide range of wave-lengths. (a) Branching structure of a 3-sensor colour camera. (b) Linear array of beam-splitters. (c) Linear array of dichroic filters. These act as mirrors for a certain range of wavelengths and transmit others. No attempt is made in (b) and (c) to equalise the path lengths, which would ensure that the images received by the photo-sensor arrays are all of equal size and in focus

4.3 Human Colour Vision

It is now widely accepted that the retina of the human eye contains three different types of colour receptor cells, or cones. One type, relatively distinct from the other two and misleadingly called *blue cones* (or more correctly *S* cones), is most responsive to light that we perceive as violet (wavelengths around 0.42 µm). The other two types (*green* and *red cones*, properly called *M* and *L* cones) are more closely related to each other and are most sensitive to green and yellowish-green light (wavelengths of about 0.534 µm and 0.564 µm respectively) (➋ *Fig. 4.13*).

Rod cells in the retina cannot sense differences in wavelength and are reputedly not involved in colour vision, except under very special conditions. Notwithstanding the fact that the "normal" eye actually contains *four* wavelength-selective sensors (A, M and L cones, as well as rods), most colour scientists believe that cones are the principal sensors involved in human colour vision. Based on this idea, the so-called *Tristimulus Theory* has been devised. This leads us to understand that every optical spectrum, however complex, can be represented within the eye by three values (*tristimulus* values) indicating the strength of the response of the S, M and L cones. The sensitivity curves of the cones overlap (➋ *Fig. 4.13*). Notice that some combinations of responses are impossible, irrespective of the shape of the spectrum of the incoming light. For example, it is impossible to stimulate only the M cones, without also stimulating the S and L cones. to some extent. (The reason is, of course, that rods and cones are very small and are packed together very tightly in the retina. Furthermore, there is no easy way to identify whether a given cone cell is S, M or L type.)

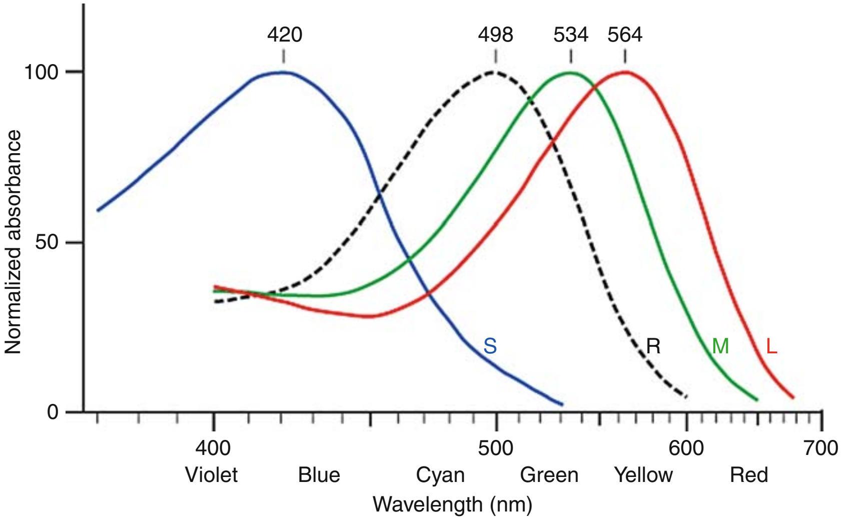

Fig. 4.13
Normalised spectral response of the cones (curves labelled S, M and L) and rods (R) in the human eye. The peak responses are at 0.42 µm (S cones), 0.534 µm (M cones), 0.564 µm (L cones) and 0.498 µm (rods)

Two important facts have been discovered experimentally:

(a) Any colour can be matched by visual observation to a combination of not more than three spectral colours. However, not all colours can be matched to any one set of spectral colours. It should also be noted that it may be necessary to use "virtual" light sources that have no physical existence and to allow negative amounts of light to do this.

(b) Additive relations in colour mixtures have been found to hold under a wide range of conditions.

These are important because they allow us to begin building a mathematical model of colour vision.

4.3.1 Tristimulus Model

Like most children, the author learned at school that *any* colour can be created by mixing red, yellow and blue paint. This is not true! Later, he was taught that mixing red, green and blue light can generate *all* colours, including white (➋ *Fig. 4.14*). This is not true either! A wide range but not all colours can be reproduced in this way, as is evident from colour television; the receiver display screen produces tiny red, green and blue spots of light. Since the viewing conditions are such that these spots cannot be resolved by the eye, they merge to create a wide variety of different colour sensations. In fact, the picture quality is so good that most people are not normally aware of the fact that there are certain colours that television cannot show.

4.3.2 Subtleties of Human Colour Perception

If one or more types of the colour-sensing cones are missing or less sensitive than normal, the person concerned is said to be *colour deficient*, or in popular terms *colour blind*. The latter term can be misleading, since only a small proportion of colour-deficient people are totally unable to detect colour at all. It is of interest to note that some animals (e.g., marsupials, birds, reptiles,

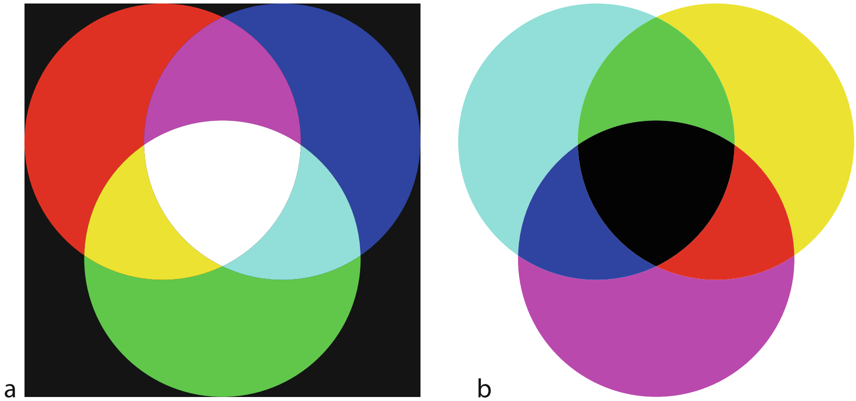

Fig. 4.14

Colour mixing. (a) Additive, produced by mixing coloured lights and hence is relevant to film and video. (b) Subtractive, relevant to painting, dyeing and printing and colour film photography

and fish) are thought to have more than three different types of colour sensor, or fewer (most mammals). Human beings and other old-world primates are actually rather unusual in possessing three kinds of receptors. (*trichromats*) Some women (*tetrachromats*) are thought to have four, rather than three, distinct types of cone cell. The most common form of colour deficiency leads to an inability to distinguish red and green properly and occurs in about 8% of men. A variety of factors can change colour perception, including eye disease, neurological disease, head injury, stroke, dementia, narcotics and severe alcohol abuse.

Numerous optical illusions have been devised that disturb our normal perception of colours. Under certain conditions, alternating red and green stripes on a computer display will "disintegrate" into a shimmering jumble. The naming of a colour can be altered by its context. We are all familiar with the formation of after-images and the changes in colour perception that they introduce. After staring at a coloured patch for a few seconds, an after-image containing the complement of that colour is perceived by the eye for some time after it moves (➲ *Fig. 4.15a*). When a small area of one colour is enclosed within a much larger region of another contrasting colour, a human observer may experience some change (➲ *Fig. 4.15b*). Optical illusions such as these can provide Colour Scientists with insight into the working of the human visual system.

In the 1950s, the BBC Television Service experimentally broadcast grey-scale images that vibrated. Since motion can cause apparent changes of colour, this was done in the hope of exploiting this curious feature of human vision for public television broadcasting. However, the experiment was soon abandoned as the results were unreliable and many people find vibrating images disconcerting. Also see [29].

The apparent brightness of a light source depends upon the number of photons reaching the eye from it each second. The source brightness can alter its perceived colour. For example,

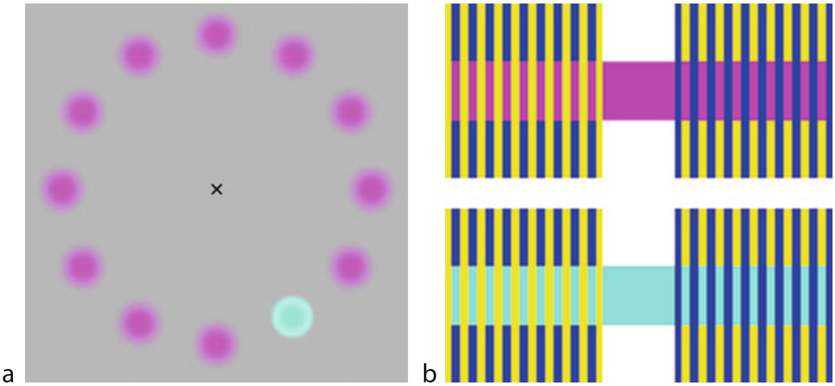

Fig. 4.15

Subtleties of human vision revealed in optical illusions. (a) Troxler fading (due to adaptation of the eye) and the creation of complementary colour as a negative after-effect. In a web-based animated sequence, 11 fuzzy violet spots are shown, with the "empty space" rotating around the centre of the image. When an observer stares at the central cross, a fuzzy green spot appears to rotate instead. After a short while, the violet spots disappear and the green spot continues to rotate but now against a uniform grey background. The animated version can be viewed at [29]. This illusion is capable of creating colours outside the gamut of the display device. (b) Colour perception depends on context. The mauve/turquoise bands seem to change colour when they are viewed against different backgrounds

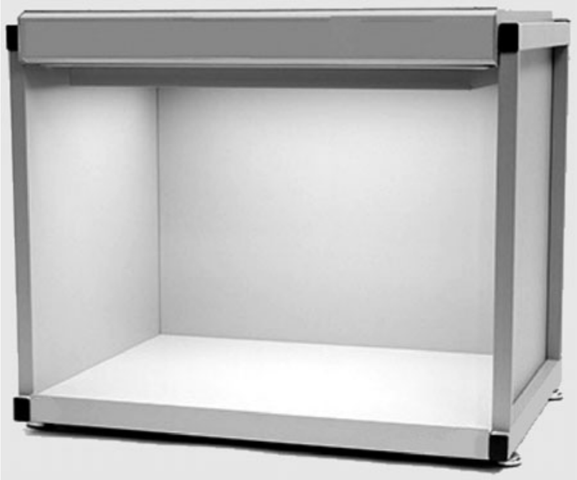

Fig. 4.16

Viewing booth for colour matching experiments. All surfaces are matt grey. The coloured background is shown here merely to emphasise this point and would normally be grey too. In addition, subdued room lighting would be used. In order to match colours under standard daylight conditions, the booth should use 5,000 K lighting

a low-intensity orange-yellow appears to be brown, while at low-intensity yellow-green appears to be olive-green.

In human beings, the polarisation of the light reaching the eye does not significantly affect visual sensation. However, in some fish and mollusks, it does. Of course polarising sun-glasses can alter perceived colours.

An important issue that affects colour perception is ambient lighting. Within quite broad limits, people are able to compensate for changes in the spectral distribution of the light falling on a multi-colour surface. This effect is known as *colour constancy*. However, it can sometimes be misleading and can lead to spectacular mistakes, when witnesses in court differ in their descriptions of the colour of a car seen under sodium or mercury street lighting.

An experimental arrangement, based on a viewing booth in which the total viewing experience is both simplified and held constant, allows a person to see large blocks of colour in a standard way (➋ *Fig. 4.16*). This is necessary to obtain reliable "naming" of colours for teaching a vision system. Under carefully controlled lighting-viewing conditions, many of the complications outlined in this section can be avoided.

4.3.3 Language and Culture

Different cultures have different terms for colours. This is not simply a matter of translation; there are no equivalent words. For example, in Welsh, there is no word corresponding exactly to grey, green or blue (➋ *Fig. 4.17*). French *jaune* has a slightly different meaning from English *yellow*, although the author was taught otherwise when he was at school! The Han character 青 (*qīng* in Mandarin and *ao* in Japanese) covers both blue and green in English. Italians refer to

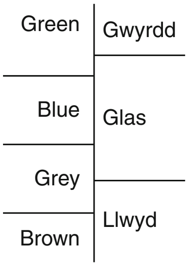

Fig. 4.17
Colour terms in English and Welsh do not correspond exactly, despite their having been in close proximity to one another for 1,400 years

the "red" of an egg, when refering to its yolk. Russian and English differ in the terms used for light blue and dark blue. In some languages, there are fewer colour terms than we are able to employ in English [10]. As a result, it is often impossible to translate a colour term exactly into another language. For example, this chapter cannot be translated exactly into Japanese, Chinese, Russian, Italian, French or Welsh! Colour terms change over time. Colour terms that have long been familiar to English speakers have been adopted in Japan only since 1945.

People working in the printing and clothing industries develop the ability to discriminate fine colour differences that are often missed by the general population. Gardeners, farmers, vetinary surgeons and doctors are all acutely aware of the importance of palour as an indicator of health in living things. Workers in steel and other hot-metal industries learn to sense the temperature of the incandescent, or molten, material from its colour. Apple Macintosh Computers are used frequently in printing, fashion and other colour-based industries. For this reason, they are provided with a non-coloured operating environment, called *Graphite*. This avoids users' colour vision being upset by gazing at vividly coloured screen displays for long periods of time.

4.3.4 Metamerism

In order to understand the processes involved in colour vision better, Colour Scientists often use mathematical notation. We shall adopt this approach to explain another interesting feature of the human vision: *metamerism*. If two surfaces appear to be similar under one set of lighting conditions but different under another, their colours are said to be *metamers*. As we shall see, metamerism is inevitable for any system, including Machine Vision, that relies on an RGB sensor. Metamerism can sometimes be beneficial in Machine Vision.

The following analysis is based on the tristimulus theory and *Grassmann's Law* [15]. The latter is essentially a statement that, over a wide range, the subjective sensation, achieved when light beams are added, can be predicted by adding their individual effects. Consider two monochromatic light beams *P* and *Q*. Suppose that a human observer chooses $[R_P,G_P,B_P]$ as the mixture of the RGB primaries that match beam P and $[R_Q,G_Q,B_Q]$ as the strengths of the primaries that match beam Q. Then, if P and Q are combined by adding them together, the matching values for the combined beam will be $[R,G,B]$ where:

$$[R, G, B] = [R_P, G_P, B_P] + [R_Q, G_Q, B_Q]$$

Consider an additive mixture of pure spectral components with wavelengths λ_1, λ_2 and λ_3, of intensities K_1, K_2 and K_3 respectively. This will excite the cones in the retina by the following amounts

$$\text{S cones} \quad S = K_1S(\lambda_1) + K_2S(\lambda_2) + K_3S(\lambda_3)$$

$$\text{M cones} \quad M = K_1M(\lambda_1) + K_2M(\lambda_2) + K_3M(\lambda_3)$$

$$\text{L cones} \quad L = K_1L(\lambda_1) + K_2L(\lambda_2) + K_3L(\lambda_3)$$

In these equations $S(\lambda)$, $M(\lambda)$ and $L(\lambda)$ are the spectral response functions of the S, M and L cones respectively (see ❯ *Fig. 4.13*). Let us now consider what happens when the eye receives light with a continuous spectral function $F(\lambda)$. This will excite the cones by the following amounts:

$$E_S = \int F(\lambda)S(\lambda)d\lambda$$

$$E_M = \int F(\lambda)M(\lambda)d\lambda$$

$$E_L = \int F(\lambda)L(\lambda)d\lambda$$

(These three integrals are computed over the range of visible wavelengths: 0.38–0.74 µm). Clearly, if $F(\lambda)$ is such that

$$E_S = S$$

$$E_M = M$$

and

$$E_L = L,$$

the spectra $F(\lambda)$ and $[K_1\delta(\lambda - \lambda_1) + K_2\delta(\lambda - \lambda_2) + K_3\delta(\lambda - \lambda_3)]$ are indistinguishable. ($\delta(.)$ is the impulse function.) If two different spectral functions $F(\lambda)$ and $G(\lambda)$ both satisfy these same conditions, they too are indistinguishable from one another and are called *metamers* (❯ *Fig. 4.18*). In addition, note that if $F(\lambda)$ and $G(\lambda)$ are metamers, so too is

$$H(\lambda) = \alpha \cdot F(\lambda) + \beta \cdot G(\lambda)$$

where α and β are scaling parameters. (This is true only if the resulting function, $H(\lambda)$, is always positive.)

Before describing the details of some of the more important colour models, we shall digress for a short while to consider metamerism in more detail. This is important in understanding human vision but, as we have already seen is an inevitable consequence of using only three different colour sensing channels.

Colour scientists studying human vision use the term metamerism in four ways, to include

- *Illuminant metamerism* which occurs when two spectra match according to an observer when using one light source, but fail to do so with another. This is often referred to simply as *metamerism*. We shall use this terminology, except where the term *metamerism* is explicitly qualified.
- *Geometric metamerism* which occurs when two surfaces match when viewed from one angle, but then fail to do so when viewed from a different angle. Geometric metamerism occurs when the spectral reflectance characteristics vary with viewing angle.
- *Observer metamerism* occurs when two spectrally dissimilar surfaces may match for one observer but fail to do so when a second observer views them under the same light source.

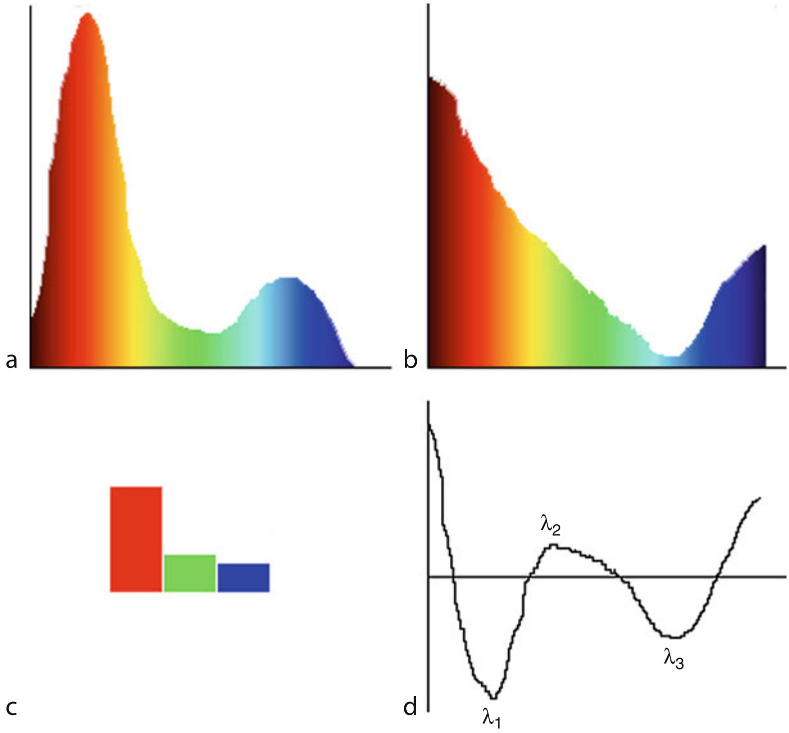

Fig. 4.18
Metamers. (a) and (b) Reflectance characteristics for two surfaces, S_1 and S_2 respectively. When S_1 and S_2 are viewed in perfect white light, the spectra of the reflected light have the same form. (c) RGB values generated by these spectra are identical. Hence, the visual sensation they create, in an observer or camera, is identical; S_1 and S_2 are metamers. (d) Differences between the spectra. By illuminating S_1 and S_2 with light having strong spectral peaks at λ_1, λ_2 or λ_3 the visual contrast is enhanced. These spectra were verified as being metamers, using a Java program [17]

This phenomenon occurs when two people have S, M and L cones in different proportions in the retina.

- *Field-size metamerism* occurs because the proportions of the three cone types varies across the retina. In the central part of the retina where there are no S cones. It is possible, therefore, for two surfaces to match when viewed from a distance but then fail to match when viewed from close up.

Metamerism is an inevitable consequence of using a small number (3) of wavelength-selective sensory channels. (Metamerism is akin to *aliasing*, caused when we fail to satisfy the Nyquist Sampling Criterion.) As a consequence, metamerism is encountered in human beings, animals and artificial vision systems. Despite the apparent crude coding for colour implicit in the tristimulus theory, healthy "normal" human beings can distinguish roughly 10^7 different colours. (This was established experimentally.) Furthermore, we are able to function very effectively as we interpret everyday colour scenes without our being continuously made aware of metamerism. However, the effect is of great significance and sometimes, of considerable benefit, when we are building colour recognition systems.

Since people normally view the world in nearly white light, they are often unaware of the presence of metamers in our everyday lives. However, when designing a Machine Vision system, it is a good idea to keep metamerism in mind. To understand how we can exploit metamerism, reconsider ➲ *Fig. 4.18*, which shows the reflectance characteristics of two metameric surfaces. Illuminating them with three monochromatic light sources of wavelength λ_1, λ_2 or λ_3, perhaps generated by carefully selected LEDs, can produce a significant improvement in contrast, compared to white light illumination.

4.3.5 Emulating Human Colour Recognition in a Machine

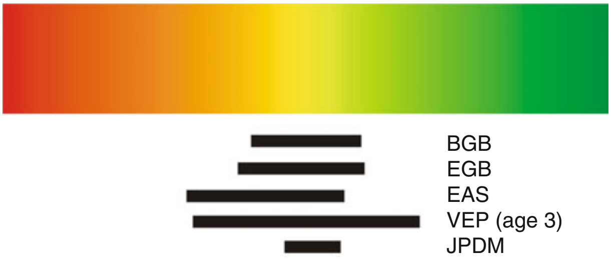
The exact meaning of "colour" is a matter that continues to vex philosophers. However, it is almost universally agreed that it is a psychophysical phenomenon that only exists within the human mind. The naming of colours is highly subjective, being dependent on experience, state of health, culture and language. My concept of colour is different from yours and yours is different from everybody else's. Even people who have lived together for many years do not always agree on the naming of colours. A French proverb implicitly acknowledges this:

- *Les Goûts et les coleurs ne se discutent pas.*
  (One should not argue about taste and colour.)

The subjective and individual nature of colour classes can be demonstrated quite easily. When people are asked to define the limits of what they perceive to be the limits of a certain colour (e.g., "yellow") on a continuous spectrum, they do not agree perfectly (➲ *Fig. 4.19*).

Given that they both have no obvious colour deficiency, no one person's definition of "yellow" is more/less valid than any other. This has significant repurcussions for building colour vision systems. Our subject is concerned with building machines that we hope can emulate a human being in associating a given set of surfaces with a particular colour name (e.g., "sulphur yellow"). We can formalise our objective in the following way.

A human teacher can separate colours into a large set of categories, *S*. On the other hand, a factory-based Machine Vision system will normally be expected to classify colours into just a few categories. (The exact number depends upon the application requirements.) Let the



■ Fig. 4.19

teacher output in response to receiving light with a certain spectrum, $\boldsymbol{X}$, be $T(\boldsymbol{X})$. Notice that $T(\boldsymbol{X}) \in S$, for all spectra $\boldsymbol{X}$ within $\boldsymbol{Y}$, the set of spectra that our vision system may reasonably be expected to experience through its working life. We would like to build a Machine Vision system that, on observing light with a spectrum $\boldsymbol{X}\in\boldsymbol{Y}$, produces an output $M(\boldsymbol{X})$, such the following equality is true.

$$M(X) = T(X)$$

We have not specified precisely how the teacher reaches his/her decision. Indeed, the *teacher* may not be a single person but may, in fact, be a committee of experts, who generate $T(\boldsymbol{X})$, perhaps on a majority-voting basis. In theory, one possible way to build a machine to recognise colours would be to show the teacher an example of light with every possible spectrum and then build a machine that simply remembers the colour labels that the teacher ascribes to each one (➋ *Fig. 4.20*). In this way, we circumvent many of the philosophical questions surrounding the concept of colour. We can do this by simply copying an expert (i.e., the teacher) whose opinion about the naming of colours is well respected and authoritative. This pragmatic engineering approach to colour vision in machines neatly avoids many of the more subtle aspects of human vision; as stated earlier, the traditional approach to Colour Science has little relevance to the design colour recognition machines for Automated Visual Inspection. Nevertheless, we need to explain some of the fundamentals of this subject.

4.4 Standards and Models

Philosophers including Aristotle, had speculated on the nature and origins of colour many centuries before Isaac Newton used a prism to separate sun-light into its spectral components (➋ *Fig. 4.21*). Nowadays, it is common practice to use a diffraction grating instead, as this is more efficient. The theory of diffraction gratings is given in [2, 16].

Decomposing light into its spectral components was a crucial step towards understanding the real nature of colour as a psycho-physical phenomenon. By using a second prism to reconstruct a single light beam, it is possible to modify the spectrum at will and thus create whatever colour we desire (➋ *Fig. 4.22*. Also see lighting-viewing method number 44,

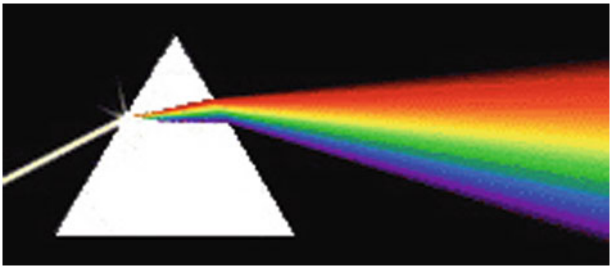

Fig. 4.21

Decomposing white light into its spectral components using a prism

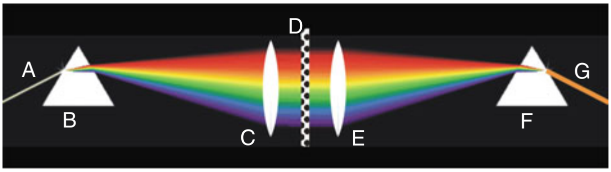

Fig. 4.22

Generating light with an arbitrary spectrum. Prism B decomposes the incident beam (A, white light). Lens C forms a set of parallel rays, which are then filtered by the transparent mask (D). Lens E refocuses the rays, which are then recombined by prism F to form a coloured emergent beam (G). The optical system is symmetrical about the mask (monochrome grey), which may be a photographic transparency or LCD spatial light modulator

Chap. 40) The physics of colour is well understood but its neurophysiological-psychological basis is not. The reason is it is not possible to measure the internal response within the human brain to a colour stimulus. Hence, we have to resort to indirect means of probing its internal working. One of the prime experimental techniques used in Colour Science is that of visually comparing a test sample to a set of standard reference surfaces. This is called *colour matching*. This section discusses both mathematical models of colour vision. These have been established in large part by colour matching experiments. In addition, we shall describe a pragmatic method of describing a given colour by visually comparing it to a set of standard reference surfaces that have previously been placed on an ordered scale.

4.4.1 Tristimulus Theory

At the beginning of the nineteenth century, Thomas Young observed that three primary colours (of either paint or light beams) could be added to create a wide variety of other colours. This led him to formulate the *Tristimulus Theory*. This postulates that any colour (C) can be obtained by mixing (adding) light from three primary sources. Let us call these P_1, P_2 and P_3. (Originally, these were taken to be red, green and blue.) Although nearly all visible colours can be matched by additive mixing, some cannot. Suppose that one of the primaries (say, P_3) is added to C and the resulting mixture can be matched by a combination of P_1 and P_2. Then, C may be considered to have a positive mixture of P_1 and P_2, and a negative amount of P_3. By allowing subtractive mixing of colours, a greater range of colours can be created. We must be careful to distinguish between superimposing coloured light beams (additive mixing) and mixing paint or other pigments (subtractive mixing). The primaries used in these two situations to create the same colour are quite different.

A *colour model* is a mathematical aid to understanding human colour vision and is usually expressed in terms of a three- or four-element vector. Colour models are inherently approximate; each one is valid only over a finite range of conditions and has its own special merits and disadvantages. In this respect, a colour model is no different from any other model of a complex physical system Most colour models were developed to assist in the production/reproduction of colour images, on paper, film or video. Ideally, a colour model should provide

- A means of describing visible light or surface colour, as a mixture of fundamental colour components, called *primary colours.*
- Clues as to how a given colour can be reproduced using physically available media: pigments, paints, inks, light sources, optical filters, phosphors.
- A framework that relates colours to each other, so that, for example, complimentary and harmonising colours can be identified. Many such frame-works are based on a geometric representation, such as a segmented wheel.
- A systematic nomenclature enabling colour information to be communicated between people who share no direct visual history. For example, it should be possible to purchase paint and wallpaper by telephone and be totally sure that they will harmonise with one another.

Thirty-seven different models are mentioned at [23], reflecting the different purposes they are intended to serve, as well as advances in knowledge. So called *Colour Order Systems* are represented within a standardised geometric framework, while surface colours are judged visually under standardised lighting and viewing conditions. We shall describe some of these below. However, many colour models are irrelevant to us, as industrial inspection systems are only expected to verify that colours that have previously been seen are correctly placed on the object being examined. This presents quite different requirements compared to reproducing colours and harmonising the parts of a multi-colour ensemble. For Machine Vision, the usual requirement is for a system that can compare the colours in two scenes and identify differences that a person would find significant. Differences in the spectral signatures of defined points on two surfaces can be measured with ease using a spectrophotometer [26]. Machine Vision demands the analysis of large areas, not single points. We are therefore constrained to using available technology, most commonly CCD/CMOS cameras that generate RGB signals.

In this section, we shall also describe how colour standards have been established, using so called colour atlases. These provide a systematic nomenclature based on a set of precisely tinted swatches, which can be matched (normally by eye) to artefacts/features of interest. Both "general purpose" and specialist colour atlases exist. The latter are intended for diverse activities, such as printing, horticulture, grading fruit, baking and dermatology, fashion, furnishing and interior decorating.

4.4.1.1 RYB Model

Historically, the RYB model is the oldest, having been established empirically by painters, long before colour scientists discovered the response characteristics of the retinal cone cells. It is based on a subtractive set of primary colours: red, yellow and blue (➜ *Fig. 4.23a*). The RYB

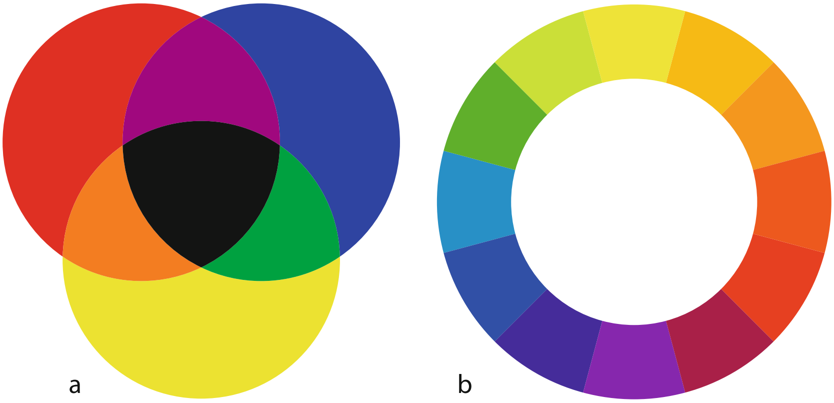

Fig. 4.23
RYB Colour Model (a) Colour subtraction, creates violet, orange and green. (b) Colour wheel

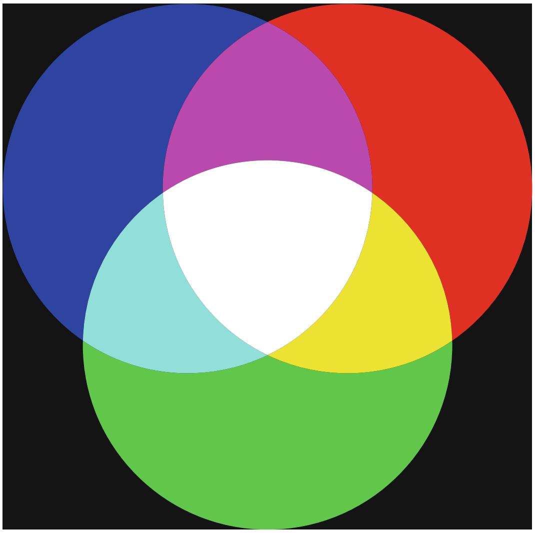
model places the primary colours and the secondary colours (violet, orange, green) around a circle, a so-called *colour wheel* (*Fig. 4.23b*). This allows complementary and harmonising pairs of colours to be identified. The RYB model is not able to reproduce bright shades of green, cyan or magenta, since these cannot be created from any combination of red, yellow, and blue paints. Furthermore, mixing a colour with its complement (i.e., the sector 180° around the RYB colour wheel), produces a shade of brown, rather than the ideal, black. As far we are concerned, the importance of the RYB model is limited to historical interest. It is still used when teaching children to paint.

4.4.1.2 RGB/sRGB

James Clerk Maxwell first devised the RGB colour model and demonstrated colour addition in an experiment conducted with Thomas Sutton The latter photographed a tartan ribbon three times, first with a red filter, then a green filter and finally a blue filter, placed in the optical path. The three images so obtained were then projected onto a white screen with three different projectors fitted with the same red, green and blue colour filters. When they were properly registered, the three monochrome images reproduced a full colour image of the tartan. Colour addition of RGB primaries is represented diagrammatically in *Fig. 4.24*.

There are several RGB colour models, based on different definitions of three primaries: "red," "green" and "blue." These can be added together in various proportions to reproduce other colours. One commonly used version is *sRGB* (*standard RGB*), which was originally devised by Hewlett-Packard and Microsoft. It has since been widely applied by companies including Intel, Pantone and Corel. sRGB defines red, green, and blue primaries in terms of the CIE xy chromaticity coordinates (see below), as follows

Red is at [0.6400, 0.3300]
Green at [0.3000, 0.6000]
Blue is at [0.1500, 0.0600]
White is at [0.3127, 0.3290]



■ Fig. 4.24
Additive mixing of RGB primaries

sRGB also defines a non-linear transformation between the numbers stored in an image and the intensities of the primaries (light beams) that are actually added together. This enables sRGB to provide the basis for efficient short-integer computation, while displaying images that are acceptable to a human observer. sRGB was designed to match the performance of CRT monitor technology as it existed in 1996. The sRGB model does not naturally fit more modern hardware, such as liquid crystal displays, digital cameras, and printers, although they incorporate compensating circuitry/software to accommodate the differences.

sRGB remains of great importance, despite the fact that it is sometimes criticised, especially by printers because it has a limited colour gamut compared to CMYK (see below). Another variant, Adobe RGB is sometimes preferred. There is one feature of the sRGB colour model that makes it very important for Machine Vision: it is ubiquitous, being the basis for a large majority of colour cameras. Even cameras that generate signals conforming to other models, such as HSI or YUV, begin by sensing RGB data. The reason for this is simple: video cameras work on the same principle as that first devised by Maxwell, using colour filters to separate the RGB channels. The overwhelming forces of finance, availability, versatility and familiarity combine to make RGB the dominant colour model for Machine Vision. The RGB model is the nearest we currently have to one based on direct measurement of the spectrum. Conceptually, it is attractive because it provides a direct analogue of the colour sensing achieved by retinal cone cells. Moreover, other models, including HSI and YUV, can be related directly to the RGB model.

4.4.1.3 CMYK

CMYK (cyan, magenta, yellow, black) is a subtractive colour model. Its great importance arises from the fact that it is used extensively in colour printing. Magenta plus yellow produces red, magenta plus cyan makes blue and cyan plus yellow generates green. Theoretically, a mixture of

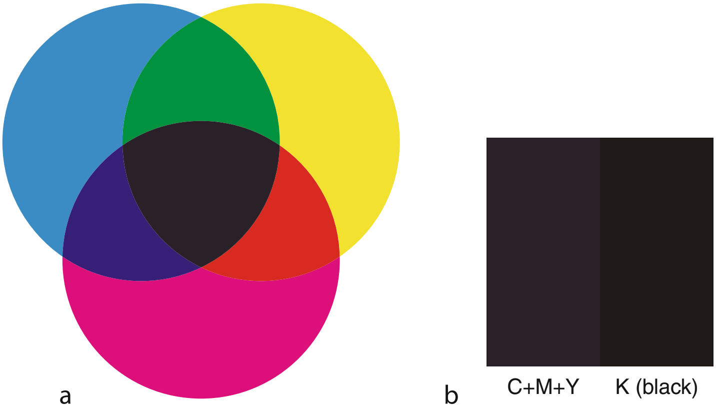


Fig. 4.25
CMYK (a) CMY colour subtraction. (b) Comparison of "black" produced by CMY and K. A "rich black" is sometimes produced by imprinting all four of the CMYK channels

ideal cyan, magenta, yellow pigments, printed together on white paper, would result produce black. However, in practice, the colour generated by mixing the CMY primaries is not ideal, being dark murky brown, rather than black. Using four-colour (CMYK) printing generates a better result with high contrast (➋ *Fig. 4.25*). To obtain really high quality images, orange and green imprints are added, requiring a six-stage printing process designated as CMYKOG. Hexachrome® (Pantone Corporation) was created in 1994 to provide a wider colour gamut for the printing industry and is claimed to provide brighter greens, more vibrant purples, and more accurate rendering of skin tones.

When printing computer-generated (RGB) images, they must be converted to CMYK format first. This process is imperfect, because CMYK and RGB have different gamuts. It is possible to produce an invertible conversion from RGB to a subset of CMYK, although conversion in the reverse direction is not always possible. It is a common experience to see quite different colours on a computer screen and on a paper print-out. Pseudo-code for converting between RGB, CMYK and a variety of other colour models is given at [13].

4.4.1.4 HSI (Hue, Saturation, Intensity)

Consider the RGB colour space, assuming that each of the RGB variables is limited to the same range: [0,W] (➋ *Fig. 4.26*). This defines a cube of side W in which

White is [W,W,W];	Black is [0,0,0]	
Pure red is [W,0,0];	Pure green is [0,W,0];	Pure blue is [0,0,W]
Pure cyan is [0,W,W];	Pure magenta is [W,0,W];	Pure yellow is [W,W,0].

Notice that we have emphasised that these are pure colours. Points close to [W,W,0], such as [0.95 W, 0.95 W,0.05 W], would probably be called "yellow" too. The plane defined by the points [W,0,0], [0,W,0], [0,0,W] intersects this cube to produce a triangle, called the *Colour Triangle*, or *Maxwell Triangle*. The point P is at the intersection of the vector [R,G,B] and the

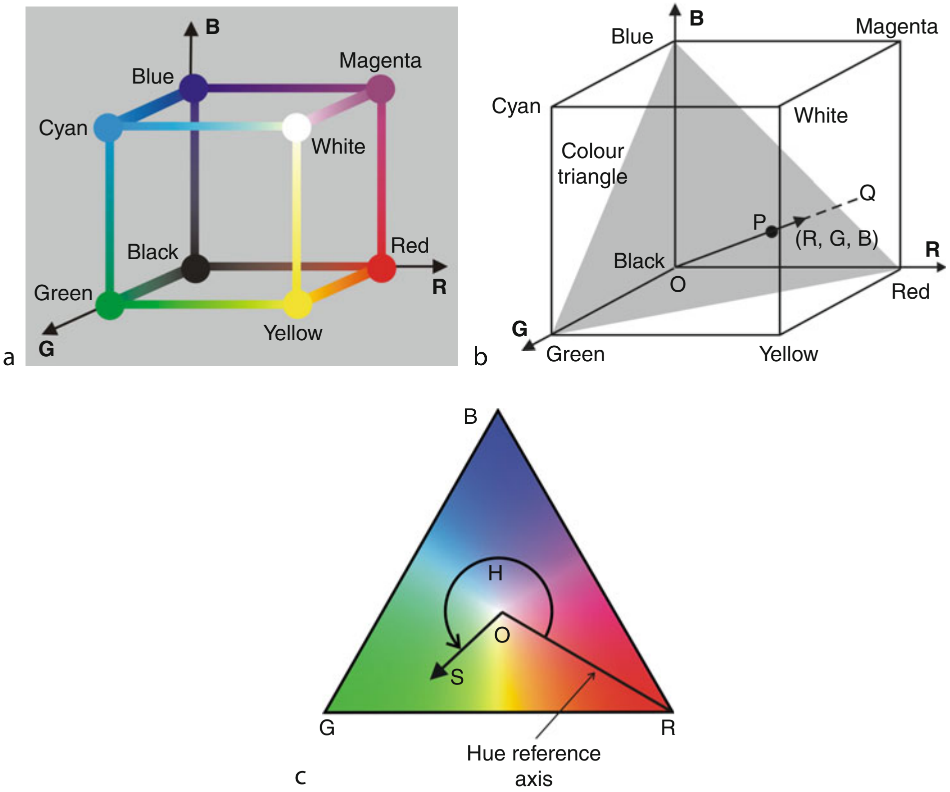

Fig. 4.26

The colour cube in RGB space and the Colour triangle. (a) Colour cube. (b) Relationship between RGB space and the colour triangle. (c) The colour triangle represents hue (H) and saturation (S) but not intensity (Colours are approximate)

Colour Triangle. This line is extended if necessary. Q is the point of intersection of that vector and the external surface of the cube. P can lie on any one of three faces, defined by the equations

$$R = W; \quad G = W; \quad B = W.$$

Apart from points very close to the origin, O, where scotopic (low light) vision prevails, all points along the line OQ have the same chromaticity (i.e., the same hue and saturation) but with different intensities. That is, they are perceived as being the same colour. The orientation of the line OQ can be determined by two angles, not shown, or the position of the point P in the colour triangle. Within the Colour Triangle, the chromaticity can be defined using polar coordinates (*H* and *S*) or Cartesian coordinates.

Conversion between HSI and RGB is invertible using the following transformations:

$$H = \cos^{-1}\left((2R - G - B)/\left(2\sqrt{\left(R^2 + G^2 + B^2 - GB - BR - RG\right)}\right)\right)$$

$$S = 1 - 3\mathrm{MIN}(R, G, B)/(R + G + B)$$

$$I = (R + G + B)/3.$$

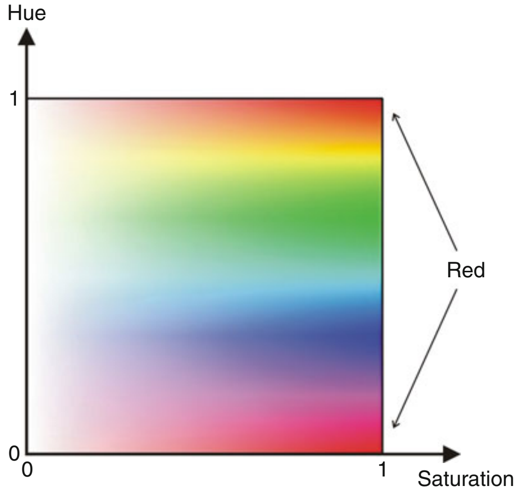

Fig. 4.27
HS plane rendered in colour. Notice that "*red*" is split into two distinct regions (Colours shown are approximate)

Later, we shall find it convenient to plot HS using Cartesian coordinates (➋ *Fig. 4.27*). This merely represents a geometric warping of the Colour Triangle.

4.4.2 CIE 1931 Colour Model

The CIE Colour Model [3] was one of the first mathematically defined colour models. It has been up-dated since its inception to accommodate new thinking and knowledge. It forms the basis upon which many other colour models have subsequently been defined. However, it remains of great importance in its own right, because it is based on direct measurement of the human visual system. The CIE XYZ Colour Model was derived from experiments performed in the late 1920s by W. D. Wright and J. Guild and is based firmly on the tristimulus theory. The CIE 1931 Chromaticity Diagram is central to understanding this colour model (➋ *Fig. 4.28*).

Despite the ubiquitous appearance of this diagram in text-books on photography, video and Colour Science, its conceptual and experimental basis is often not explained clearly. As a result, it is frequently misunderstood and mis-used. The model is based on the assumption that there are three separate colour channels in the human visual system and that their responses to a given colour input, *C*, are values that we shall denote by *X*, *Y* and *Z*. These parameters are actually the amounts of monochromatic light at wavelengths of 0.7000 μm, 0.5461 μm, and 0.4358 μm that are needed to match *C*. Notice that *X*, *Y* and *Z* correspond to specific instances of red, green and blue, respectively. The spectral responses of these hypothesised colour channels are shown in ➋ *Fig. 4.13* and are closely related to the responses of the L, M and S cones in the eye. In order to normalise for varying intensity, it is sensible to define three new variables thus:

$$x = X/(X + Y + Z)$$

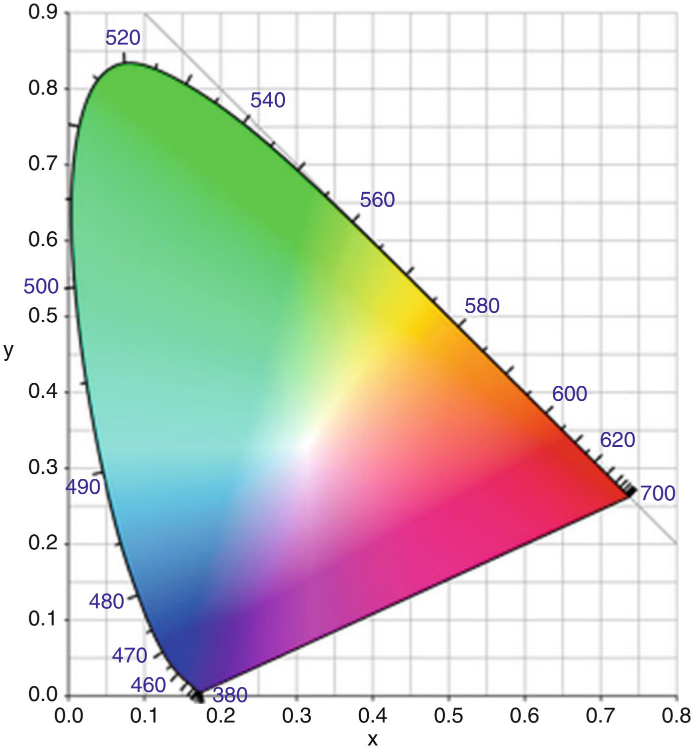

Fig. 4.28
CIE (1931) Chromaticity diagram. This represents the full range of colours that can be seen by a human being. The colours shown here are approximate as the range of visible hues that can be represented in printing (gamut) is smaller than the diagram requires. The numbers around the edge indicate the wavelengths of the spectral colours, measured in nanometres. The x and y axes are explained in the text

$$y = Y/(X + Y + Z)$$

$$z = Z/(X + Y + Z)$$

Since

$$x + y + z = 1$$

we need only specify two of these numbers in order to calculate the third one. The famous CIE Chromaticity Diagram (➋ *Fig. 4.28*) has an inverted U-shaped arc, which is the locus of [x, y] values that match the pure spectral colours. (Numbers around this arc indicate the wavelength.)

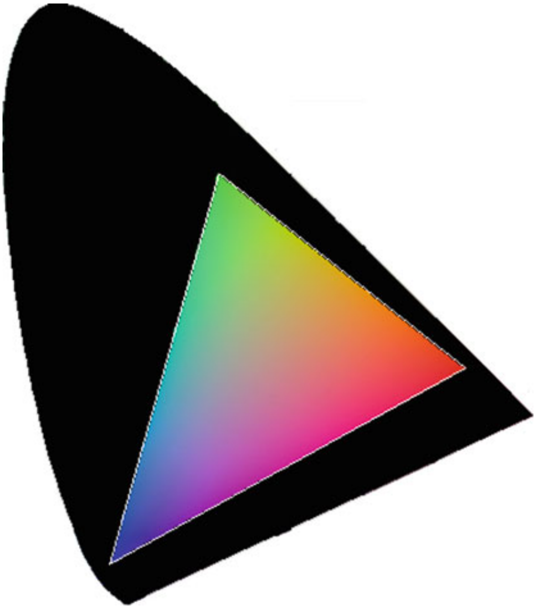
- The straight line across the bottom of the inverted U is called the *Line of purples*. It represents the non-spectral colours that can be obtained by mixing red and blue light. Despite its representation in the diagram, the line of purples is not a hard limit and should properly be drawn as having a fuzzy boundary.

- Colours on the periphery of the locus are saturated; colours become progressively desaturated and tend towards white near the middle of the plot. The point at

  $$x = y = z = 0.333$$

  represents white.
- Suppose we choose three points within the shaded region, to define three primaries. Any colour within this triangle can be created by adding various proportions of those primaries. The range of colours that can be reproduced in this way is called the gamut.
- The gamut of colours that can be reproduced on a video monitor, or by photography, is often defined by drawing a triangle in the CIE Chromaticity Diagram. See, for example, ➲ *Fig. 4.29*.
- The 1931 CIE chromaticity diagram is not *perceptually uniform*. That is to say the *area* of any region of the plot does not correlate at all well with the number of perceptually-distinguishable colours in that region. In particular, the vast area of green-turquoise inaccessible to televisions and monitors is not quite as serious as it appears.

Since it is so important, the CIE Chromaticity Diagram has often been attributed with meaning that was not intended when it was first introduced. One potentially misleading use has been the addition of spots to indicate colours of familiar objects, such as lettuce, tomato, etc. By measuring one point, on one tomato, on one particular day, a set of XYZ coordinates was found and a point labelled “tomato” was added to the diagram. This was intended, quite correctly, to assist people to understand the diagram. The danger is that it can be



■ Fig. 4.29
Gamut for a computer/television display; colours in the black region cannot be displayed properly

misinterpreted as meaning that the colour set with the name *"tomato"* can be identified with a point. It cannot! *"Tomato"* is a set and should therefore be represented on the CIE Chromaticity Diagram as a blob. If this convention were to be adopted, we could, in theory, use membership of that set of points as a basis for colour recognition. As this would not lead to a very efficient recognition procedure, we shall seek other methods for doing this.

4.5 CIE L*a*b* (CIELAB)

This is one of the most complete colour models yet devised. It was developed for by the CIE (*Commission Internationale d'Eclairage)* in an attempt to describe all of the colours visible to the human eye. Notice that $L^*a^*b^*$ and *Lab* are two different colour models; the asterisks indicate the fact that the parameters L^*, a^* and b^* are derived from parameters derived for the earlier model and denoted by *L, a* and *b* [19]. These are, in turn, based on a mathematical approximation to the Munsell colour ordering system (see below), which was devised empirically after detailed colour matching experiments.

L* measures lightness between black (L* = 0) and white (L* = 100)
a* indicates position on the magenta – green continuum ($a^* < 0$ indicates green; $a^* > 0$ indicates magenta)
b* indicates position on the yellow – blue continuum ($b^* < 0$ indicates blue; $a^* > 0$ indicates yellow)

Since it purports to represent all colours perceived by human beings, the full gamut of colours allowed by the $L^*a^*b^*$ model cannot be represented perfectly accurately, either on paper or a video display. It can only be represented properly in a three dimensional space. However, since L^* measures lightness, just a few a^*b^* plane slices allow the whole gamut to be represented reasonably satisfactorily.

The $L^*a^*b^*$ colour model was devised specifically to serve as a device independent, absolute reference. It is one of the most important models for Colour Science but it does not provide us with any practical help in building industrial inspection systems.

4.6 YUV/YIQ

The YUV model is used to define the PAL and NTSC television broadcasting standards, which are both widely used throughout the world. YUV defines a colour space with one luminance (brightness Y) and two chrominance components (U and V). These can be calculated from the RGB parameters using the following equations:

$$\mathrm{Y} = 0.299\mathrm{R} + 0.587\mathrm{G} + 0.114\mathrm{B}$$

$$\mathrm{U} = 0.492(\mathrm{B} - \mathrm{Y}) = -0.147\mathrm{R} - 0.289\mathrm{G} + 0.436\mathrm{B}$$

$$\mathrm{V} = 0.877(\mathrm{R} - \mathrm{Y}) = 0.615\mathrm{R} - 0.515\mathrm{G} - 0.100\mathrm{B}$$

where, R, G and B are assumed to be in the range [0,1]. Another standard, YIQ, is closely related to YUV and can be calculated thus:

$$Y = 0.299R + 0.587G + 0.114B (\text{i.e., same as for } YUV)$$

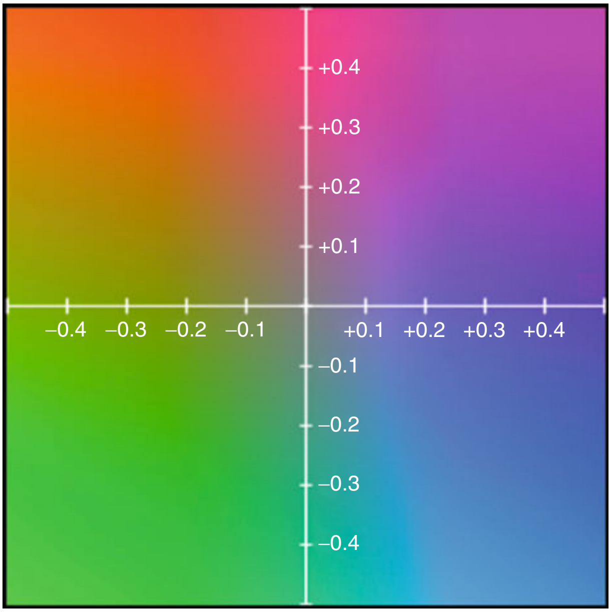


Fig. 4.30
UV colour space. (In this context UV does *not* refer to ultra-violet.) Abscissa, U. Ordinate, V. IQ colour space is similar but the coordinate axes are rotated counter-clockwise by 33°

$$I = 0.735514(R - Y) - 0.267962(B - Y) = 0.595716R - 0.274453G - 0.321263B$$

$$Q = 0.477648(R - Y) + 0.412626(B - Y) = 0.211456R - 0.522591G + 0.311135B$$

The importance of YIQ has diminished in recent years as it was formerly used to define the NTSC television standard, which is now based on the YUV model. YUV and YIQ are compatible with black and white analogue systems. (UV/IQ are simply discarded.) The calculations given above can be performed in real time, using low cost analogue or digital hardware. IQ and UV represent different coordinate systems in the same plane (➋ *Fig. 4.30*).

YUV and YIQ do not define absolute colour spaces. Notice that the actual colour generated depends on the RGB colourants used to display the image. That is, the colour generated by given values of YUV, or YIQ, is only predictable if known RGB colourants are used in the display hardware. Of particular importance for us in building colour recognition systems is the fact that any two sets that are separable in either YUV or YIQ space are also separable in RGB space.

4.7 Munsell Colour Standard

The Munsell System is widely recognised as providing a standard for colour notation. It is used throughout the world in painting, printing, advertising, commerce, manufacturing, science and education. It provides a means for selecting, specifying, and controlling colour. The Munsell System is recognised as a standard system of colour specification in Standard Z138.2

of the American National Standards Institute; Japanese Industrial Standard for Colour, JIS Z 8721; the German Standard Colour System, DIN 6164; and several British national standards.

In the Munsell System, every colour is represented by three numeric quantities: *hue (H)*, *value (V)* and *chroma (C)*. At the beginning of the twentieth century, A. H. Munsell first produced numerical scales, with visually uniform steps, for each of these attributes. The *Munsell Book of Colour* [21, 28] displays an ordered collection of coloured swatches, each of which is identified numerically by a three-element vector [H,V,C]. It is used in a very simple way: the colour of a surface can be identified by visually matching it to the swatches. Illumination and viewing conditions are closely controlled during the matching process. Proprietary viewing booths are available for this purpose (➔ *Fig. 4.16*) [14].

Hue is that attribute of a colour by which we normally attribute names, such as red, yellow, green, blue, purple. Munsell exploited the fact that there is a natural order of hues. We can mix paints of adjacent colours in the series just mentioned to obtain intermediate colours. For example, red and yellow light may be mixed in varying proportions to generate all of the hues on the red-orange-yellow continuum. Similarly, we can obtain intermediate colours by mixing yellow and green, green and blue, blue and purple, or purple and red. Notice that the sequence is cyclic. Hence, it is natural to arrange these colours around a circle. Munsell termed red, yellow, green, blue, and purple the *principal hues* and therefore placed them at equal intervals around the circle. He then interposed the five intermediate hues: yellow-red, green-yellow, blue-green, purple-blue and red-purple between them. Hence, the Hue circle has a total of making ten hues (➔ *Fig. 4.31*).

Munsell arbitrarily sub-divided the hue circle into 100 steps of equal visual change. Zero is referred to the edge of the red sector. Hence, *hue* can be represented by an integer in the range [0, 99]. An alternative representation uses a letter (sector name) followed by an integer

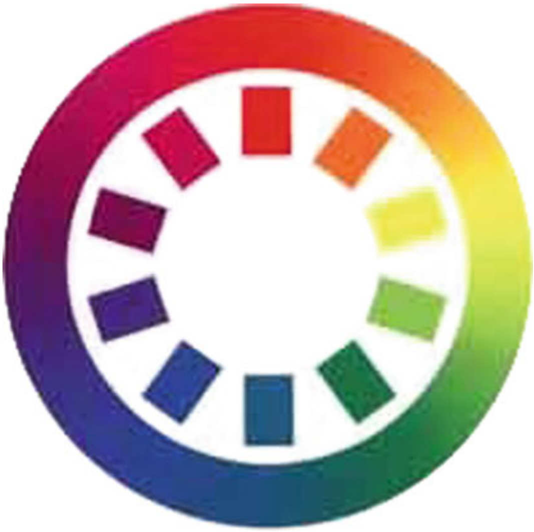

Fig. 4.31
The Hue circle

(position within the sector). The hue in the middle of the red sector is called *five red (5R)*. Hence orange is 5YR and 8BG is blue-green (blue turquoise) (see *Fig. 4.32*).

Minor adjustments in the nomenclature for hue have been introduced to compensate for an anomaly that exists in the blue region of the Munsell System. Awkward features like this are not unusual in Colour Science; as we indicated earlier, no colour model yet devised perfectly matches human vision.

Value indicates the lightness of a surface. Zero (0) represents pure black and 10 pure white. Achromatice colours (or “neutral” colours: black, white and grey) have zero hue. The term *chromatic colours* refers to colours where the hue (H) is not zero. The value scale applies to both chromatic and achromatic colours. The value scale is illustrated for a series of neutral colours in *Fig. 4.33*.

Chroma measures the strength of a colour in terms of the degree of departure from that achromatic colour with the same value. Colours with high chroma are termed *highly saturated*,

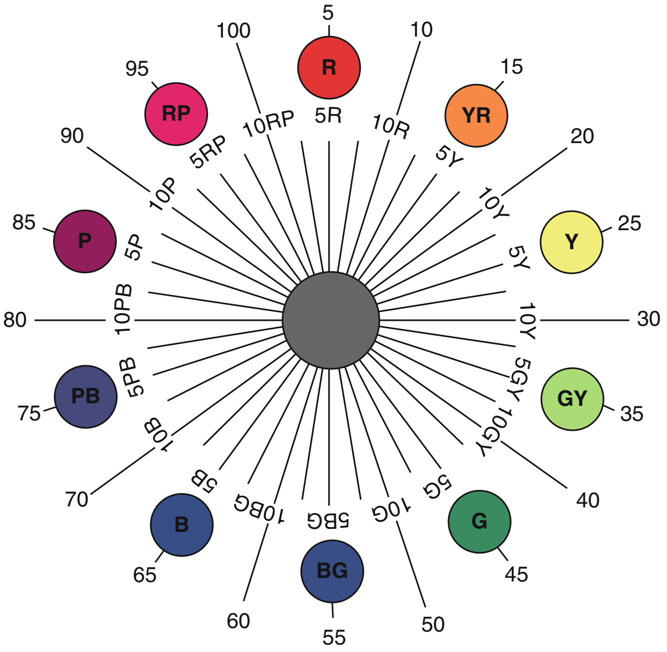

Fig. 4.32
Munsell Hue designations

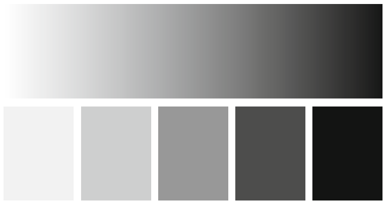

Fig. 4.33
Munsell value parameter, achromatic colours

or *vivid*. To understand the nature of chroma, imagine mixing yellow and grey paints that have the same value. Starting with pure grey and gradually adding more yellow until saturated yellow is achieved, the chroma of the paint mixture increases progressively (➋ *Fig. 4.34*).

The chroma scale was designed to be visually uniform, although the units are arbitrary. Achromatic colours have zero chroma but there is no arbitrary maximum. As new pigments have been manufactured, Munsell colour swatches with higher chroma have been made.

4.7.1 Munsell Notation

The complete Munsell notation is written as follows:

- *hue value/chroma*

Saturated red with a hue of 5R, a value of 6 and a chroma of 14, is represented as 5R 6/14. When greater precision is needed, decimal parameters are used (e.g., 5.1R 5.2/12.9.) The Munsell colour parameters (hue, value and chroma) are often presented graphically using cylindrical coordinates (➋ *Fig. 4.35*). Hue is a cyclic parameter and is therefore equated with

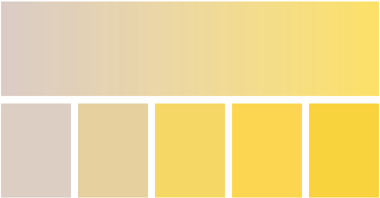

Fig. 4.34
Varying chroma

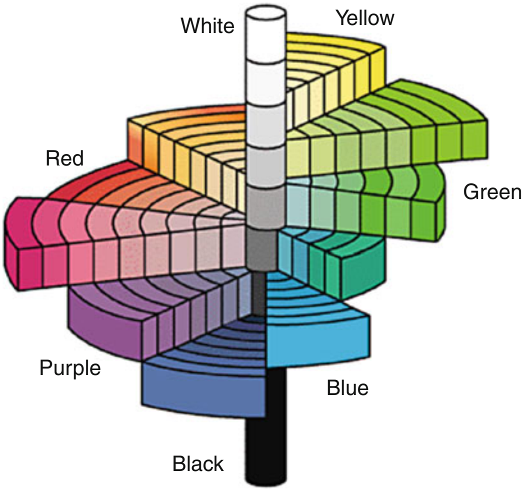

Fig. 4.35
Munsell colour solid

angular position. Chroma is measured by the radius from the central axis, which represents the value scale. This leads to the *Munsell Colour Solid.* This is not a perfect cylinder, since the scales are not defined on an absolute scale. Moreover, the model is modified to include only those pigments for which a swatch can be made. As a result, the Munsell colour solid is irregularly shaped figure that is enlarged from time to time, as new pigments are developed.

4.7.2 Colour Matching

The apparent colour of a surface depends on the spectrum and polarisation of the illumination, the directions of illumination and viewing, the reflection, polarisation and scattering characteristics of that surface, its surrounding area/background and the state of adaptation of the eyes of the observer. To ensure precise colour matching, it is standard practice to view specimens illuminated by daylight from a lightly overcast northern sky in the northern hemisphere. An artificial source that produces light with a very similar spectrum may be used instead. (Lamps providing an approximation to daylight have been available for photographers and television program makers for many years.) Viewing booths that employ controlled artificial daylight and are normally recommended for colour matching because the lighting conditions that they produce are much more consistent over the working day than natural light. To reduce the effects of glinting to a minimum, the surface to be examined should be viewed along its normal and illuminated at 45° to the normal. Before a person is allowed to match colours, he/she should be tested to detect obvious colour deficiencies. (These are quite common, occurring at a rate of about 5% for men and 2% for women.) Among normal observers, the ability to match colours varies significantly and gradually diminishes with age. In this area of Colour Science, it is not possible to guarantee precise measurements, because subjective judgements are involved. Colour swatches are available with matt and glossy surfaces in the Munsell System.

4.7.3 Pantone® Colour Reference System

The Pantone Matching System® is used very extensively in the printing industry. It is used by artists and commercial printers to select, specify and match colours. Given a colour sample, visual matching, against a large set of standard swatches, allows the ink formulation that will reproduce it to be identified. Numerous company and other organisation logos are created with specific reference to the Pantone system. It originally included about 500 colours and has since been expanded to include over 3,000 colours, together with their CMYK ink formulations. Recently, Pantone Inc. introduced a six-colour printing system called Hexachrome®, which includes cyan, magenta, yellow, black, orange and green inks. This substantially increases the colour gamut for reproducing printed photographic images and simulated spot colours. The Pantone system also includes many special colours to be specified, including metallic finish and florescent paints/inks. Recently, the Pantone system has also been linked to screen-based colours (RGB). It has also been used to specify the colours used in flags and company logos. The Union Jack (flag of the United Kingdom) contains PMS186(red) and PMS280 (blue), while the BP logo consists of elements with colours PMS355 (dark green), 368 (light green) and yellow (109 coated, or 108 uncoated). Knowing the Pantone index numbers enables a person to order paints or inks to reproduce their colours accurately.

The Pantone Matching System is the intellectual property of Pantone Inc. [24]. Since it is a proprietary system, PMS lacks the transparency that the Munsell system enjoys. This is frequently cited as a reason why Pantone colours are not supported in open source software, such as GIMP, and are not often found in low-cost software. The Pantone company asserts that its collection of colour swatches is a database that could be copyrighted. However, Pantone palettes supplied by other companies, such as paint and printer manufacturers, are freely distributed, without undue restriction as to their use. The Pantone Matching System is intended specifically for the print industry, whereas the Munsell system is more appropriate for other, more general applications. For example, to specify the range of colours that might be expected on a manufactured food product, the Munsell system would normally be preferred. However, to print a photograph of it, the Pantone system would be used. The Munsell system has been matched, as far as is possible, to mathematically based colour models, such as $L^*a^*b^*$.

4.7.4 Colour Gamut

The following notes indicate the sizes of gamuts for a number of colour systems

- *Photographic film* This is one of the best systems for reproducing colour as it has a large gamut. It far exceeds the gamut for television.
- *Laser light projectors* produce images containing just a few nearly monochromatic components, which are therefore highly saturated. However, it is more difficult to generate less saturated colours.
- *CRT video displays* have a gamut that covers a significant portion of the visible colour space. The gamut is limited by the phosphors built into the display screen. In practice, the video sensor also has a limiting effect, as it is the intersection of the gamut of the camera and that of the monitor that determines the gamut of a complete camera-display system.
- *Liquid crystal display (LCD) screens* filter the light emitted by a backlight. Hence, the gamut of an LCD display based on fluorescent tube back-lighting is smaller than that for a CRT screen, while one using LED back-lighting has a larger gamut.
- *Broadcast television* using a CRT display has a gamut limited by transmission coding, rather than the screen. High definition television (HDTV) is better, but the gamut is still less than that for a computer display employing the same display screen.
- *Paint* can produce some highly saturated colours. Artists have long exploited the huge range of pigments available from animal, plant and mineral sources. More recently, synthetic dyes have been used. Paints are available with highly saturated colours that cannot be generated by video displays. Paint colours for industrial and commercial applications are often specified with reference to the Pantone® Matching System [24].
- *Spot Colour Printing* refers to a process in which each colour is created by a different ink. It is most cost-effective when there are only three or different colours, or when special-purpose inks (e.g., UV reflective, fluorescent, photo-chromic, chemically sensitive, etc.) are required. The same remarks apply here as for paint.
- *Process Colour Printing* is used for “general purpose” image reproduction in newspapers, books, magazines, etc. and usually relies on CMYK, CMY or CMYKOG imprints. The gamut for CMYK printing is smaller than that for a video monitor.

A Java program for calculating display gamuts is on-line available at [4].

5.1 Basic Concepts

The image acquisition sub-system is responsible for collecting information in optical form about the scene that is to be examined and then projecting it onto the image sensor (the camera's "retina"). It is important that the very best image possible is presented to the camera; lack of attention to the design of the optical "front end" is tantamount to throwing away information and/or introducing noise into the system deliberately. The well-worn adage "*Rubbish in, rubbish out*" is worth remembering. It is also worthwhile bearing in mind that, once an effective optical system has been set up, good quality images will be produced indefinitely without further expense (apart from minimal costs for regular cleaning of optical components). In many cases, complicated digital processing may be avoided altogether. Good optical design will very often make the overall system faster, cheaper and more reliable.

5.1.1 Image Acquisition Sub-System

➋ *Figure 5.1* shows how information flows in the optical "front end" of a typical Machine Vision system; information is carried via electro-magnetic radiation in the visible wave band

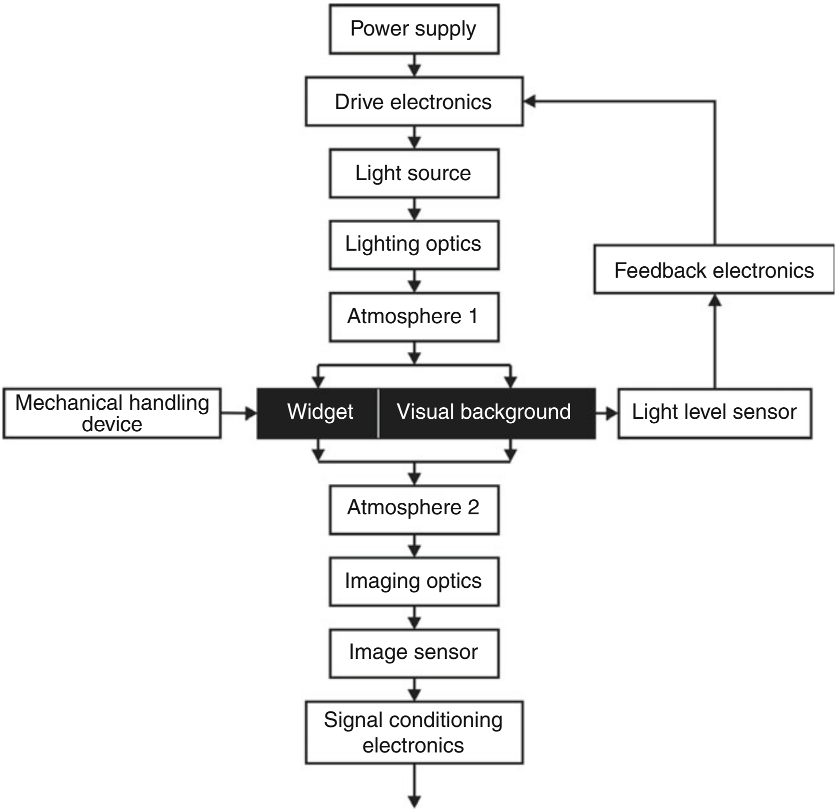

Fig. 5.1
Information flow in the image acquisition sub-system of a Machine Vision system

(roughly 0.36–0.74 μm). Occasionally, we may use the ultra-violet, infra-red, or x-ray regions of the spectrum instead. An imaging sub-system may include a variety of components: lenses, filters, mirrors, prisms, polarisers, gratings, apertures, fibre optics, beam-splitters, diffusers, protective windows, light absorbing backgrounds and shrouding. This diagram also indicates that the image presented to the image sensor (the camera) is affected by a series of what might be regarded as secondary factors: the power supplied to the lamps, the means of presenting the widget for inspection, and the atmosphere in the relevant part of the factory. If we do not control each of these properly, the quality of the image reaching the camera will be degraded, possibly seriously. In fact, these "secondary" factors are all critical for success and we neglect them at our peril. We concentrate in this chapter on imaging optics. The other "primary" topics (i.e. illumination sources, lighting-viewing methods and image sensors) are covered elsewhere (➋ Chaps. 7 and ➋ 40).

5.1.2 Waves, Particles and Rays

Physicists conventionally represent light, in one of three ways:

(a) Waves
(b) Particles
(c) Rays

For almost all purposes in Machine Vision, the ray model is perfectly adequate. Occasionally, we must take into account the wave nature of light, so that we can understand interference effects caused by very small obstacles/apertures. (This is not necessary if we are only considering the colour of large objects, even though we frequently use the term wavelength.) The concept of light travelling in finite packets (photons) is hardly ever of significant interest when considering vision, whether it be in an animal, human being or machine. The reason is that so many photons are required for vision that we may conveniently measure light levels as analogue, rather than digital quantities. A light ray is merely a convenient mental model that we can use when designing normal (i.e. non-coherent) optical systems. We can also make several simplifying assumptions:

- In an homogenous medium (e.g. air, glass, water), light travels in a straight line.
- Light effectively travels with zero delay from one end of an optical system to the other. The system is small enough to allow us to ignore the fact that the speed of light is finite.
- Each ray can be characterised by two numbers:
  - Wavelength, which determines the sensation of colour that a person will perceive when that ray enters his/her eye.
  - Intensity, which determines how bright that ray will appear when it is viewed by a human being.

A ray has zero width. A "bundle" of rays travelling in the same general direction is called a *beam.*

This simple model is not unduly restrictive and is very convenient for out purposes. For example, it is possible to represent a very narrow beam with a complicated spectrum as a collection of rays superimposed upon one another and with different wavelengths.

There is one more parameter that a ray may have: *polarisation.* This does not alter its perception by either the eye, or a camera, but it does affect the way that a ray behaves when it

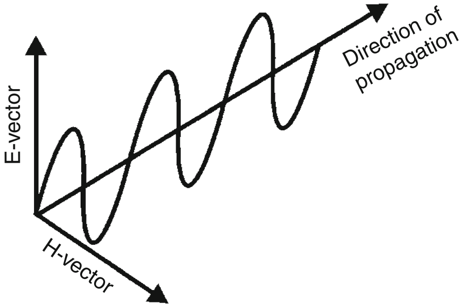

Fig. 5.2
The polarisation of light is described by referring to the E-vector (electric-field vector). The magnetic field vector (H-vector) is orthogonal to both the E-vector and the direction of propagation but is not normally considered when designing optical systems. The sinusoidal graph represents the variation of the electric field in space at a given moment. The magnetic field (not shown) also has a sinusoidal form and is 90° out of phase with the electric field. As time progresses, these two graphs move along the axis labelled "direction of propagation"

strikes a surface. Polarisation is determined by the orientation of the E-vector, which located in the plane orthogonal to the direction of travel (➋ *Fig. 5.2*). Light from an incandescent filament lamp, fluorescent tube or LED contains rays with no preference for the angle of polarisation. However, after specular reflection from a dielectric surface, or transmission through a polarising device, the emergent rays will almost all be polarised with their E-vectors orientated in the same direction. (Rays with their E-vectors in the orthogonal direction are attenuated, not rotated.)

There are six major physical effects that affect the behaviour of optical components:

(a) Absorption. (This leads to olive oil being coloured yellow, emeralds being green, etc.)
(b) Reflection (This property is exploited in making mirrors.)
(c) Scattering (This is caused when light strikes tiny particles suspended in a clear medium such as glass, water or air. Fog and milk are prime examples of light scattering media.)
(d) Diffraction (This effect is responsible for the colouration of beetles' wings and is exploited in optical gratings.)
(e) Refraction (This property is exploited in lenses and prisms.)
(f) Polarisation (Polarisation of light, either occurring naturally due to the nature of the object being viewed or deliberately introduced into the optical system, can often be used to good effect.)

5.1.3 Absorption, Transmittance, and Optical Density

5.1.3.1 Absorption

All materials absorb radiation in some parts of the electromagnetic spectrum. The amount of absorption depends on the wavelength, the amount of absorbing material in the radiation path, and the absorption of that material at that wavelength. Materials that absorb some visible wavelengths appear coloured. For purposes of this chapter, the term coloured glass also refers to material that is a wavelength-selective absorber in the near-ultraviolet to the near-infrared region.

Absorption occurs when the electric field of a light wave interacts with absorbing atoms or molecules that form an oscillating dipole. The photon is absorbed and the atom or molecule is placed in an excited state. This process occurs only at resonant wavelengths, which alters the spectrum of the light emitted from that material. In a solid or liquid absorber, excitation energy is dissipated as heat (vibrations of particles). Therefore, filters that rely mainly on absorption are not ideal for high-power laser applications. The intense local heating can lead to structural damage.

5.1.3.2 Transmittance

As a beam of light passes through an absorbing medium, the amount of light absorbed is proportional to the intensity of incident light times the absorption coefficient. Consequently, the intensity of an incident beam drops exponentially as it passes through the absorber. This is often expressed as *Beer's law*:

$$T_{\mathrm{i}} = 10^{-\alpha c x} \tag{5.1}$$

where T_{i} is internal transmittance, α is the absorption coefficient, c is the concentration of absorbers, and x is the overall thickness of the absorbing medium. Clearly α, and T_{i} are wavelength dependent. For solid absorbing mediums, $c = 1$.

Internal transmittance is the transmittance of an optical element when surface (coated or uncoated) losses are ignored. The measured transmittance of the element (including surface effects), transmittance, is called external transmittance, T.

Alternatively, a filter is defined by the amount of light it blocks, as opposed to the amount of light it transmits. This parameter is opacity, which is simply the reciprocal of the transmittance, $1/T$.

The transmittance of a series of filters is the product of their individual external transmittance, $T_1 \times T_2 \times T_3$, etc. Because transmittance (and hence opacity) is multiplicative, and since transmittance may extend over many orders of magnitude, it is often more convenient to use a logarithmic expression to define transmittance.

5.1.3.3 Optical Density

Optical Density (or *density*) is the base-10 logarithm of opacity:

$$D = \log(1/T). \tag{5.2}$$

As optical density increases, the amount of light blocked by the filter (by reflection and/or absorption) increases. The most important point to note is that optical density is additive. If several filters are stacked in series, their combined optical density is the sum of the individual optical densities.

Optical density is particularly useful for neutral-density (ND) filters. These filters, which have a very flat wavelength response, are used to attenuate light in a calibrated, chromatically invariant fashion. In this catalogue, ND filters are supplied in sets of various calibrated densities. Combinations of these filters can be used to produce many different calibrated optical densities.

5.1.4 Reflection of Light

5.1.4.1 Reflections at Uncoated Surfaces

Whenever light is incident on the boundary between two media, some light is reflected and some is transmitted (undergoing refraction) into the second medium. Several physical laws govern the direction, phase, and relative amplitude of the reflected light. For our purposes, it is necessary to consider only polished optical surfaces. Diffuse reflections from rough surfaces are not considered in this discussion. The law of reflection states that the angle of incidence (θ_1) equals the angle of reflection (θ_r). This is illustrated in ➲ *Fig. 5.3*, which shows reflection of a light ray at a simple air/glass interface. The incident and reflected rays make an equal angle with respect to the axis perpendicular to the interface between the two media.

5.1.4.2 Intensity

At a simple interface between two dielectric materials, the amplitude of reflected light is a function of the ratio of the refractive index of the two materials, the polarization of the incident

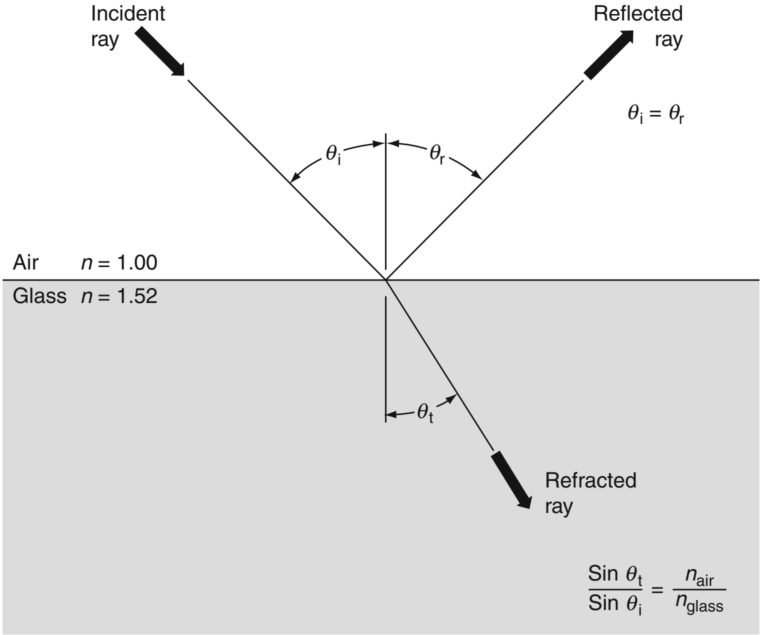

Fig. 5.3
Reflection and refraction at a simple air-glass interface

light, and the angle of incidence. When a beam of light is incident on a plane surface at normal incidence, the relative amplitude of the reflected light, as a proportion of the incident light, is given by

$$\frac{(1-p)}{(1+p)} \tag{5.3}$$

where p is the ratio of the refractive indexes of the two materials ($n1/n2$). Intensity is the square of this expression. The greater the disparity between the two refractive indexes, the greater the reflection. For an air/glass interface, with glass having a refractive index of 1.5, the intensity of the reflected light will be 4% of the incident light. For an optical system containing ten such surfaces, the transmitted beam will be attenuated to approximately 66% of the incident beam due to reflection losses alone, emphasizing the importance of antireflection coatings to system performance.

5.1.4.3 Incidence Angle

The intensity of reflected and transmitted beams at a surface is also a function of the angle of incidence. Because of refraction effects, it is necessary to differentiate between external reflections, where the incident beam originates in the medium with a lower refractive index (e.g., air in the case of an air/glass or air/water interface), and external reflection, where the beam originates in the medium with a higher refractive index (e.g., glass in the case of a glass/air interface, or flint glass in the case of a flint/crown-glass interface), and to consider them separately.

5.1.4.4 External Reflection at a Dielectric Boundary

Fresnel's laws of reflection precisely describe amplitude and phase relationships between reflected and incident light at a boundary between two dielectric media. It is convenient to think of the incident radiation as the superposition of two plane-polarized beams, one with its electric field parallel to the plane of incidence (p-polarized), and the other with its electric field perpendicular to the plane of incidence (s-polarized). Fresnel's laws can be summarized in the following two equations, which give the reflectance of the s- and p-polarized components:

$$r_{\mathrm{s}} = \left[\frac{\sin(\theta_1-\theta_2)}{\sin(\theta_1+\theta_2)}\right]^2 \tag{5.4}$$

$$r_{\mathrm{p}} = \left[\frac{\tan(\theta_1-\theta_2)}{\tan(\theta_1+\theta_2)}\right]^2. \tag{5.5}$$

In the limit of normal incidence in air, Fresnel's laws reduce to the following simple equation:

$$r = \left(\frac{n-1}{n+1}\right)^2. \tag{5.6}$$

It can easily be seen that, for a refractive index of 1.52 (crown glass), this gives a reflectance of 4%. This important result reaffirms that, in general, 4% of all illumination incident normal

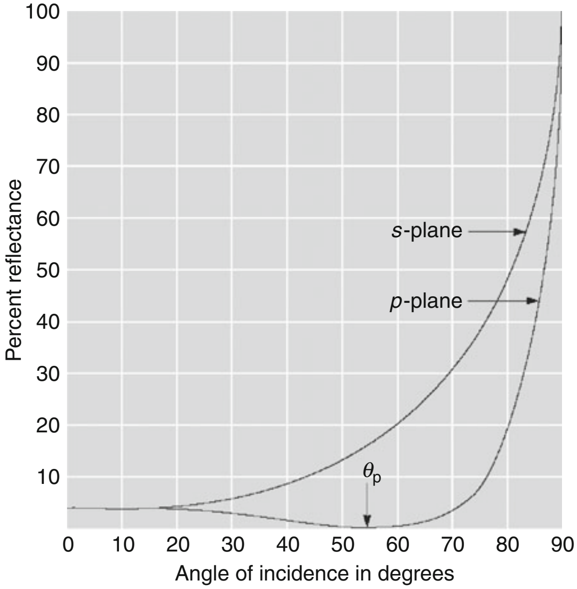

Fig. 5.4
External reflection at a glass surface (n = 1.52) showing *s*- and *p*-polarized examples

to an air-glass surface will be reflected. The variation of reflectance with angle of incidence for both the *s*- and *p*-polarized components, plotted using the formulas above, is shown in *Fig. 5.4*.

It can be seen that the reflectance remains close to 4% over about 25° incidence, and that it rises rapidly to nearly 100% at grazing incidence. In addition, note that the *p*-component vanishes at 56° 39′. This angle, called *Brewster's angle*, is the angle at which the reflected light is completely polarized. This situation occurs when the reflected and refracted rays are perpendicular to each other ($\theta_1 = \theta_2 = 90°$), as shown in *Fig. 5.5*.

This leads to the expression for Brewster's angle, θ_B:

$$\theta_1 = \theta_B = \arctan(n_2/n_1). \tag{5.7}$$

Under these conditions, electric dipole oscillations of the *p*-component will be along the direction of propagation and therefore cannot contribute to the reflected ray. At Brewster's angle, reflectance of the *s*-component is about 15%.

5.1.4.5 Internal Reflections at a Dielectric Boundary

For light incident from a higher to a lower refractive index medium, we can apply the results of Fresnel's laws in exactly the same way. The angle in the high-index material at which polarization occurs is smaller by the ratio of the refractive indices in accordance with Snell's law. The internal polarizing angle is 33° 21′ for a refractive index of 1.52, corresponding to the Brewster angle (56° 39′) in the external medium, as shown in *Fig. 5.6*. The angle at which the emerging

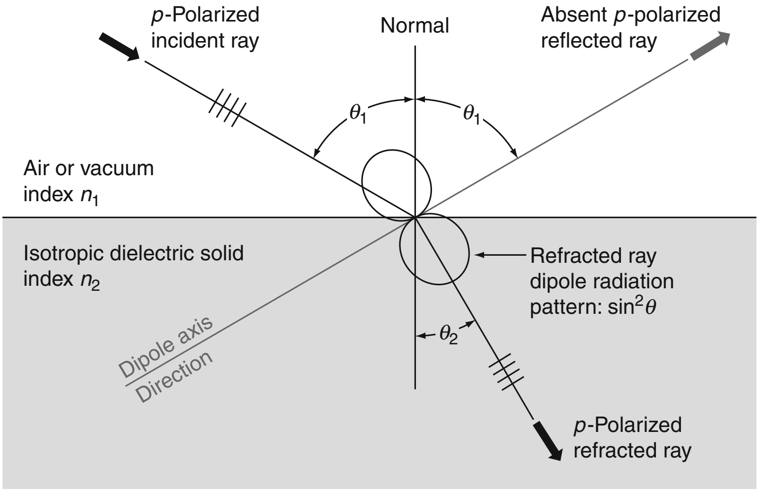

Fig. 5.5
Brewster's angle. The *p*-polarized component is completely absent in the reflected ray

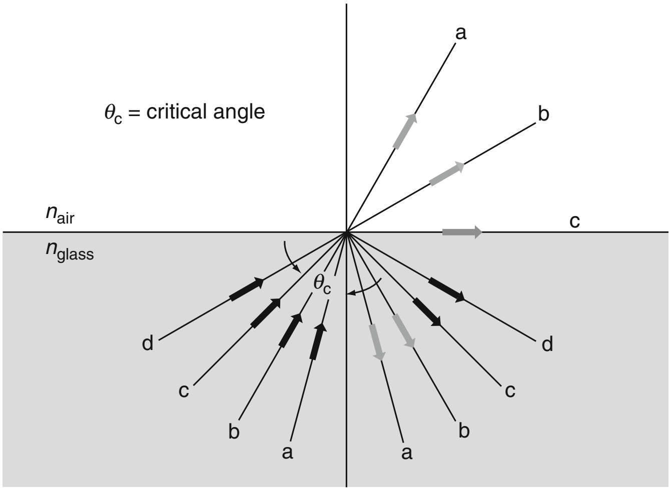

Fig. 5.6
Internal reflection at a glass-air interface (n = 1.52) showing *s*- and *p*-polarized components

refracted ray is at grazing incidence is called the critical angle (see Fig. 5.7). For an external medium of air or vacuum ($n = 1$), the critical angle is given by

$$\theta_c(\lambda) = \arcsin\left(\frac{1}{n(\lambda)}\right) \tag{5.8}$$

and depends on the refractive index *n*1, which is a function of wavelength. For all angles of incidence higher than the critical angle, total internal reflection occurs.

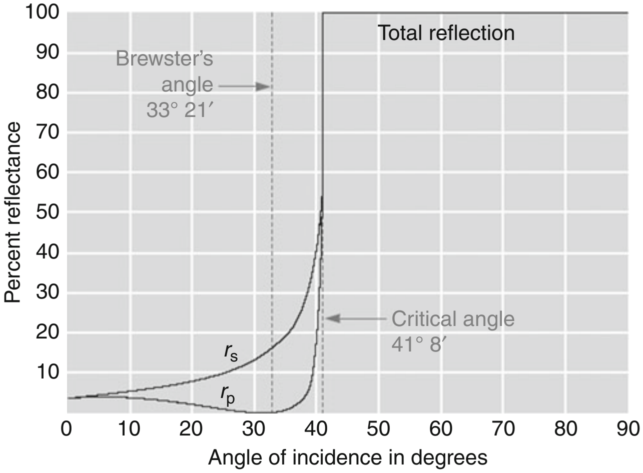

Fig. 5.7
Critical angle. The emerging ray is at grazing incidence

5.1.4.6 Phase Changes on Reflection

There is another, more subtle difference between internal and external reflections. During external reflection, light waves undergo a 180° phase shift. No such phase shift occurs for internal reflection (except in total internal reflection). This is one of the important principles on which multilayer films operate.

5.1.5 Diffraction

Electromagnetic waves are described by electric and magnetic field components. They travel in the form of a wave. A wavelength can be associated with these fields. A relatively small part of the electromagnetic *spectrum* is physiologically detected as colour by our eye. We commonly describe this part of the spectrum as *light*, or visible light and denoted by *VIS*. The spectrum spans shorter wavelengths: ultraviolet (*UV*), X-rays and Gamma rays. Longer wavelengths span the infrared (*IR*), microwaves, radio and television. Electric and magnetic field components can be physically measured. The height (amplitude) of the wave varies with time. If we were to observe the wave-like propagation of the electric field, $\mathbf{E}(x,t)$, we would find it can be described mathematically as:

$$E(x,t) = E_0 \sin(\omega t - kx) \tag{5.9}$$

where

E_0 Maximum amplitude of the electric field (Vm^{-1})
ω $2\pi/T$ where T is the period of oscillation (s).
$1/T$ is referred to as the frequency υ (Hz). (Frequency of light: $4 \times 10^{14} < \upsilon < 7.9 \times 10^{14}$ Hz)
k $2\pi/\lambda$ where λ is the wavelength (m). ($0.380\ \mu\mathrm{m} < \lambda < 750\ \mu\mathrm{m}$). $1/\lambda$ is the wave number.
x position coordinate
t time

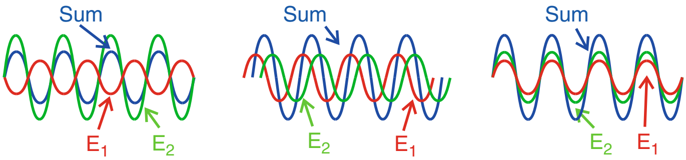

Fig. 5.8

Two propagating sinusoidal wave. (a) The sum is always a sinusoid. (b) Constructive interference. (c) Destructive interference

The frequency of light and the corresponding wavelength are related by:

$$\lambda = c/\upsilon \tag{5.10}$$

where c is the speed of light in a vacuum: $2.9979 \times 10\ \mathrm{m}^{-1}$.

The expression in parenthesis on the right hand side of Eq. 5.9 should be noted. The first term, ωt, is the time component and the second, kx, the spatial component of propagation. The following example shows the effect these components have on wave propagation. *Figure 5.8* shows two independent waves propagating. At $t = 0$, the one has an electric field strength, $E_1 = 0$, while the other E_2, has a non-zero amplitude. At time $t = 0$, the argument of the sine function in (1) becomes kx. We therefore have $E1(x{,}0) = 0$. This means the product, kx, must equal $N\pi$, (where $N = 0{,}+1{,}+2{,}\ldots$). E_2 has a negative amplitude at $t = 0$, suggesting that kx is not a multiple of π. In this case we refer to the E_2 wave as being "phase shifted" from E_1. The condition of this shift in position between the two waves will not change as the waves propagate further in space, so long as the waves are undisturbed. The contribution of kx describes the spatial phase of a wave at position x.

5.1.6 Interference

If two or more waves meet at a point x, the contribution and position of the field components, E_1 and E_2, can be superimposed on each other. Superposition (*Positive* or *Constructive Interference*) does not take place if the field amplitudes are oriented perpendicular to each other. *Figure 5.8a* shows the superposition of two sine waves. Their sum is a sinusoid, in the general case when the phases differ from each other. Comparing the resultant field amplitude, E, with the individual components, E_1 and E_2, we observe in *Fig. 5.8b* an increase in amplitude. This is constructive interference: the phase difference between E_1 and E_2 is zero or multiples of 2π. ($\Delta\varphi = N \times 2\pi$, $N = 0{,}\pm1$, ±2, ...) Destructive interference is shown in *Fig. 5.8c* where there is a decrease in the resultant field amplitude. The phase difference between the two waves is half of one wavelength ($\Delta\varphi = (2\ N + 1) \times \pi$). If the constituent amplitudes would have the same amplitude and differ in phase by half a wavelength ($\Delta\varphi = (2\ N + 1) \times p$), the resultant amplitude would be zero. Superposition of a constructive nature leads to an increase in light intensity (high intensity), whereas destructive interference leads to a decrease in intensity, or even zero intensity. This effect can be seen in the case to two beams propagating in different directions, which simultaneously impinge on a screen at the same coordinate. One can observe the periodic pattern of light and dark stripes (double slit interference). This pattern will appear everywhere the two beams superimpose. The ability of light to interfere, along with the observations of Christian von Huygens, that wavefronts themselves can become wave centres of point source propagation explains the effect of diffraction.

5.1.6.1 Diffraction

A plane wave impinging on a geometric structure with an opening (wall with a round opening aperture) will emit elementary point source waves from each opening. The projected pattern of these waves oscillates between bright and dark areas, which are not sharply separated. This oscillatory transition is the result of interference of these elementary waves. The phase difference between neighbouring maxima or minima is always 2π.

Diffraction therefore means that wave fronts travelling in a straight line, which are then restricted by some opening, divert off their straight path into light/dark patterns. This assumes, of course, that the waves don't experience other phenomena such as reflection or refraction. In *Fig. 5.9*, one can see deviation of the diffracted light from the original angle impinging the wall. The optical path difference, ($N\lambda$), between rays emanating from the edges of the opening and the size of the geometrical opening, D, will determine the Nth order diffraction angle.

Each $N = \pm1, \pm2$, defines a direction α, or for small angles, $N\alpha$, of an intensity maximum. The intensity pattern at the edges due to contributions from non-diffracted rays leads to a reduced sharpness of bright/dark transition. We refer to this as *reduced contrast.*

The *direction* of rays and therefore of diffracted rays is always perpendicular to their wave surface. Geometrical optics neglects diffraction in progressive ray calculations. One assumes = 0 to be a boundary condition of wave optics. All cross rays in the system have a diffraction angle of zero ($\lambda = 0 = > \alpha = 0$).

5.1.7 Scattering and Diffusion

In a perfect vacuum, a ray of light travels, without loss, in a straight line. In a defect-free, homogenous, transparent material, such as optical-quality glass, there is a little loss, due to a combination of absorption and scattering. In glass of lower quality, such that used for making bottles and windows, there is likely to be a greater level of scattering but still at a tolerable level for non-critical optical functions. In media such as smoke, fine water/oil mist, aerosols, milk and mayonnaise, scattering is the dominant optical property.

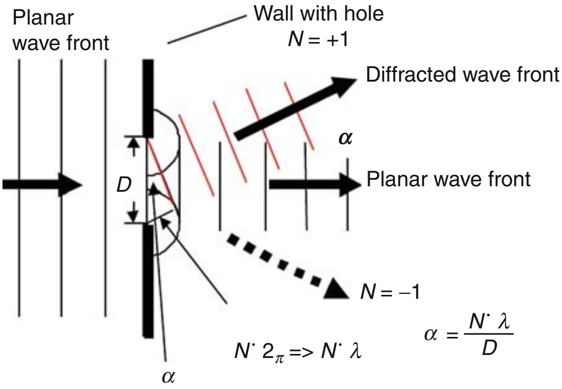

Fig. 5.9
Diffraction through a small aperture of width D

Scattering can occur either as a surface effect, or one that involves the bulk material and can be caused in various ways:

- *Refractive index changes in a transparent material.* Light deviates from a straight-line trajectory when it passes through localized non-uniformities in the refractive index of a transmissive medium. This type of scattering is caused by aerosols, as well as tiny air bubbles in water and glass. These behave like numerous tiny lenses, inevitably causing parallel beams to diverge.
- *Tiny opaque particles suspended in a transparent medium.* Airborne dust and smoke particles scatter light by diffraction (➲ *Fig. 5.10*). Inclusions and crystal-structure defects in gems also cause scattering.
- *Tiny opaque particles adhering to a reflective surface.* Particles deposited from fumes and smoke scatter light by diffraction.
- *Contamination of a surface by liquid droplets.* These may be deposited from steam, water/oil sprays, fingerprints, spittle, etc.
- *Rough surfaces on a transparent material.* Ground glass provides a good example of this type of scattering. Scratches and pits on glass surfaces form sites for localised scattering.
- *Rough surfaces on an opaque material.* Textiles, cut unpolished wood, unglazed china are examples. Cells in animal/plant tissue also cause scattering.

Due to their complex structural and chemical nature, biological materials scatter light by a variety of means. Indeed, they do it so well, that it can be difficult to obtain good contrast images, as it is often impossible to control the diffusion of light from one part of a sample to another. As evidence of this, recall that the ends and edges of the fingers glow when they are held in front of a bright light.

5.1.7.1 Physical Origins of Scattering

To understand diffuse reflection, consider a rough surface as consisting of a series of very small facets, with random orientations. Each of these provides a mirror-like (specular) reflection.

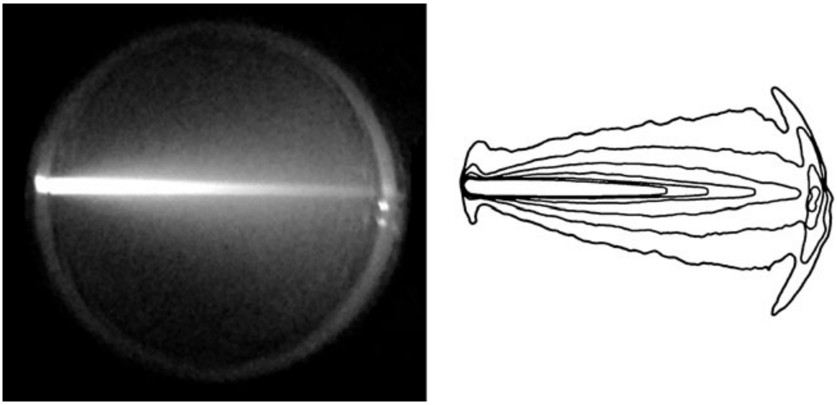

Fig. 5.10

Scattering of light in milk diluted with water. (a) Laser beam enters the glass container from the left. (b) Intensity contours (isophotes) emphasise the conical spreading of the beam

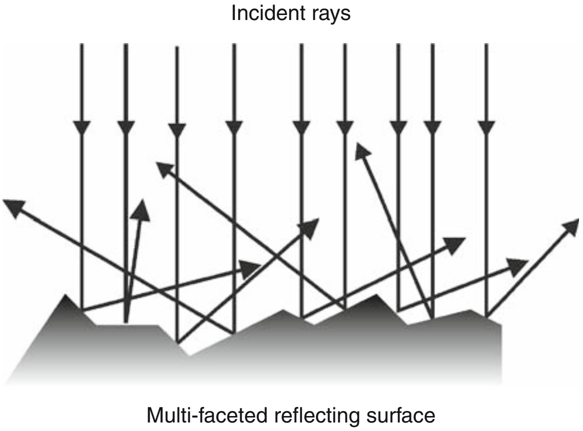

Fig. 5.11

Diffuse reflection. Each ray may be regarded as undergoing specular reflection from a tiny mirror with random orientation

The macroscopic effect is to see light emerging from the surface in all directions (➋ *Fig. 5.11*). A surface exhibits *Lambertian reflectance* if light falling on it is scattered such that its apparent brightness is the same regardless of the observer's angle of view. That is, the luminance is isotropic. The reflection from a cross-grain wood surface is approximately Lambertian, as it is from the surface of unglazed bone china and a clean button mushroom and an egg. The Lambertian reflection model is often used as the basis for generating realistic images in Computer Graphics. Of course, if a matt surface has a glossy coating (e.g. polyurethane or lacquer), a mixture of effects combine to provide the total effect that we see (➋ *Fig. 5.12*). (This diagram does not take into account the partial polarisation of light reflected from a dielectric surface.

There are two principal types of scattering that have been subjected to detailed mathematical analysis:

- *Rayleigh scattering* occurs when light is deflected by very small objects, usually taken to be of diameter less than λ/10, where λ is the wavelength. For objects of this size or less, the exact shape is not significant; mathematical analysis is reasonably accurate if we replace complex (real) particles with spheres of equivalent volume. Rayleigh scattering is responsible for the sky appearing to be blue at midday and reddening at sun-rise and sunset. It also occurs in fog, industrial mists, smoke, aerosols and perhaps most importantly low-grade glass.
- For larger particles, *Mie scattering* occurs. In this case, the shape of the scattering objects is more important; no general closed-form mathematical analysis has been discovered for particles of arbitrary shape.

The interaction of light with particles of diameter greater than about 10λ can usually be described adequately using geometric (i.e. ray) optics. This is not usually described as scattering. In order to model scattering from large irregularly shaped particles, computational methods are used.

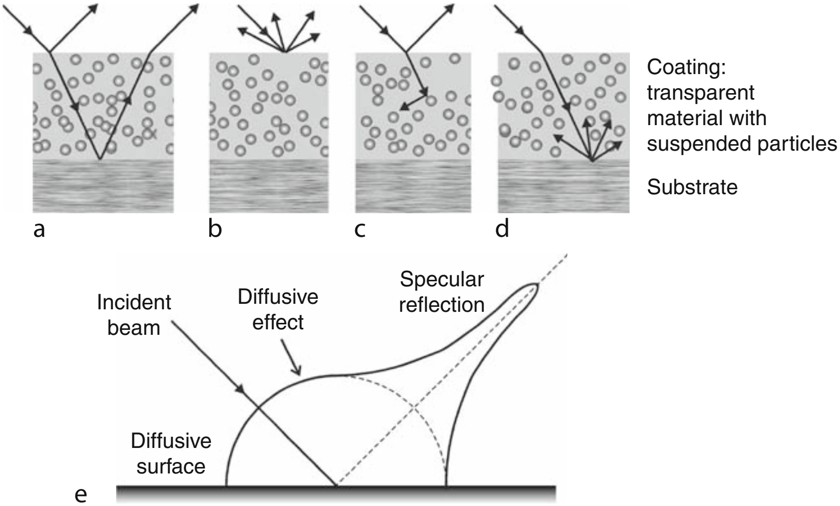

Fig. 5.12

Diffusion and reflection from a painted surface. The paint is a thin coating containing minute suspended particles. In practice, the reflection and scattering effects shown here all occur to some extent. (a) Some light rays penetrate the coating and undergo specular reflection from the interface between it and the substrate. Some rays are reflected from the outer surface of the coating. (b) Some rays are scattered by the external surface of the coating. (c) Some light rays are scattered by particles suspended in the coating. Some of these scattered rays re-emerge from the coating (not shown). (d) Scattering occurs at the interface. (e) Polar energy distribution. Again, some of these scattered rays re-emerge from the coating (not shown). The polar energy plot for a perfect Lambertian reflector is an hemisphere

Light that has already been scattered by one diffusing reflection may fall onto another, then onto another and so on. This gives rise to *multiple scattering*. *Single scattering*, as described above, can be treated as a random phenomenon and can conveniently be represented in terms of probability distributions. On the other hand, multiple scattering is more deterministic; it can be analysed on a macroscopic level using intensity distributions (➲ *Fig. 5.13*). Multiple scattering is analogous to the diffusion of heat in a solid and is treated mathematically in the same way. *Diffusers* are optical elements designed to produce multiple scattering and are useful in improving the homogeneity of lighting for Machine Vision. They may be either transmitting or reflecting devices.

5.2 Optical Materials

5.2.1 Criteria for Optical Materials

There are several important criteria for optical materials:

- The *index of refraction* (or *refractive index*) is the ratio of the speed of light in that material to the speed of light in a vacuum. By definition, the refractive index for a vacuum is 1.00. The refractive index of all materials varies to some extent with wavelength.

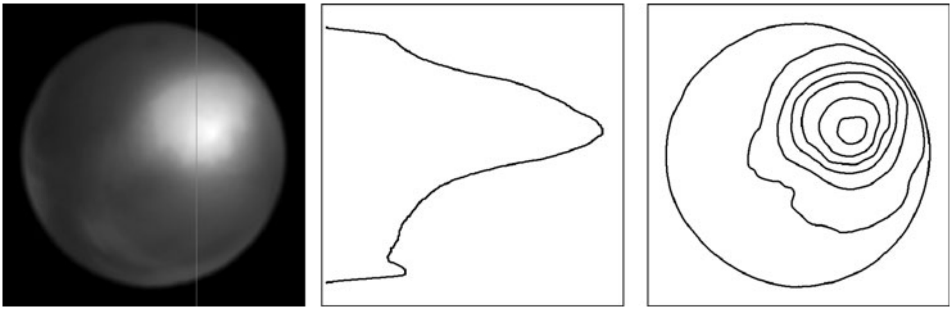

Fig. 5.13
Diffuse and specular reflection from a sphere with a small ("point") light source. (a) Original image, computer simulation. (b) Intensity profile along the vertical line in (a). (c) Intensity contours (isophotes)

- The *Abbé number* of a material quantifies the amount of dispersion (i.e., variation in refractive index) over a specific spectral range. A high Abbé number generally gives less colour dispersion and reduces colour aberration.
- The density of a glass is a factor determining the weight of an optical component. It is unlikely to be critical for many industrial applications.
- The hardness of an optical material indicates its resistance to scratching. Surface damage can seriously degrade the performance of an optical component.
- The coefficient of thermal expansion is important for applications involving rapid changes of temperature and large spatial temperature differentials.

A list of refractive index values for some common optical and other transparent materials is given in *Table 5.1*, while *Fig. 5.14* shows the variation in refractive index for a range of optical materials. Typical values for the reflectance from opaque materials are provided in *Table 5.2*.

5.2.2 Important Characteristics

Glass manufacturers provide hundreds of different glass types with differing optical transmissibility and mechanical strengths. The most important material properties to consider in regard to an optical element are as follows:

- *Spectral transmission characteristics* A material must be transparent at the wavelength of interest, if it is to be used for a transmissive component. A transmission curve allows the optical designer to estimate the attenuation of light, at various wavelengths, caused by internal material properties. For mirror substrates, the attenuation is not important.
- *Refractive index* The index of refraction, as well as the rate of change of index with wavelength (dispersion), might require consideration. High-index materials allow the designer to achieve a given power with less surface curvature, typically resulting in lower aberrations. On the other hand, most high-index flint glasses have higher dispersions, resulting in more chromatic aberration in polychromatic applications. They also have poorer chemical characteristics than lower-index crown glasses.

Table 5.1
Refractive index values

Material	Refractive index
Acetone	1.36
Acryilic (Polymethyl methacrylate, PMMA)	1.490–1.492
Air	1.00029
Alcohol, ethyl	1.36
Alcohol, methyl	1.329
Amethyst	1.532–1.554
Benzene	1.501
Beryl	1.57–1.60
Calcite	1.486–1.658
Crown glass (impure)	1.485–1.755
Crown glass (pure)	1.50–1.54
Diamond ($\lambda = 0.6563$ μm)	2.417
Emerald	1.560–1.605
Flourite, CaF_2	1.434
Glass, arsenic trisulfide	2.04
Glass, crown (spectacles)	1.523
Glass, flint, 29% lead	1.569
Glass, flint, 55% lead	1.669
Glass, flint, 71% lead	1.805
Glass, fused silica	1.459
Glass, lanthanum flint	1.82–1.98
Glass, pyrex (borosilicate)	1.474
Glycerol	1.4729
Lithium niobate	2.283
Magnesium fluoride (MgF_2)	1.3777
Mineral oil, $\lambda = 0.4678$ μm	1.47685
Mineral oil, $\lambda = 0.4800$ μm	1.47583
Mineral oil, $\lambda = 0.5086$ μm	1.47373
Mineral oil, $\lambda = 0.5461$ μm	1.47149
Mineral oil, $\lambda = 0.5893$ μm	1.46945
Mineral oil, $\lambda = 0.6438$ μm	1.46744
Mylar (boPET)	1.65
Vegetable oil (50°C)	1.47
Poly(ethylene terephthalate) (PET)	1.5750
Plastic	1.46–1.70
Polycarbonate	1.584–1.586
Polystyrene	1.55–1.59
Quartz	1.543–1.545

Table 5.1 (Continued)

Material	Refractive index
Ruby	1.76–1.77
Sodium chloride (NaCl, salt)	1.544
Sapphire	1.76–1.77
Sugar solution, 30%	1.38
Sugar solution, 80%	1.49
Turpentine	1.472
Vacuum (by definition)	1.00

- *Thermal expansion* The thermal expansion coefficient can be particularly important in applications in which the part is subjected to high temperatures, such as high-intensity projection systems. This is also of concern when components must undergo large temperature cycles, such as in optical systems used outdoors.
- *Mechanical characteristics* The mechanical characteristics of a material are significant in many areas. They can affect how easy it is to fabricate the material into shape, which affects

product cost. Scratch resistance is important if the component will require frequent cleaning. Shock and vibration resistance are important for military, aerospace, or certain industrial applications. The ability to withstand large pressure differentials is important for windows used in vacuum or pressure chambers. An important mechanical property of glass is microhardness. A precisely specified diamond scribe is placed on the glass surface under a known force. The indentation is then measured. The Knoop and the Vickers microhardness tests are used to measure the hardness of a polished surface and a freshly fractured surface, respectively.

- *Chemical Properties* The chemical properties of materials are important to manufacturers of optical equipment and users, especially when the component will be used in a harsh environment. To quantify the chemical properties of glasses, manufacturers rate each glass according to four categories: climatic resistance, stain resistance, acid resistance, and alkali and phosphate resistance.
- *Climatic Resistance* Humidity can cause a cloudy film to appear on the surface of some optical glass. Climatic resistance expresses the susceptibility of a glass to high humidity and high temperatures. In this test, glass is placed in a water-vapour-saturated environment and subjected to a temperature cycle which alternately causes condensation and evaporation. The glass is given a rating from 1 to 4 depending on the amount of surface scattering induced by the test. A rating of 1 indicates little or no change after 30 days of climatic change; a rating of 4 means a significant change occurred in less than 30 hours.
- *Stain Resistance* Stain resistance expresses resistance to mildly acidic water solutions, such as fingerprints or perspiration. In this test, a few drops of a mild acid are placed on the glass. A coloured stain, caused by interference, will appear if the glass starts to decompose. A rating from 0 to 5 is given to each glass, depending on how much time elapses before stains occur. A rating of 0 indicates no observed stain in 100 hours of exposure; a rating of 5 means that staining occurred in less than 0.2 hours.

- *Acid Resistance* Acid resistance quantifies the resistance of a glass to stronger acidic solutions. Acid resistance can be particularly important to lens manufacturers because acidic solutions are typically used to strip coatings from glass or to separate cemented elements. A rating from 1 to 4 indicates progressively less resistance to a pH 0.3 acid solution, and values from 51 to 53 are used for glass with too little resistance to be tested with such a strong solution.
- *Alkali and Phosphate Resistance* Alkali resistance is also important to the lens manufacturer since the polishing process usually takes place in an alkaline solution. Phosphate resistance is becoming more significant as users move away from cleaning methods that involve chlorofluorocarbons (CFCs) to those that may be based on traditional phosphate-containing detergents. In each case, a two-digit number is used to designate alkali or phosphate resistance. The first number, from 1 to 4, indicates the length of time that elapses before any surface change occurs in the glass, and the second digit reveals the extent of the change.

5.2.3 Material Types

Crown glass is a low-index commercial-grade glass. The index of refraction, transmittance, and homogeneity are not controlled as carefully as they are in some other optical-grade glasses. Optical crown glass is suitable for applications in which component tolerances are fairly loose and is a substrate material for mirrors. Transmittance characteristics are shown in ➲ *Fig. 5.15*.

Fused silica (SiO_2) is an ideal material for many optical applications. It is transparent over a wide spectral range (➲ *Fig. 5.16*). It has a low coefficient of thermal expansion, and is resistant to scratching and thermal shock. Synthetic fused silica (amorphous SiO_2) should not be confused with fused quartz, which is made by crushing and melting natural crystals, or by fusing silica sand. Both of these processes result in a granular microstructure with trapped impurities and bubbles. These lead to local variations of refractive index and reduced

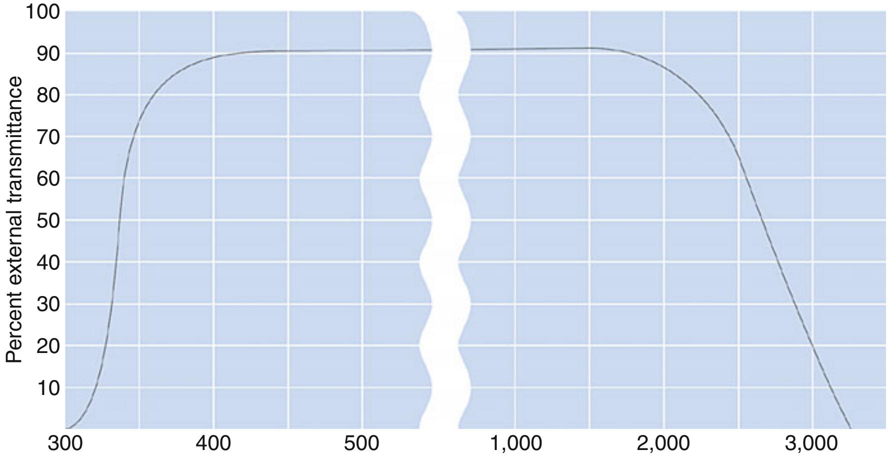

Fig. 5.15
Transmittance of crown glass versus wavelength (nm)

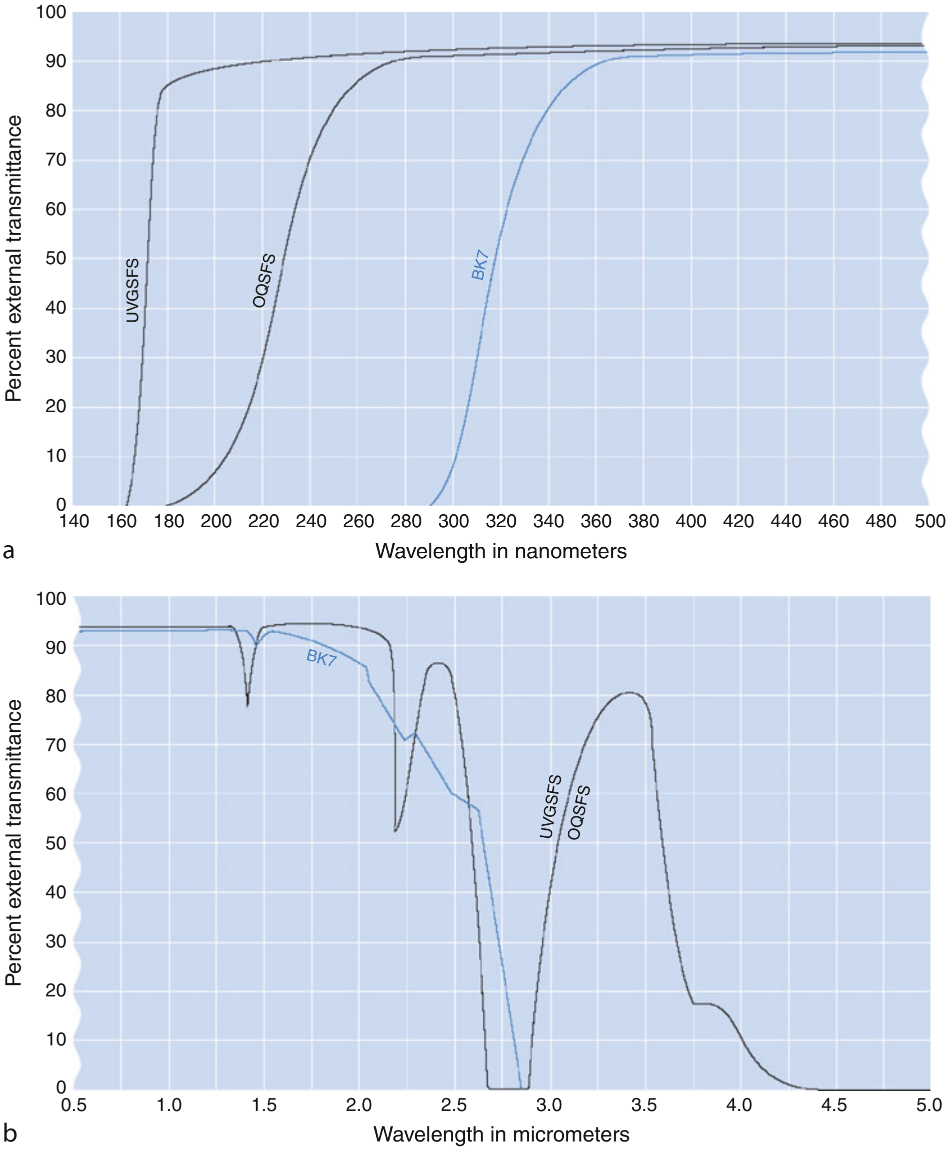

Fig. 5.16

Transmittance of optical quality synthetic fused silica (OQSFS) compared to ultra-violet grade synthetic fused silica. (a) UV waveband. (b) Visible and IR wavebands

transmission throughout the spectrum. Synthetic fused silica is far purer than fused quartz and provides a number of advantages:

- Greater ultraviolet and infrared transmission
- Low coefficient of thermal expansion, which provides stability and resistance to thermal shock
- Wider thermal operating range

- Increased hardness and resistance to scratching
- Much higher resistance to radiation darkening from ultraviolet, x-rays, gamma rays, and neutrons
- Reduced chromatic aberration
- Very low fluorescence levels (approximately 0.1% that of fused natural quartz excited at 0.254 μm. UV-grade synthetic fused silica does not fluoresce in response to wavelengths longer than 0.290 μm)

Glass transmittances are affected by thermal history after manufacture, as well as during the manufacturing process. Depending on the manufacturer and subsequent thermal processing (coating, annealing, or tempering), it is possible for the internal transmittance of any optical glass to be reduced by several percent across the entire spectrum. External transmittance is correspondingly affected. Transmittance of all glass is especially uncertain at wavelengths approaching the water absorption band at 2.7 μm. Synthetic fused silica also exhibits batch-to-batch transmittance variations, especially in the deep ultraviolet and infrared spectral regions. Visible batch-to-batch transmittance variations in synthetic fused silica are insignificant.

Sapphire (Al_2O_3) is an almost ideal material for optical windows, since it is very strong and extremely hard. It can be scratched by only a few substances: diamond or boron nitride and itself. As a result, it can be cleaned with impunity. It is chemically inert and insoluble in almost everything, except at highly elevated temperatures. Even hydrogen fluoride fails to attack sapphire at temperatures below 300°. Sapphire exhibits high internal transmittance from 0.150 to 6 μm. The external transmittance of sapphire is shown in ➔ *Fig. 5.17*. It has an exceptionally high thermal conductivity, so thin windows can be cooled by a forced air jet. Conversely, sapphire windows can be heated to prevent condensation. Sapphire exhibits birefringence. Most transmission losses of sapphire are due to surface reflections. Magnesium fluoride is an

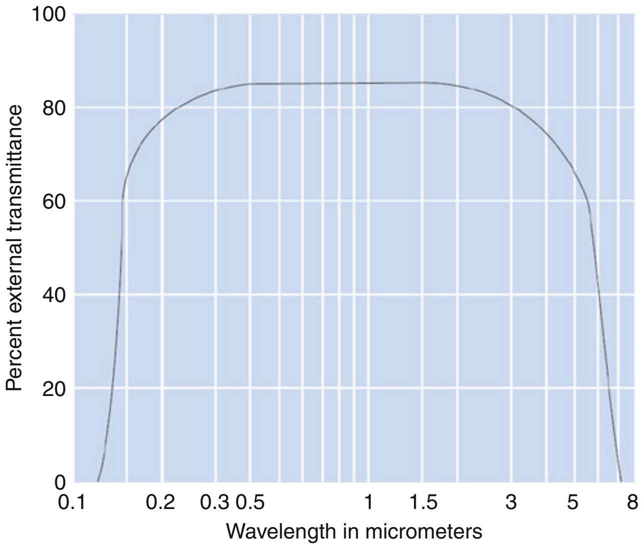

Fig. 5.17
Transmittance for sapphire

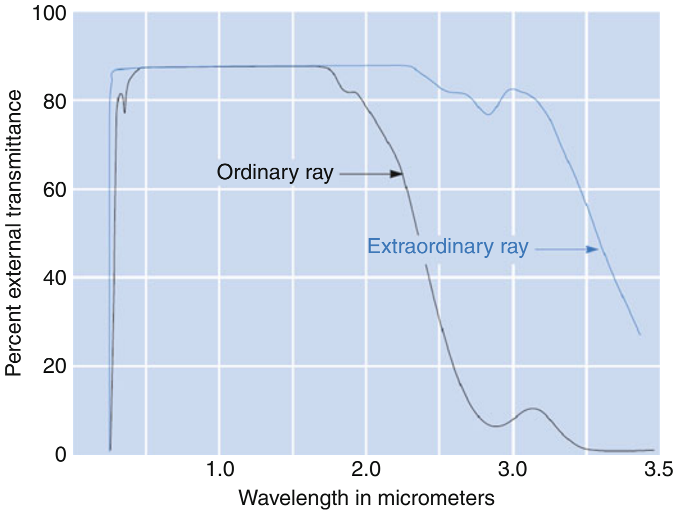

Fig. 5.18
Transmittance of calcite

almost ideal anti-reflection coating; a single layer of MgF_2 can ensure that the total transmission losses through a sapphire window are below 2%, over the entire visible spectrum.

Calcite ($CaCO_3$) exhibits pronounced birefringence. Strong birefringence and a wide transmission range make mineral popular for making polarising prisms. Most optical calcite is mined, rather than synthesised. It is a soft crystal and tends to cleave easily. These factors all contribute to the high cost of calcite prisms, compared to other types of polarisers. *Figure 5.18* shows the external transmittance of calcite. Since calcite is a natural crystal, the transmission is likely to vary from one sample to another.

Calcium fluoride (CaF_2) transmits readily over a wide spectrum (*Fig. 5.19*). As a result, it has widespread applications in the ultraviolet and infrared regions of the spectrum. It can be manufactured into windows, lenses, prisms, and mirror substrates. CaF_2 occurs naturally and can be mined. This yields a product with some impurities. A more homogenous material can be synthesised using an expensive manufacturing process.

α-Barium Borate (α-$Ba_2B_2O_4$) exhibits pronounced birefringence, is harder than calcite, has a high damage threshold, has a low coefficient of thermal expansion and is transparent over the visible and IR parts of the spectrum (*Fig. 5.20*). These properties make it an attractive alternative to calcite for polarising prisms.

ZERODUR® (Schott-AG) Many optical applications require a substrate material with a very low coefficient of thermal expansion and/or excellent thermal shock resistance. ZERODUR® is a glass ceramic material that is claimed to have the following characteristics:

- Very low coefficient of thermal expansion
- Good 3D homogeneity
- High internal quality
- Good machining properties
- Can be polished to a high accuracy
- Can be coated easily

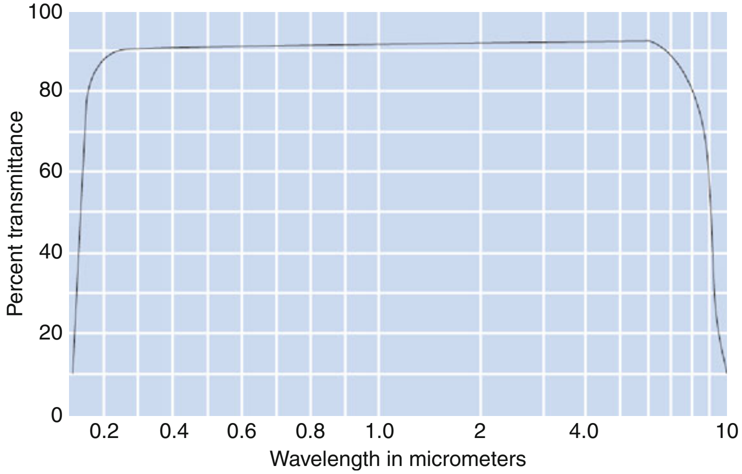

Fig. 5.19

Transmittance of calcium fluoride

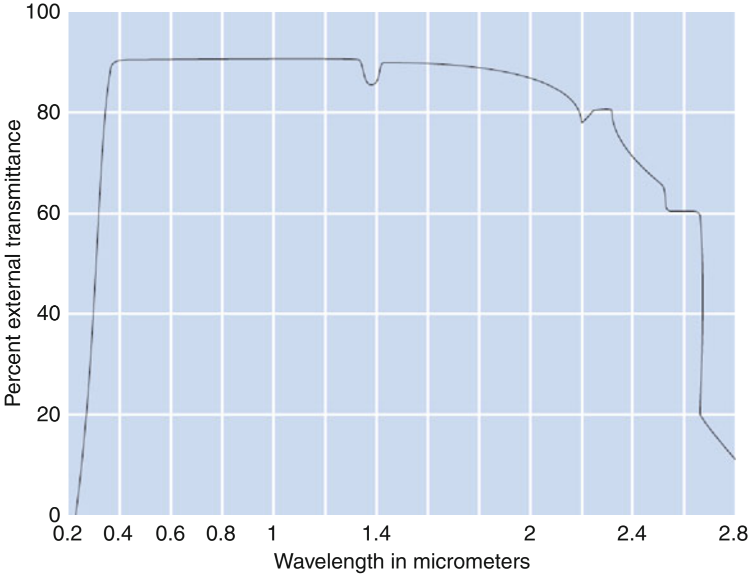

Fig. 5.20

Transmittance of α-barium borate

- Non-porous
- Good chemical stability

ZERODUR® is a glass-ceramic composite class of materials that has both amorphous (vitreous) and crystalline components. At room temperatures, the coefficients of thermal expansion of the vitreous phase (positive) coefficient and crystalline phase (negative) nearly cancel, resulting in a low overall coefficient of thermal expansion; within the temperature range 20–300°C this is $0.05 \pm 0.10 \times 10^{-6}$/°C. As a result, this type of material is well suited as a mirror substrate for high-precision applications, such as interferometry, holography and reflectors for large telescopes.

5.2.4 Light Absorbing Materials and Structures

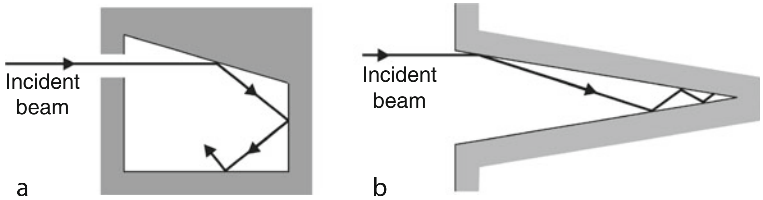
When a 50:50 beamsplitter is used in the illumination path of a vision system, half of the light it receives from the lamps is immediately discarded and must be disposed of properly. To absorb the large quantities of unwanted light that this type of system produces requires that special techniques be used. The naïve approach to producing a light absorbing surface is to use commercially available matt black paint. However, this still reflects a significant amount of light. Black velvet provides an efficient light absorbing surface but this is hardly practical for use in a dirty factory environment. Although amorphous carbon (soot) is a good absorber, it is friable. A standard approach to improving matters in photographic lens hoods, is to use rifling on the inside surface. A closed box with a small aperture in its side wall and painted matt black inside is a good absorber. A deep hollow cone is too (➋ *Fig. 5.21*). Any light reflected by the inside surface of the cone is reflected deeper into it, where more of the unwanted light will be aborbed. This leads to the idea of building a surface consisting of a series of small conical depressions. A similar idea is to use a stack of razor blades; the side of the stack is a good light absorber. Creating a sponge-like structure from a material that itself has a low reflection coefficient seems to offer the best approach to building a really efficient light absorber. One recently announced coating material aborbs 10–20 times more less light than conventional techniques [1]. (It is claimed by its inventors to be 25 times blacker than conventional black paint.) This coating consists of an alloy of nickel and phosphorus. The surface is pitted, with tiny craters. At the time of writing (April 2008) this material is expensive and not yet available in large quantities.

5.3 Optical Coatings

There are three reasons for using coated optics:

(a) To minimise reflections and thereby increase overall light transmission through an optical system

(b) To maximise the reflection of light from mirror surfaces



■ Fig. 5.21
Light absorbing structures. In both cases, the internal surface is coated with absorbent material, such as matt black paint. (a) Box, (b) Deep conical pit

(c) To protect the optical surfaces (both reflective and transmissive) from scratching and staining due to contamination

We discuss coatings for reflective surfaces in ➲ Sect. 5.5. Protective coatings require little explanation, except to emphasise that the ability to operate an optical system in a hostile environment is an essential requirement for many Machine Vision systems. The scientific basis of anti-reflection coatings is far from simple. We shall therefore concentrate here on the rationale for and use of coated optics.

The vast majority of optical components are made of various types of glass, coated with thin layers of special materials. The purpose of a coating is to modify the reflection and/or transmission properties of the component's surface. Whenever light passes from one type of material into a medium with different optical properties (most notably refractive index), part of the light is reflected and part of the light is transmitted. The intensity ratio of the reflected and transmitted light is primarily a function of the change in refractive index between the two media. The angle of incidence of the light at the interface is also important but, for the sake of simplicity, we shall assume normal incidence. Let n_1 be the refractive index of the material that the incident beam traverses prior to meeting the interface. Also, let n_2 be the refractive index after the interface. Then, the reflection coefficient is given by the equation

$$R = \frac{(n_2 - n_1)^2}{(n_2 + n_1)^2} \tag{5.11}$$

If the first medium is air, $n_1 \approx 1$, this equation reduces to

$$R = \frac{(n_2 - 1)^2}{(n_2 + 1)^2} \tag{5.12}$$

As the light beam emerges from the same optical component, the reflection coefficient is again equal to R. The insertion loss for that component is therefore R^2. For standard optical quality glass, the refractive index is about 1.5. (➲ *Table 5.1*) Hence, the insertion loss is 7.84%.

If the reflection coefficient of the ith surface is R_i and there are N surfaces in a transmissive (i.e., no mirrors) optical system, the intensity of the emergent beam is

$$I_0 \prod\nolimits_{i=1}^{N} (1 - R_i) \tag{5.13}$$

where I_0 is the intensity of the incident beam. An uncoated surface of clean polished optical quality glass might well reflect 4% ($R = 0.04$) of the incident light. Suppose that $N = 10$, a typical value in a simple system. Then, the intensity of the transmitted light is $0.665I_0$. In most industrial vision systems, this degree of attenuation is not critical, as there is power available to flood a small arena with plenty of light. However, what is important is where the "lost" light goes. In our example, on third of the light is reflected back into the optical system, where it has many opportunities to degrade the image contrast. In ➲ *Fig. 5.22*, it is clear that even a single layer coating of magnesium fluoride (MgF_2) can reduce the reflection coefficient at each surface to about 0.015. In this case, the intensity of the emergent beam is $0.86I_0$. The "lost" light has however, been reduced from 33% to 14%.

The only suitable applications for uncoated optics are those where only a few optical components are in the optical path, and significant transmission inefficiencies can be tolerated. In principle, the surface of any optical element can be coated with thin layers of various materials (called thin films) in order to achieve the desired reflection/transmission ratio. With the exception of simple metallic coatings, this ratio depends on the nature of the material from which the optical device is fabricated, the wavelength of the incident light, and the angle of

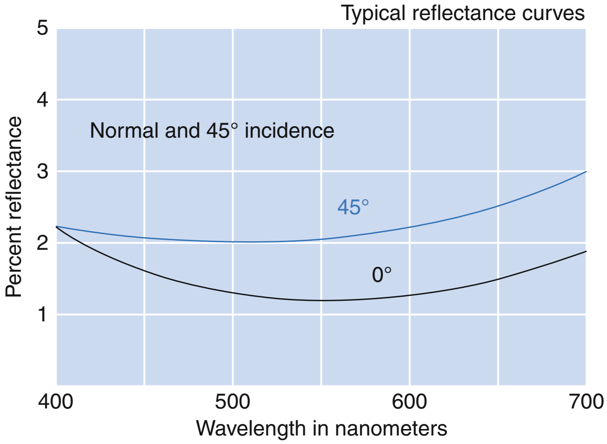


Fig. 5.22
Reflectance characteristics from a single layer of MgF_2

incidence of the light (measured from the normal to the optical surface). There is also a polarisation dependence to the reflection/transmission ratio when the angle of incidence is not normal to the surface. A multilayer coating, sometimes made up of more than 100 individual fractional-wavelength layers, may be used to optimise the reflection/transmission ratio for a specific wavelength and angle of incidence or to optimize it over a specific range of conditions. Today's multilayer dielectric coatings are remarkably hard and durable. With proper care and handling, they can have a long life. In fact, the surfaces of many high-index glasses that are soft or prone to staining can be protected with a durable antireflection coating. Several factors influence coating durability. Coating designs should be optimized for minimal overall thickness to reduce mechanical stresses that might distort the optical surfaces or cause detrimental polarisation effects. The most resilient materials should be used. Great care must be taken in coating fabrication to produce high-quality, nongranular, even layers.

5.3.1 Antireflection Coatings

Magnesium fluoride (MgF_2) is commonly used for single-layer antireflection coatings because it has an almost ideal refractive index (1.38 at 0.550 μm) and high durability. These coatings are insensitive to wavelength and angle of incidence. Single-layer antireflection coatings are routinely available for almost any angle of incidence and any wavelength in the range 0.20–1.6 μm. (However, as the upper wavelength limit is approached, the angle of incidence should be restricted to near-normal.) The performance of MgF_2 antireflection coatings improves dramatically as the substrate's index of refraction increases.

5.3.2 Multi-Layer Coatings

Although MgF_2 does not offer the same performance as multilayer coatings, it is preferred in some circumstances. On lenses with very steep surfaces (e.g., close to the edges of some aspheric lenses), MgF_2 will actually perform better than a multi-layer coating. Whatever the angle of incidence, MgF_2 always performs at least as well as an uncoated lens but, at very high angles of incidence, multi-layer coatings may be worse than no coating at all.

The so-called quarter/quarter coating was developed to circumvent the lack of a material with the index of refraction needed to optimise the performance of a single-layer coatings. The basic problem associated with single-layer antireflection coatings is that the refractive index of the coating material is generally too high, resulting in too strong a reflection from the first surface which cannot be completely cancelled through destructive interference with the weaker reflection from the substrate's top or first surface. In a two-layer coating, the first reflection is cancelled through destructive interference with two weaker out-of-phase reflections from underlying surfaces. A quarter/quarter coating consists of two layers, both of which have an optical thickness of a quarter wave at the wavelength of interest. The outer layer is made of a low-refractive-index material, and the inner layer is made of a high-refractive-index material, compared to the substrate. As illustrated in ➋ *Fig. 5.23*, the second and third reflections are both exactly 180° out of phase with the first reflection. The interference effect in thin films is, of course, sensitive to wavelength. In other words, the reflected waves only cancel one another exactly at one specific wave-length.

When considering a two-layer quarter/quarter coating optimized for one wavelength at normal incidence, the required refractive indexes for minimum reflectivity can be calculated easily by using the following equation:

$$n_0 = \frac{n_1^2 n_3}{n_2^2} \tag{5.14}$$

Here n_0 is the refractive index of air (approximated as 1.0), n_3 is the refractive index of the substrate material, and n_1 and n_2 are the refractive indices of the two film materials. If the substrate is crown glass with a refractive index of 1.52 and if the first layer is the lowest possible refractive index, 1.38 (MgF_2), the refractive index of the high-index layer needs to be 1.70. Either beryllium oxide or magnesium oxide could be used for the inner layer, but both are soft materials and will not produce very durable coatings. Although it allows some freedom in the choice of coating materials and can give very low reflectance, the quarter/quarter coating is constrained in its design owing to the lack of materials with suitable refractive index and physical or durability properties.

In principle, it is possible to deposit two materials simultaneously to achieve layers of almost any required refractive index, but such coatings are not very practical. As a consequence, thin-film engineers have developed multilayer and special two-layer antireflection coatings that allow the refractive index of each layer and, therefore, coating performance to be optimized.

5.3.3 Two-Layer Coatings of Arbitrary Thickness

Optical interference effects can be characterized as either constructive or destructive interference, where the phase shift between interfering wavefronts is 0° or 180° respectively. For two wavefronts to cancel each other completely, as in a single-layer antireflection coating, a phase shift of exactly 180° is required. Where three or more reflecting surfaces are involved, complete cancellation can be achieved by carefully choosing the relative phase and intensity of the

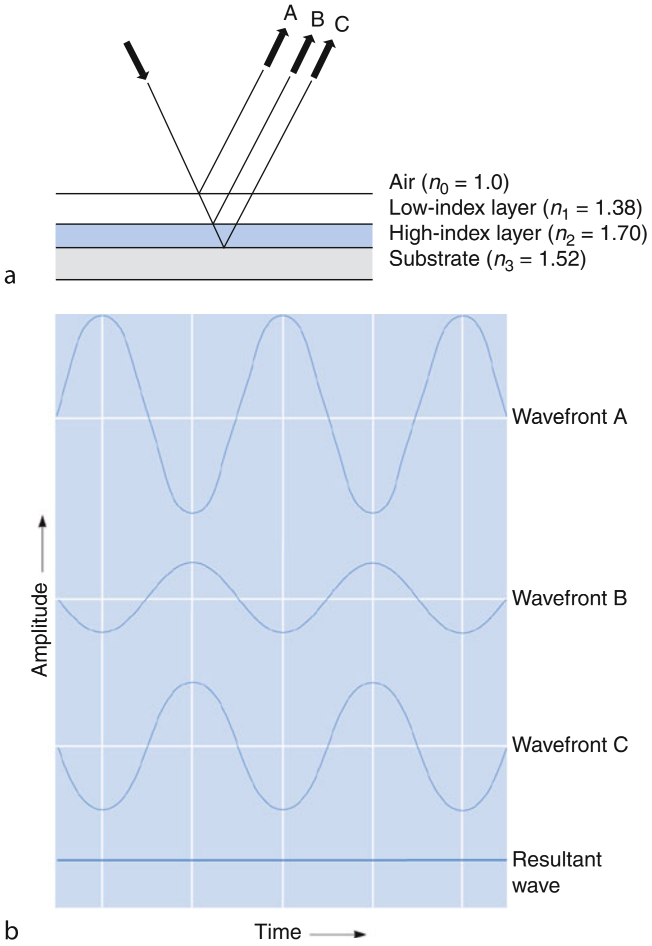

Fig. 5.23
Interference in a typical quarter/quarter coating

interfering beams (i.e., optimizing the relative optical thicknesses). This is the basis of a two-layer antireflection coating, where the layers are adjusted to suit the refractive index of available materials, instead of vice versa. For a given combination of materials, there are usually two combinations of layer thicknesses that will give zero reflectance at the design wavelength. These two combinations are of different overall thickness. For any type of thin-film coating, the thinnest possible overall coating is used because it will have better mechanical properties (less stress). A thinner combination is also less wavelength sensitive. Two-layer antireflection coatings are the simplest of the so-called V-coatings. The term V-coating arises from the shape of the reflectance curve as a function of wavelength, as shown in *Fig. 5.24*, which resembles a skewed V shape with a reflectance minimum at the design wavelength. V-coatings are very popular, economical coatings for near monochromatic applications.

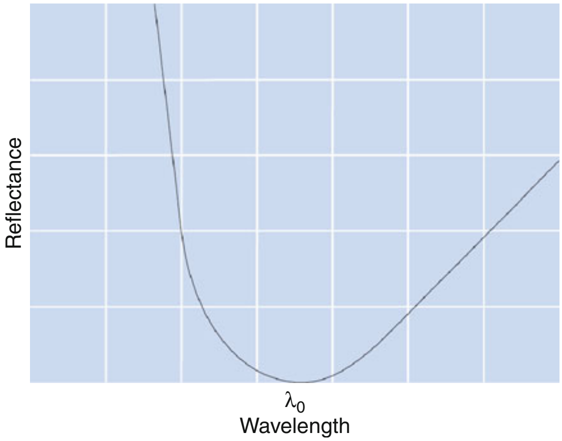

Fig. 5.24
Characteristic performance curve of a V-coating

5.3.4 Broadband Anti-Reflection Coatings

Imaging systems typically use polychromatic (more than one wavelength) light. In order for the system to have a flat response over an extended spectral region, transmitting optics are coated with a dichroic broadband antireflection coating. The main technique used in designing antireflection coatings that are highly efficient at more than one wavelength is to use “absentee” layers within the coating. Additional techniques can be used for shaping the performance curves of high-reflectance coatings and wavelength-selective filters, but these are not applicable to antireflection coatings.

5.3.5 Absentee Layers

An absentee layer is a film of dielectric material that does not change the performance of the overall coating at one particular wavelength. Usually that particular wavelength is the wavelength for which the coating is being optimized. The absentee layer is designed to have an optical thickness of a half wave at that specific wavelength. The “extra” reflections cancel out at the two interfaces because no additional phase shifts are introduced. In theory, the performance of the coating is the same at that specific design wavelength whether or not the absentee layer is present. At other wavelengths, the absentee layer starts to have an effect for two reasons: the ratio between physical thickness of the layer and the wavelength of light changes with wavelength, and the dispersion of the coating material causes optical thickness to change with wavelength. These effects give the designer extra degrees of freedom not offered by simpler designs.

The complex, computerized, multilayer antireflection coating design techniques used by manufacturers are based on the simple principles of interference and phase shifts described above. In view of the properties of coherent interference, it is meaningless to consider individual layers in a multilayer coating. Each layer is influenced by the optical properties of the other layers in the multilayer stack. A complex series of matrix multiplications, in which each matrix corresponds to a single layer, is used to model the performance of multilayer thin-film coatings mathematically. There also are multiple reflections within each layer of a coating. In the previous discussions, only first-order or primary reflections were considered. This oversimplified approach is unable to predict accurately the true behaviour of multilayer coatings. Second-, third-, and higher-order terms must be considered if the real behaviour of a coating is to be modelled accurately.

5.4 Lenses

Most lenses have spherically curved surfaces; either surface can be convex, concave, or planar. A lens is classified by the curvature of its optical surfaces (➋ *Fig. 5.25*).

- B*iconvex*, both surfaces are convex
- *Biconcave*, both surfaces are concave
- *Plano-convex*, it has one plane and one convex surface
- P*lano-concave*, it has one plane and one concave surface
- *Convex-concave, it has* one convex and one concave surface
- M*eniscus lens*, convex-concave type, where both surfaces have the same radius of curvature

The terminology used when discussing lenses is summarised in ➋ *Fig. 5.26*.

If a lens is biconvex, or plano-convex, a paraxial, collimated beam of light will be focussed behind the lens to a point on its axis called the *focal point*. (A *collimated beam* consists of a set of parallel rays. *Paraxial* means that all rays are parallel to the optical axis.) Such a lens is said to be a positive or *converging lens* (➋ *Fig. 5.27*). The distance between the lens and its focal point is called the *focal length* and is usually denoted by *f*.

A biconcave, or plano-concave, causes a paraxial beam to diverge as it emerges from the lens. This is called a negative or *diverging lens*. The beam emerging from the lens appears to be emanating from a point on the axis in front of the lens (➋ *Fig. 5.28*). This distance from this virtual focal point to the lens is also known as the focal length. In this case, it has a negative value.

Fig. 5.26
Terminology for lenses

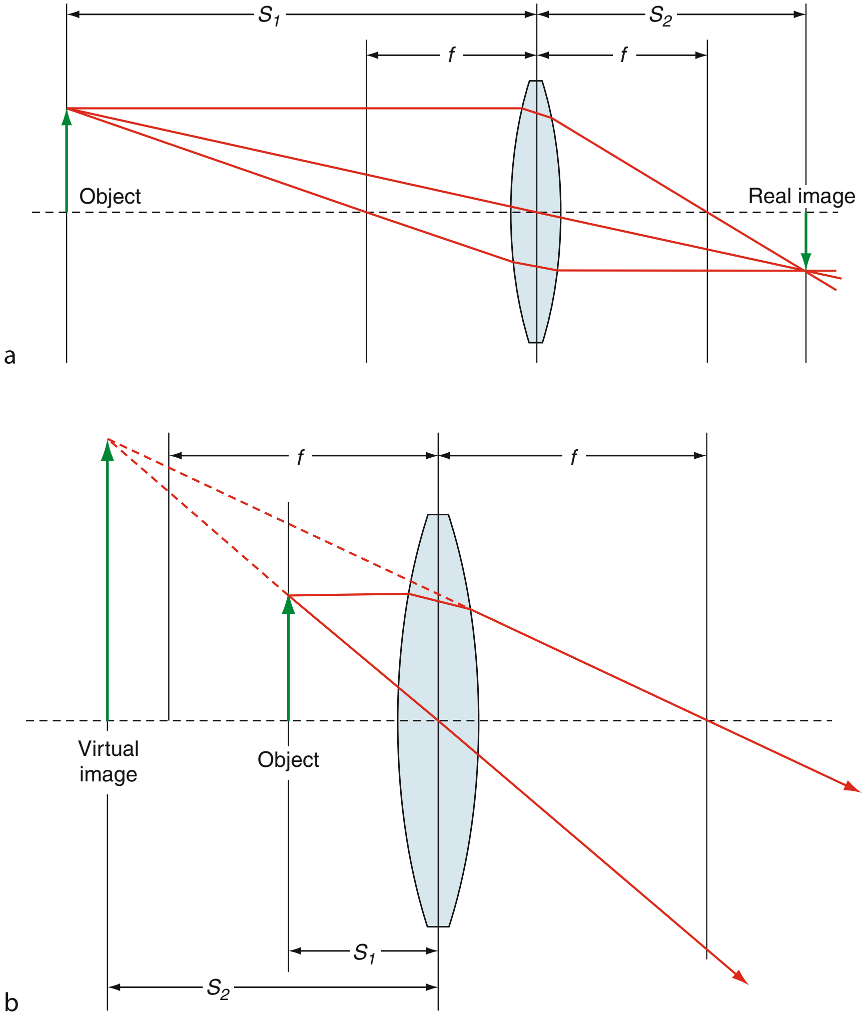

Fig. 5.27

Creating real and virtual images with a thin biconvex (i.e., converging) lens. (a) The object lies beyond the focal point. The image is real, inverted and is reduced in size. (b) The object lies between the vertex and focal point. The virtual image is not inverted and is magnified

A convex-concave lens may be converging or diverging, depending on the relative curvatures of the two surfaces. The beam is neither converged nor diverged by a meniscus lens. A paraxial beam remains paraxial but its diameter changes as a result of travelling through such a lens.

The line joining the centres of the two spherical lens surfaces is called the *axis*, or *optical axis*. Most lenses are symmetrical about the optical axis, so the focal points both lie on it. The *vertices* are those points where the axis intersects the surfaces of the lens.

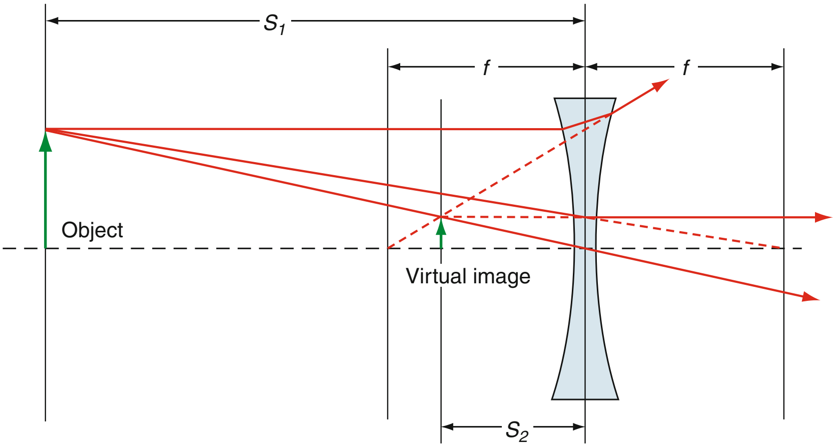

Fig. 5.28

Diverging biconcave lens. The object lies beyond the focal point. The image is virtual, upright and smaller than the object. If the object is closer than the focal point (not shown), the image is virtual, upright and enlarged. (To appreciate this, mentally reverse the direction of travel of the light rays and interchange the image and object.)

5.4.1 Lens Maker's Equation

The focal length of a lens in air can be calculated from the *lens maker's equation*:

$$\frac{1}{f} = (n-1)\left[\frac{1}{R_1} - \frac{1}{R_2} + \frac{(n-1)d}{nR_1R_2}\right], \tag{5.15}$$

where *f* is the focal length of the lens *n* is the refractive index of the lens material. (The refractive index of a vacuum is defined as being 1. The refractive index of air is 1.0008, so for most practical purposes this is taken to be 1. The refractive index of most optical glasses is about 1.5.) R_1 is the radius of curvature of the lens surface closer to the light source, R_2 is the radius of curvature of the lens surface farther from the light source*d* is the thickness of the lens (i.e., the distance between the two vertices).

The signs of the radii of curvature indicate whether the lens surfaces are convex or concave. Several sign conventions exist but in this chapter R_1 is positive if the first surface is convex and negative if it is concave. The signs are reversed for the second surface of the lens: if R_2 is positive the surface is concave, and negative if it is convex. If either R_1 or R_2 is infinite, the corresponding surface is flat.

If d is small compared to R_1 and R_2 (*thin lens condition*), we obtain the following approximation to ➋ Eq. 5.1:

$$\frac{1}{f} \approx (n-1)\left[\frac{1}{R_1} - \frac{1}{R_2}\right]. \tag{5.16}$$

Notice that the focal length *f* is positive for converging lenses, negative for diverging lenses, and infinite for meniscus lenses. The value of 1/*f* indicates the *optical power* of the lens and is measured in *diopters* (or m^{-1}).

5.4.2 Imaging Properties of Lenses

The plane perpendicular to the lens axis and situated at a distance f from the lens is called the *focal plane*. A we have already stated, a converging lens focuses a paraxial beam to a spot at a distance f from the lens. Conversely, a point source placed at the focal point will form a collimated (paraxial) beam of light as it emerges from the lens.

Let us denote the distance from the object to the lens by S_1 and that from the lens to the image by S_2. Then, for a lens of negligible thickness, in air, we can use the so-called *thin lens formula*:

$$\frac{1}{S_1} + \frac{1}{S_2} = \frac{1}{f} \tag{5.17}$$

If an object is placed at a distance $S_1 > f$ along the axis in front of a positive lens of focal length f, a *real image* is created. This means that it can be used to project an image onto a screen placed at a distance S_2 behind the lens (➋ *Fig. 5.27a*). ➋ Equations 5.16 and ➋ 5.17 are based on the assumption that the lens has zero thickness and are useful for approximate calculations.

If $S_1 < f$, S_2 is negative and a *virtual image* is formed. This cannot be projected onto a screen. However, an observer looking through the lens will see the magnified upright image, apparently located on the far side of the lens. A magnifying glass creates this kind of image.

The *magnification* of the lens is given by M, where:

$$M = -\frac{S_2}{S_1} = \frac{f}{f - S_1} \tag{5.18}$$

If the absolute vale of M (i.e., $|M|$) is greater than 1, the image is larger than the object. If M is negative, the image is inverted. For virtual images, M is positive and the image is upright. If S_1 is infinite, $S_2 = f$ and M is zero. This indicates that a collimated beam is focussed to a single spot at the focal point. (In practice, the size of the image is not zero, since diffraction effects limit the minimum size of the image.)

These formulae may also be used for negative (i.e., diverging) lenses, which can only create virtual images (➋ *Fig. 5.4*). In this case, we take the focal length (f) to be negative.

The plane at which paraxial rays appear to "bend," to converge the focal point, is called the *principal plane*. For a lens in air, this plane is often called the *nodal plane*. Any lens, except a hypothetical "thin" lens, will typically have multiple principal planes (➋ *Fig. 5.29*).

The *f-number* (*f*/#) of a lens is the focal length divided by the diameter of its aperture (*limiting aperture*) of the lens. Hence, a lens with a 50 mm focal length and a 10 mm aperture diameter is referred to as an *f*/5 lens. The *f*/# is useful in determining the relative illuminance of the image formed by the lens; the illuminance varies as the inverse of *f*/# squared. The focal length and *f*-number of a commercial lens are usually printed on the lens barrel.

5.4.3 Analysing a Compound Lens

It is possible to analyse a compound (i.e., multi-element) lens by tracing the path of rays through a series of simple lenses. We can calculate the magnification, field-of-view and aberrations of the compound lens. It is usually most convenient to perform the analysis by considering the simple lenses in the reverse of the order in which light passes through them.

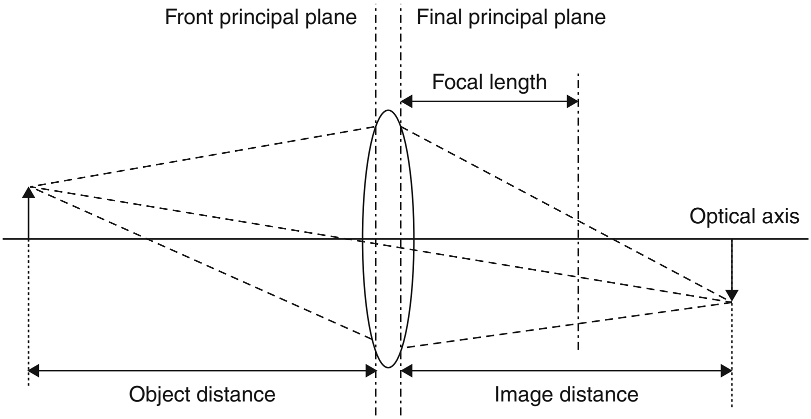

Fig. 5.29
Principal planes for a converging lens

Figure 5.30 explains how the focal length is calculated. Notice that the principal planes of the compound lens are the same as those of the end elements: lenses L_1 and L_3 in Fig. 5.30a; L_4 and L_6 in Fig. 5.30b.

5.4.4 Scheimpflug Condition

Tilting the lens relative to the object-lens axis will cause part of the image to be focus and other parts out of focus (Fig. 5.31a). This will also introduce trapezoidal distortion; a square forms an image in the form of a key-stone.) However, if we satisfy the so-called *Scheimpflug condition*, the whole image can be kept in focus (Fig. 5.31b).

5.4.5 Depth-of-Field and Depth-of-Focus

The *depth-of-field* of a lens is the distance along its optical axis through which the object can be moved while still forming a sharply focussed image (Fig. 5.32). The *depth-of-focus* is the distance along the optical axis that the sensor can be moved while keeping the image in focus. To quantify these, we introduce the concept of the *circle of confusion*, or *blur circle*. Imagine an optical system focussing light from a point source. When the system is slightly misfocussed, the image will be a small but finite-sized spot. If this is very small, the mis-focussing can be neglected. The size of the spot (i.e., the blur circle) is a measure of the level of mis-focussing. In many cases, we can take it that the maximum allowable size for the blur circle is the same as that of the individual photo-detectors in the sensor array. In this case, the depth-of-focus is equal to the f-number (*f*/#) times the size of one individual photo-detector.

Determining the depth-of-field is slightly more complicated. The distance of the far focal point (P in Fig. 5.32) from the lens is

$$D_{\mathrm{far}} = \frac{S_1 f_2}{f^2 - NC(S_1 - f)} \tag{5.19}$$

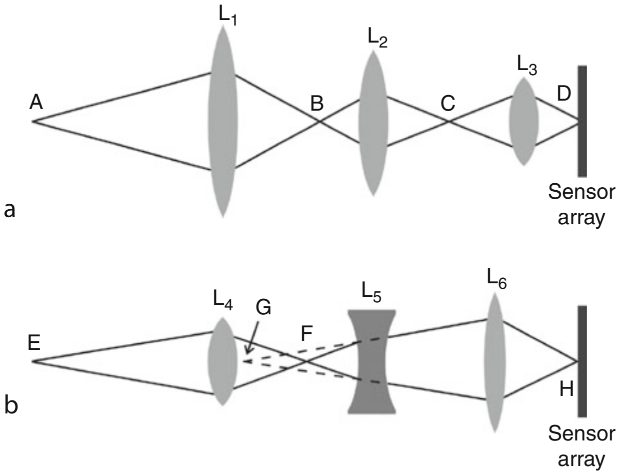

Fig. 5.30

A compound (i.e., multi-element) lens can be analysed by considering it as a chain of simple lenses. (a) All three component lenses are converging. An object at point A is focussed by lens L_1 at point B. Rays passing through point B are focussed at C by lens L_2. Rays passing through point C are focussed at D, on the sensor array by lens L_3. A real image of A appears at the sensor array. (b) A chain containing one diverging lens and two converging lens, forms a converging compound lens. E is focussed at F by lens L_4. Lens L_5 forms a virtual image at G, which is focussed by lens L_6 to form a real image at H, on the sensor array

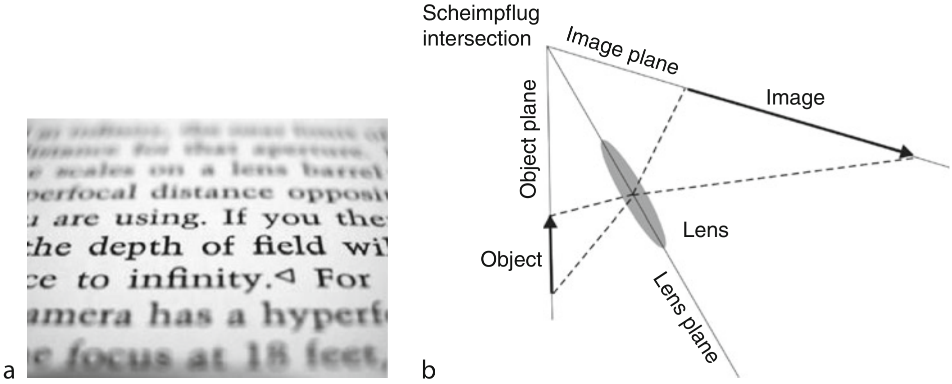

Fig. 5.31

Scheimpflug condition. (a) Effect of tilting a lens. (b) The Scheimpflug condition: the object plane, lens plane and image plane all meet in a single straight line. The normal cross section is shown here

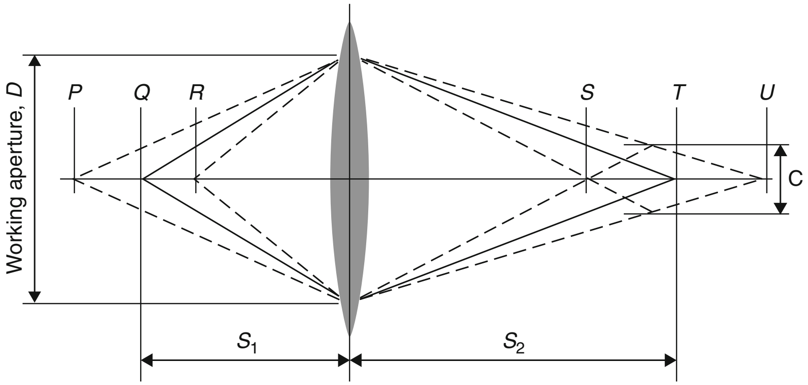

Fig. 5.32
Depth-of-field and depth-of-focus. A point in the plane Q is optimally focussed to a point in plane T. The object can be moved anywhere in the region PR while still maintaining an acceptably sharp focus. This defines the depth-of-field. An object at Q will be seen as being in acceptably sharp focus by a sensor placed anywhere within the region SU. This defines the depth-of-focus

and the distance of the near focal point (R in *Fig. 5.32*) from the lens is

$$D_{\mathrm{near}} = \frac{S_1 f^2}{f^2 + NC(S_1 - f)} \tag{5.20}$$

Where N is the f-number ($f/\#$) of the lens, D is the working diameter of the lens (usually less than its physical diameter), C is the diameter of the blur circle in the image plane, S_1 is the object-lens distance.

The depth-of-field (DoF) is the difference between D_{far} and D_{near}.

$$\mathrm{DoF} = \frac{2NCS_1 f^2\,(S_1 - f)}{f^4 - N^2C^2\,(S_1 - f)^2} \tag{5.21}$$

5.4.6 Aberrations and Resolution of an Optical System

Degradations in the quality of the image can be caused by imperfections in the lens. However, even a good lens, used in an inappropriate way will produce a poor quality image. The most important aberrations for Machine Vision are summarised below. Higher order aberrations are usually of less concern.

5.4.6.1 Spherical Aberration

Lenses with spherical surfaces are not ideal. They are widely used, because they are relatively simple to form, grind and polish. The effect of spherical aberration caused by a biconvex lens is shown in *Fig. 5.33*. Beams parallel to but away from the lens axis are focussed at different points along that axis. This results in a blurring of the image formed in the (optimal) focal plane. A paraxial beam is focussed to a spot of finite size. *Aspheric lenses* have non-spherical surfaces and can reduce spherical aberration very considerably. (Hitherto, they were difficult to make and consequently were expensive. Modern manufacturing methods have greatly reduced the cost.) Spherical aberration can be minimised by careful choice of the lens. For example, a plano-convex lens, focussing a collimated beam, produces a smaller focal spot when the light strikes the convex surface first. The size of the focal spot circle decreases as the cube of *f*/#, So, stopping the lens down greatly reduces the mis-focussing effect. Spherical aberration is important in applications requiring high spatial resolution, for example when trying to detect small "point" or narrow streak defects (e.g., cracks or scratches).

5.4.6.2 Coma

Another common type of aberration is coma. It produces a comet-like spot in the focal plane, when a parallel but non-paraxial beam is focussed (➋ *Fig. 5.34*). Suppose the rays travel at some non-zero angle θ relative to the optical axis. Rays that pass through the centre of the lens are focused to a point at a distance of $f.\tan(\theta)$ from the axis. (Remember this is a thin lens.) On the other hand, rays passing through the lens periphery are focused at different points. These are either further from the axis (positive coma) or closer to the axis (negative coma). A circular beam containing parallel rays, passing through the lens at a fixed distance from its centre, forms a disc-shaped image in the focal plane. This is known as a *comatic circle*. The superimposition

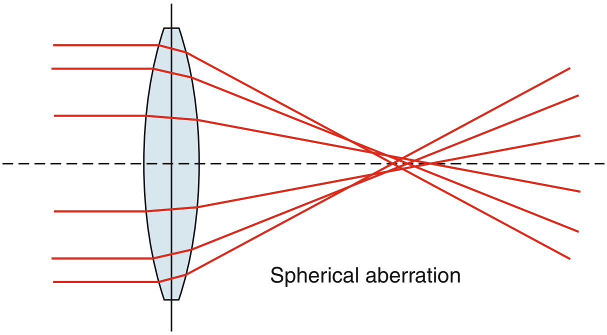

Fig. 5.33
Spherical aberration

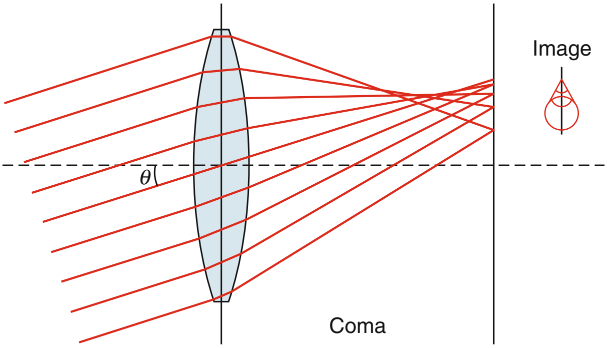

Fig. 5.34
Coma

of all these circles results in a comet-like spot. As with spherical aberration, coma can be reduced by using aspheric lenses. For lenses with spherical surfaces, the magnitude of the comatic aberration increases linearly with distance from the optical axis, but decreases as the square of *f*/#. Reducing comatic aberration is important when it is necessary to provide constant medium-to-high resolution over the whole visual field.

5.4.6.3 Chromatic Aberration

Think of a biconvex lens as approximating two prisms stuck together. With this in mind, we should not be surprised that the lens will disperse white light, into its spectral components. A dark opaque object, viewed in silhouette against a white light source through the lens, will appear to have a multi-coloured periphery. This is the manifestation of the effect known as *chromatic aberration* and is caused by the fact that the refractive index of the lens material varies with the wavelength of light. Hence the focal length (*f*) of the lens depends upon the wavelength. Chromatic aberration can be reduced by using an *achromatic doublet* (or *achromat*) lens (➜ *Fig. 5.35*). Two lenses made of different materials are cemented together and are treated conceptually as a single lens. *Achromatic* lenses are only able to compensate for

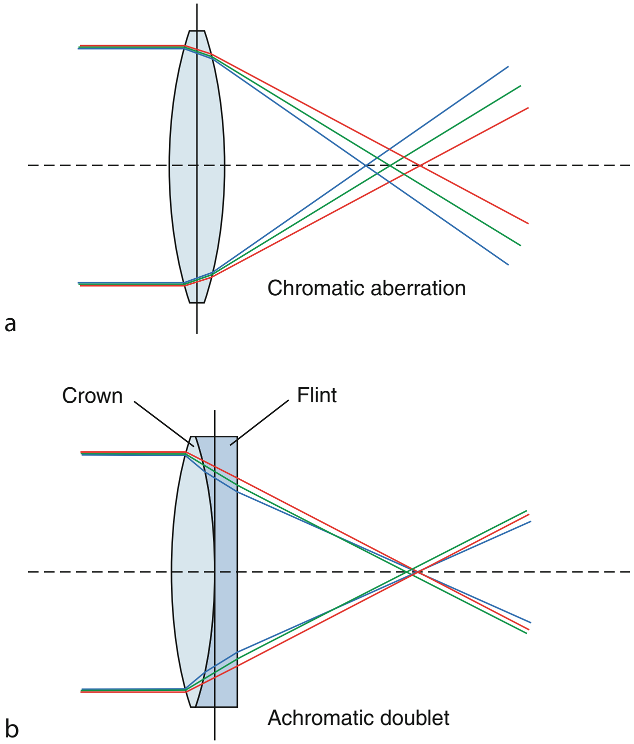

Fig. 5.35
Chromatic aberration. (a) The focal length of a lens depends upon the wavelength. (b) By combining two lenses with different forms, it is possible to reduce chromatic aberration

chromatic aberration over a limited range of wavelengths and normally do not produce perfect correction over the full visible spectral band. An *apochromat* is a lens (or lens system) that is corrected for both chromatic and spherical aberrations. Reducing chromatic aberration to an absolute minimum is clearly essential for accuracy in tasks such as colour inspection. It is also important where high spatial resolution is needed.

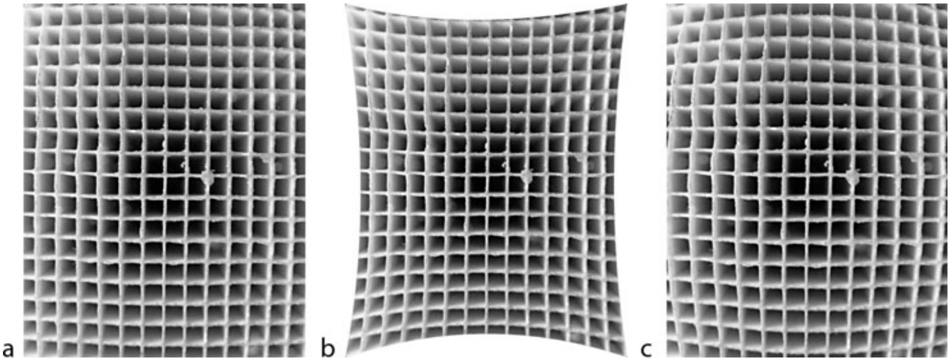
5.4.6.4 Other Aberrations

Field curvature is manifest when evenly spaced points focus at a variable distance from the lens. The effect decreases as the lens is stopped down and is important in any precise measurement or position-locating application.

Astigmatism occurs when horizontal and vertical features focus at different distances from the lens. This results in the resolution being different for horizontal and vertical size measurements.

Distortion Features in the image become noticeably mis-shaped. Important for most vision applications, especially those requiring the measurement of shape/size of discrete parts (➲ *Fig. 5.36*).

Vignetting This occurs when a uniformly illuminated scene is mapped to an image that is uneven in brightness, usually bright in the middle and darker towards the sides corners (➲ *Fig. 5.37*). Vignetting is not strictly an aberration; it occurs when there is a different apparent aperture size for off-axis and on-axis rays. Poorly designed multi-lens assemblies cause vignetting; rear elements are partially shaded by elements in front of them. This reduces the effective lens opening for off-axis rays. This form of vignetting can be cured by stopping down the lens. Lenses are designed for a particular image format. Provided they are used for their intended purpose, most lenses will produce a fairly uniform image brightness. Telecentric lenses (described later) are often designed specifically to provide very even image brightness. Vignetting also occurs when peripheral light rays are blocked by external objects, such as secondary lenses, or inappropriately fitted lens hoods. The corner darkening can be gradual or abrupt, depending on the lens aperture. Vignetting is important because it renders fixed-level image thresholding impractical.



■ Fig. 5.36

Distortion. (a) Original. Catalytic converter. The Barrel distortion present here is due to the lens. (b) Pin-cushion distortion produced by software. (c) Barrel distortion exaggerated by software

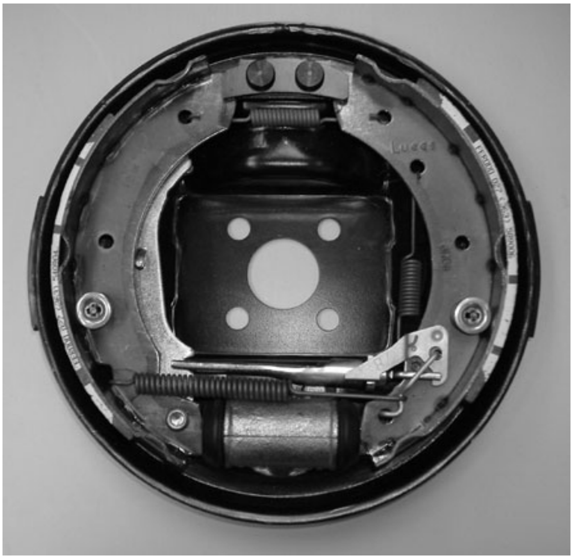


Fig. 5.37

Vignetting. Close to the *right-hand side*, the intensity of the background varies from 110 (*top and bottom corners*) to 157 (*centre-right*) (Gradual changes in shading like this are not immediately obvious to the human eye, although this represents a contrast ratio of 1.42)

5.4.7 Resolution

The resolution of an optical system is defined in terms of its ability to distinguish between two closely spaced points. Following the example of John Strutt (Lord Rayleigh), it is customary to take the limit of resolution to be that occurring when their blur circles are just touching. A (single) beam of light of diameter *A* can be focussed to a spot of diameter not less than

$$\frac{1.22\lambda f}{A} \tag{5.22}$$

where is the wavelength and *f* is the focal length of the lens. Strictly, *A* is the original beam diameter, or the aperture of the lens if that is smaller. Hence, the minimum value for this limit is equal to 1.22 times the *f*/#. This limit is a fundamental limit, imposed by diffraction effects. Hence, it is known as the *diffraction limited resolution* of the lens. The diffraction-limited image is actually a bright spot, surrounded by a series of concentric rings, whose brightness varies inversely with their radius. This is known as the Airy disc. The disc whose diameter given by Eq. 5.22 accounts for about 70% of the light energy in the beam. A disc of twice that diameter contains 83.8% of the light energy. This is used sometimes to define the diffraction-limited spot size. Expression 6.22 is a theoretical limit, which is very difficult to achieve in practice. Lenses that are claimed to provide a resolution even close to this limit should be avoided!

Resolution should not be confused with the ability to detect something. The latter depends on both the optical system and the sensor. The human eye can easily detect a bright star in the night sky, but can only do so because the lens is imperfect! As far as a human being on earth is concerned, the star is an extremely small source of light that is imaged by the lens of the eye to form the blur circle. We incorrectly interpret this as the image of the star. On the other hand, in a video system, the smallest resolvable object is usually determined by the size of an individual photo-detector; most lenses have no problem producing a blur circle that is much smaller than the camera can use.

5.4.8 Modulation Transfer Function (MTF)

The modulation transfer function (MTF)is a sensitive quantitative measure of image quality and describes the ability of a simple lens, or a complete imaging sub-system, to maintain high contrast for small features. Standard bar-chart testing of the resolution of a lens/system is deceptive, because almost 20% of the optical energy is contained within the third harmonic and higher spatial frequencies. A sine-wave test chart, like that shown in *Fig. 5.38a* is used to measure the MTF. This chart may be in the form of a transparency, or a high-quality printed card. The spatial frequency varies along one axis, which is calibrated in terms of cycles/mm. We shall denote the maximum and minimum transmittances of the transparency by $T_{\max}$ and $T_{\min}$. It is viewed against a uniformly illuminated background and the test lens forms a real image. For a given spatial frequency, the resulting image intensities $I_{\max}$ and $I_{\min}$ are measures. The contrast ratios of the chart and image are defined, thus:

$$\mathrm{CR}_{\text{chart}} = \frac{T_{\max} - T_{\min}}{T_{\max} + T_{\min}} \tag{5.23}$$

and

$$\mathrm{CR}_{\text{image}} = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \tag{5.24}$$

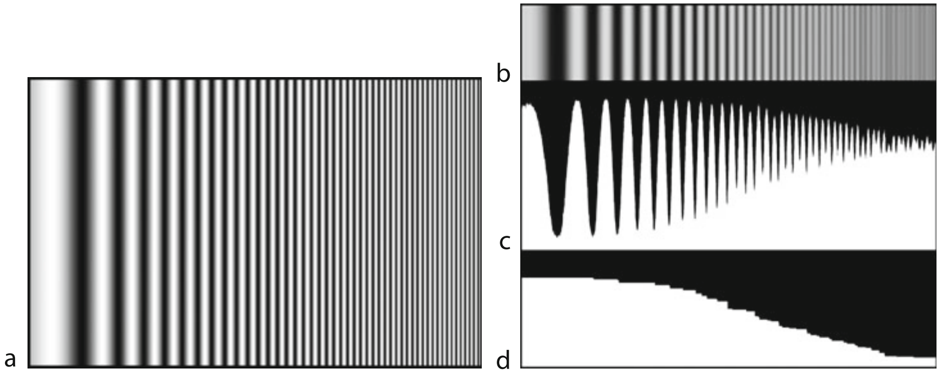

Fig. 5.38
Modulation Transfer Function (MTF) (a) Sine-wave test pattern. The horizontal scale is non-linear and may vary logarithmically, or as a polynomial ($X^{1.5}$ here). (b) The test pattern is photographed through the lens. (c) Intensity profile. (d) Contrast ratio versus spatial frequency. This is the MTF

The modulation transfer function (MTF) of the optical system is then defined to be

$$\mathrm{MTF} = \frac{\mathrm{CR}_{\mathrm{image}}}{\mathrm{CR}_{\mathrm{chart}}} \tag{5.25}$$

It should be understood that MTF is defined only for lenses, or optical systems that can form real images (i.e., have positive focal length). MTF is plotted against spatial frequency (➔ *Fig. 5.38d*). The resulting curve is very useful for assessing the quality of a lens.

It should be understood that the MTF curve is not a unique description of a lens, as it varies with the measurement conditions:

- Where the test chart is placed within the field. (Different MTF curves will be obtained at the centre and periphery of the visual field. Near the periphery, the MTF often varies with the orientation of the test chart.)
- The ratio of object distance to image distance. (This is known as the *conjugate ratio*. The object and its focussed image are called *conjugate pairs*.)

For this reason, MTF measurements are taken under standard conditions. Lenses with astigmatism or comatic aberration produce variable MTF curves, depending on the experimental arrangement. MTF curves are sometimes quoted for different wavelengths and will show the effect of chromatic aberration. While the MTF can be measured for a converging cylindrical lens, it must be remembered that it is only valid along one axis. The MTF can also be defined for concave mirrors (➔ Sect. 5.5).

The MTF is normally favoured over bar-chart test patterns for the reason given above. There are also theoretical advantages in using sine-wave test patterns, since the results can be analysed using Fourier transform methods. In practice, when a lens is used to image a point source, the result is an ill-defined spot of finite size. The intensity distribution of this spot defines the *point-spread function* and its 2-dimensional Fourier transform is called the *optical transfer function (OTF)* of the lens. The MTF is the magnitude of the OTF. The phase component of the OTF is unimportant in a non-coherent optical system, such as that found in a conventional Machine Vision installation. Other ways of measuring the response of a lens may use concentric-ring or radial sine-wave patterns (➔ *Fig. 5.39a–c*). It is simpler and cheaper, of course, to produce test patterns that consist only of binary elements: white and black. Hence, for many undemanding applications, testing the lens with a bar chart is perfectly adequate (➔ *Fig. 5.39d*). Again, this may consist of parallel stripes, radial patterns or concentric rings. The *Contrast Transfer Function (CTF)* is calculated from the image created by a bar chart in a similar way to the MTF. The resolution is normally expressed in terms of line pairs per mm.

5.5 Mirrors

5.5.1 Reflection

The familiar plane mirror is one of the simplest optical components. A ray of light striking the mirror at an angle θ is reflected so that the emergent ray is at an angle $-\theta$ (➔ *Fig. 5.40*). An important point to note is that the reflected light appears to come from a virtual image which is at the same distance behind the mirror as the object is in front of it. No light actually passes through the virtual image.

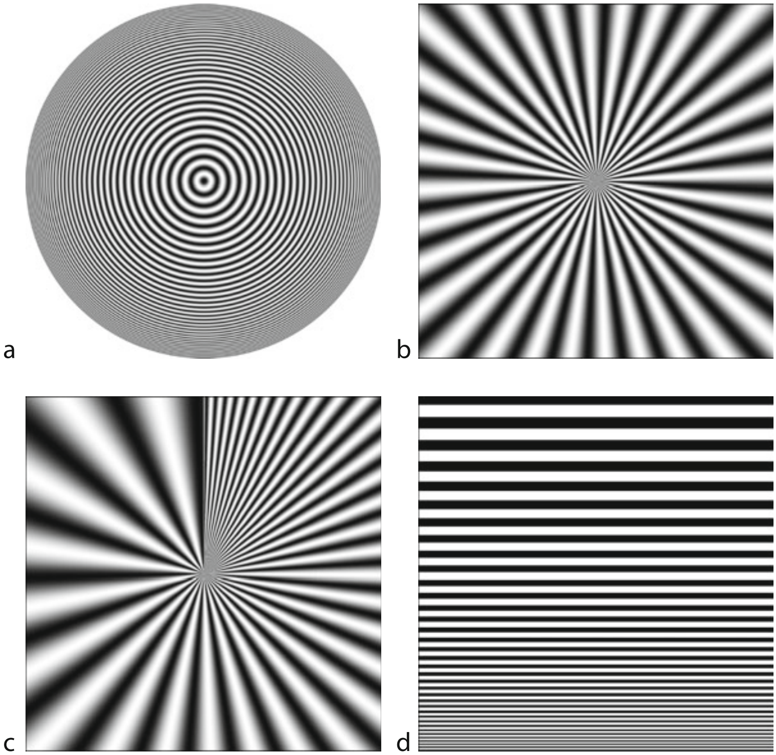

Fig. 5.39

Alternative patterns for testing optical systems. (a) Frequency varies with radius. (b) Angular frequency is constant. (c) Angular frequency varies logarithmically. (d) Bar chart (Binary image; usually calibrated in line pairs per mm)

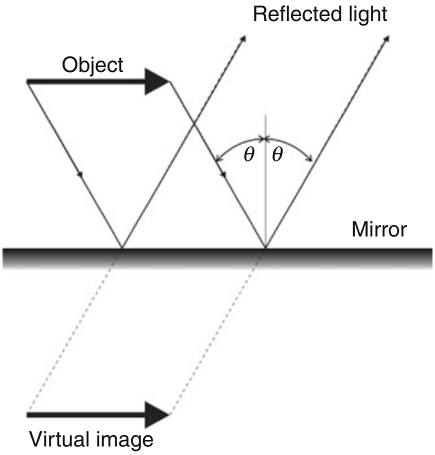

Fig. 5.40

Metal coating with protective film overlaid on it

Fig. 5.41
Ghosting in a second-surface mirror

Despite its familiarity, choosing a plane mirror is not as straightforward as we might suppose. Even a good quality domestic mirror can introduce significant aberrations or irregularities into an image. Standard, domestic quality mirrors are not accurate enough for most Machine Vision applications, since they rely on reflection from a "silvered" coating at the rear of a glass plate. Rear-silvered mirrors, also called *second-surface* reflectors, are liable to cause ghosting (➲ *Fig. 5.41*). A front-faced, or *first-surface*, reflector avoids this altogether but does expose the reflecting surface to contamination and physical damage. For certain low-resolution applications, where the image contrast is very high, it may be possible to employ domestic mirror tiles. However, high precision, first-surface mirrors should be used, unless there are clear indications that it is safe to do otherwise. For some applications a prism provides a better reflector that a simple coated plate of glass.

5.5.2 Factors to Be Considered When Choosing a Mirror

Five primary factors should be considered when specifying a mirror:

- Coating
- Substrate material
- Flatness or surface accuracy
- Cosmetic surface quality
- Shape and dimensions

5.5.3 Coatings for Mirrors

Metallic coatings are effective over a broad waveband and are relatively insensitive to the angle of incidence. The most commonly used coatings are summarised below. Multilayer dielectric coatings are able to maintain good performance over a specific range of wavelengths and are insensitive to small changes of angle of incidence. The improve durability and damage resistance. Like all optical surfaces, mirrors can easily be damaged by negligent, or over-zealous, cleaning.

Bare aluminium has a very high reflectance value but oxidizes over time. For this reason, protected aluminium is normally preferred.

Protected aluminium coating (➋ *Fig. 5.42*) is normally preferred to bare aluminium because its dielectric overcoat eliminates oxidation, with minimal sacrifice in performance. This is a good general-purpose coating for first-surface reflectors in the visible and near-infrared spectrum; the average reflectance is greater than 87% from 0.40 to 0.80 µm. Another type of dielectric coating prevents oxidation and maintains aluminium's reflectance in the UV waveband but must be cleaned with care.

Enhanced aluminium coating (➋ *Fig. 5.43*) is an aluminium coating overlaid with a durable multilayer dielectric film. This increases reflectance throughout the visible spectrum and provides protection from the environment and handling damage. The peak reflectance is 95% with average reflectance across the visible spectrum of 93%. Enhanced aluminium coatings are as durable and reliable as protected aluminium but have higher reflectance in the mid-visible region.

UV-enhanced aluminium (➋ *Fig. 5.44*) This provides an additional dielectric coating that prevents oxidation and preserves the reflectance of bare aluminium in the ultraviolet. The average reflectance is greater than 86% from 0.25 to 0.40 µm.

Bare silver tarnishes quickly in the atmosphere and hence is used only as a second surface coating, where it can be protected by an overcoat. It is often used on prism faces. Silver provides total internal reflection at high angles of incidence.

Protected silver (➋ *Fig. 5.45*) These coatings combine high reflectance throughout the visible and near infra-red spectral region with good durability. An overcoat and edge seal prevent the silver from oxidizing and deteriorating. Protected silver has higher reflectance than aluminium throughout the visible and near-infrared spectral region.

Bare Gold (➋ *Fig. 5.46*) This combines high reflectance throughout the near, middle, and far infrared with good tarnish resistance. However it is soft and easily scratched. Bare gold provides over 96.5% average reflectance from 0.70 to 2.0 µm.

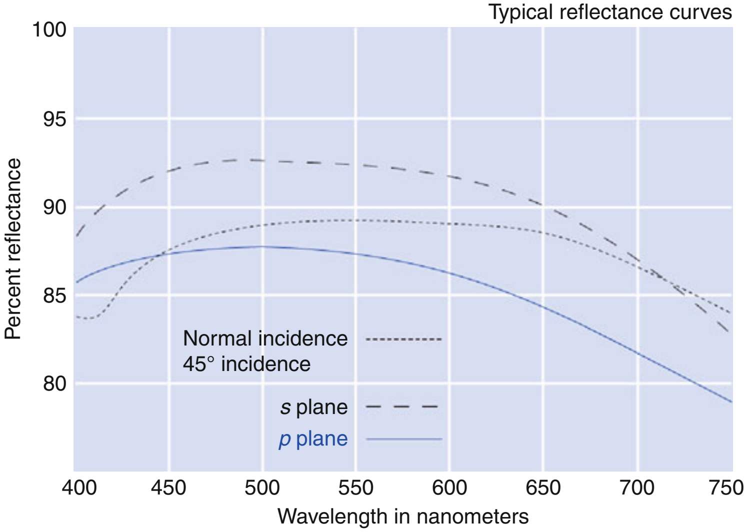

Fig. 5.42
Reflectance characteristic for a first-surface mirror with a protected aluminium coating

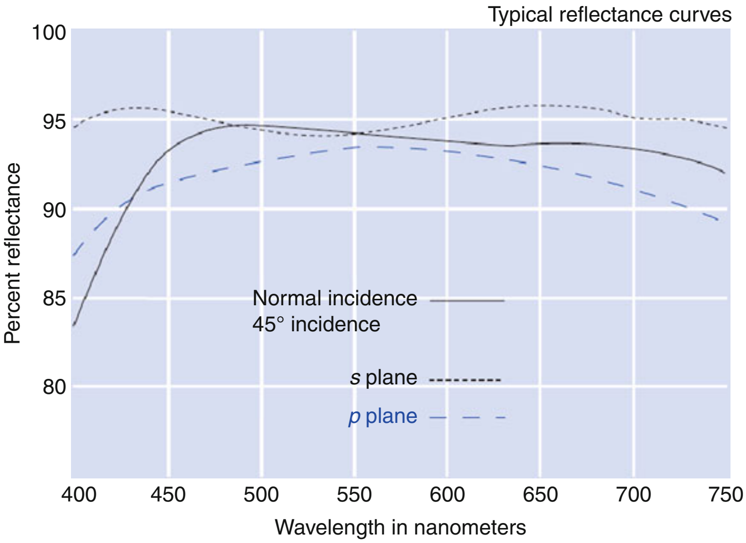

Fig. 5.43

Reflectance characteristic for a first-surface mirror with an enhanced aluminium coating

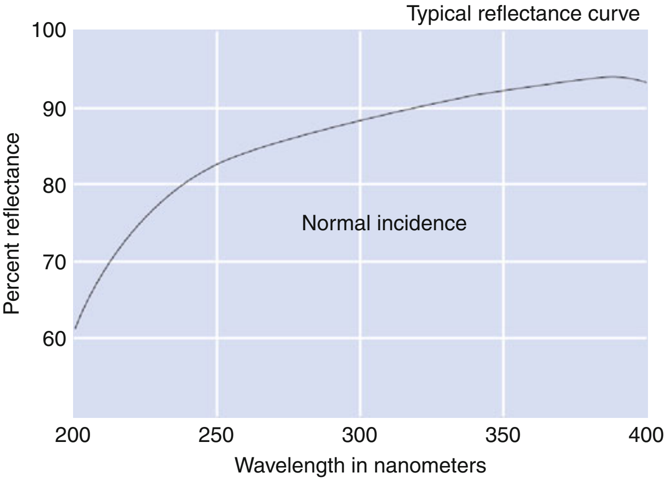

Fig. 5.44

Reflectance characteristic for a first-surface mirror with an enhanced aluminium coating. Notice that this mirror is operating in the ultra-violet region

Protected gold (➋ *Fig. 5.47*) This combines the natural spectral performance of gold with the protection of a durable dielectric overcoat, which improves abrasion resistance. It provides 95.5% average reflectance from 0.65 to 1.70 µm, and over 98% average reflectance from 2 to 16 µm.

MAXBRIte™ (➋ *Fig. 5.48*. MAXBRIte is a product of CVI Melles Griot, Inc.) These coatings provide high reflectance over a broad range of wavelengths. Most of the ultraviolet,

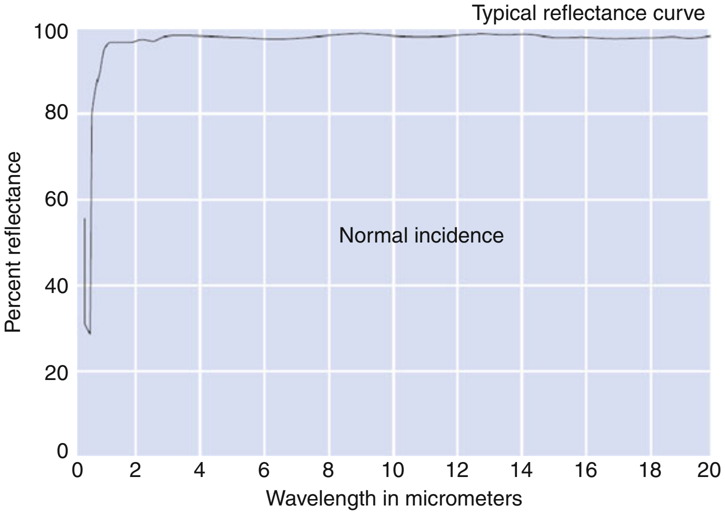

Fig. 5.45
Reflectance characteristic for a first-surface mirror with an protected silver coating. Notice that this mirror is operating in the infra-red region

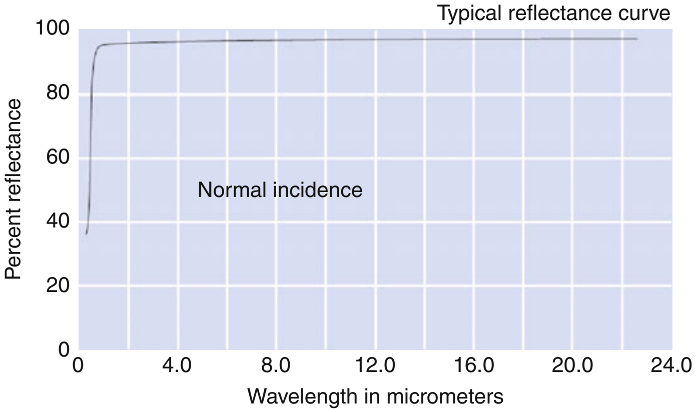

Fig. 5.46
Reflectance characteristic for a first-surface mirror with a bare gold coating. Notice that this mirror is operating in the infra-red region

visible, and near-infrared laser wavelengths are covered by one of the four MAXBRIte coating ranges. MAXBRIte coatings operate for angles of incidence as high as 45°. A minimum of 98% reflectance is achieved over a wide wavelength range at angles of incidence from 0° to 45°.

5.5.4 Substrate Materials

There are several different substrate materials available for mirrors. The main factors affecting choice are thermal expansion coefficient and cost. Mirrors can become temporarily distorted,

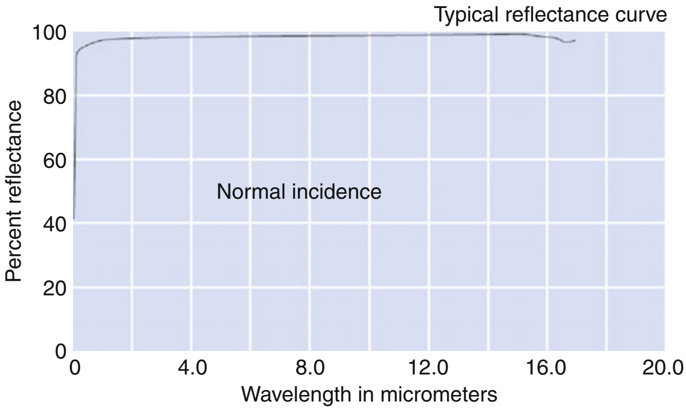

Fig. 5.47

Reflectance characteristic for a first-surface mirror with a protected gold coating. Notice that this mirror is operating in the infra-red region

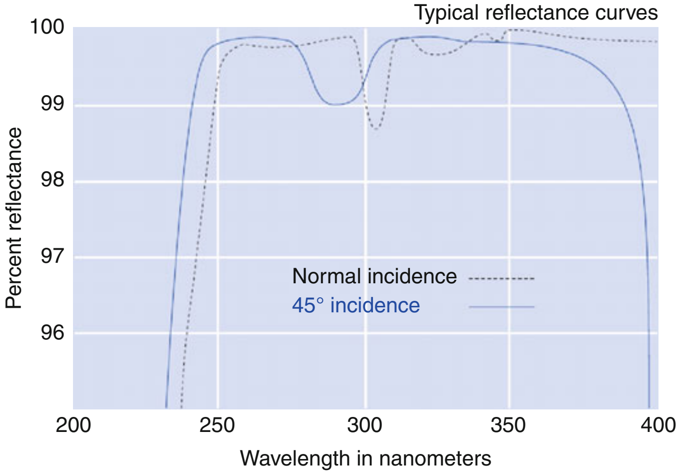

Fig. 5.48

Reflectance characteristic for a first-surface mirror with a MAXBRIte™ coating

or even permanently damaged, when subjected to wide temperature variations, particularly local thermal shock. For applications requiring high precision, low-expansion materials are a key requirement for a successful optical system.

- Optical crown glass is typically used in non-imaging applications, including light gathering or conventional beam-manipulation tasks. It has a relatively high coefficient of thermal expansion and is employed when thermal stability is not a critical factor.
- Low-expansion borosilicate glass is better known by its brand name: Pyrex® (Corning Inc). This material is well suited for high-quality first surface mirrors and optical flats but not for demanding light-transmission applications.

- Synthetic fused silica is a popular material for lenses and makes an excellent mirror substrate, as it has a very low coefficient of thermal expansion.
- Zerodur® (CVI Melles Griot, Inc) is a glass-ceramic material and offers high dimensional stability. It is not used in lenses and other transmissive components.

5.5.5 Quality

5.5.5.1 Flatness and Surface Accuracy

For plane mirrors, flatness is specified as *peak-to-valley* variations of surface height. (λ is the working wavelength.)

- 3λ per 25 mm, acceptable for nonimaging applications or noncritical visual optics.
- λ/4, the most commonly used general-purpose flatness specification. It is acceptable for the majority of research and industrial tasks.
- λ/10, suitable for imaging optics requiring low beam distortion.
- λ/20, needed for the most demanding laser-based setups.

5.5.5.2 Cosmetic Surface Quality

Defects that can be seen on the surface of an optical component reduce its cosmetic surface quality and are important, because they can scatter light. Scratches and digs are indentations on the surface that began much bigger and were not completely removed by polishing. Cosmetic surface quality is specified by two numbers. The first of these (*scratch*) indicates the width of scratches on the surface. This measure can be affected by the sharpness of the edges of the scratch and any unpolished area around it. The second number (*dig*) refers to the diameter of pits in the surface. These two parameters are not dependent on how accurately the surface matches the desired shape: flat, sphere, ellipse, paraboloid, etc. Surface accuracy leads to aberrations, while surface quality factors such as scratch and dig will introduce optical noise in the form of light scattered into the system.

- 80–50 is specified for applications typically not involving lasers, or situations where beam cross section is spread over a wide area.
- 60–40 is used for most research and scientific applications in the visible and infrared.
- 40–20 is appropriate where scattered light can begin to affect system performance, especially with small beam cross sections.
- 10–5 is reserved for high-power laser applications, where the presence of defects can lead to component damage.

5.5.5.3 Other Defects

Within a glass component, such as a lens or mirror, there may be various inclusions, such as air bubbles, striae (local variations in the index of refraction of the material), or physical inclusions, such as dirt and sand (a component of glass). Striae will appear as streaks within the glass that cause local distortion of an image. Minor local irregularities are often tolerated in window glass, domestic mirrors and other mass-produced glass products but can be serious in optical systems.

5.5.5.4 Surface Cleanliness

However, precisely it is made, no optical system will work properly if any one of its working surfaces is dirty. For this reason, it is common practice to enclose the optical components and camera within a sealed protective box (➋ Sect. 5.12. Also see Lighting Viewing Method 93 in ➋ Chap. 40). Light enters this enclosure via an optical window, which must be kept clean, either by regular manual maintenance or by some automated cleaning machinery. This may take the form of an air-jet purge, or washers/wipers like those fitted to automobiles. All optical surfaces on the light source must also be kept clean too. This includes the lamps and their optical diffusers/reflectors.

5.5.5.5 Shape and Dimensions

Optical quality plane mirrors are available in a wide range of sizes (5–200 μm), in both square and round formats. Very much larger, low precision mirrors can be made, using aluminised mylar film, or plastic sheeting (see Lighting Viewing Method 111 in ➋ Chap. 40).

5.5.6 Concave and Convex Spherical Mirrors [2]

Simple ray diagrams can be used to determine the magnification, image location, orientation (upright or inverted) and type of image (real or virtual) formed by concave and convex mirrors (➋ *Figs. 5.49* and ➋ *5.50* respectively). These diagrams provide useful qualitative information about object-image relationships, but do not provide precise quantitative information. To obtain this, the equations given below are used. These are applicable to both concave and convex mirrors, provided we observe the following sign convention:

Focal length, f
 Positive for a concave mirror
 Negative for a convex mirror
Object distance, S_1
 Positive (object is in front of the mirror)
Image distance, S_2
 Positive, real image, in front of the mirror
 Negative, virtual image, located behind the mirror
Object height, h_1
 Positive
Image height, h_2
 Positive if the image is upright (same orientation as the object)
 Negative if the image inverted compared to the object

Mirror Equation

$$1/f = 1/S_1 + 1/S_2 \tag{5.26}$$

Magnification Equation

$$M = S_2/S_1 = h_2/h_1 \tag{5.27}$$

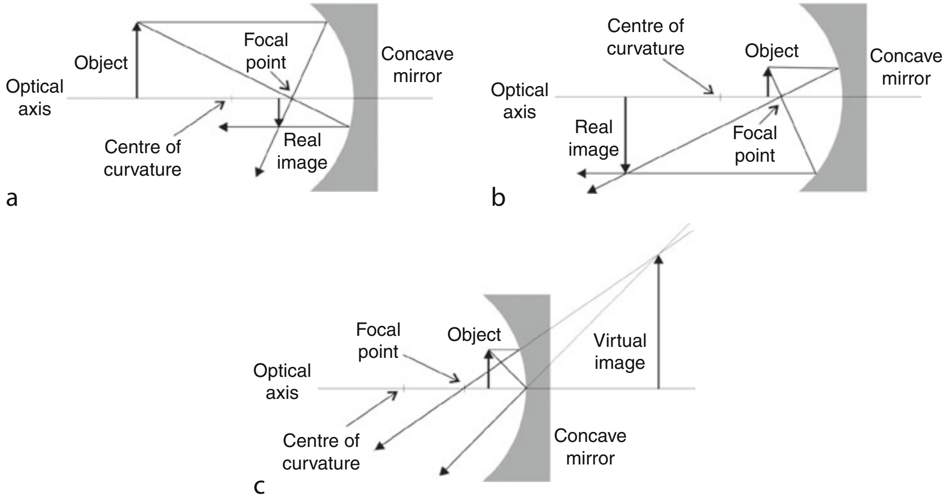

Fig. 5.49

Image formation by a concave mirror. (a) Remote object. When the object is at the centre of curvature, the image is real and inverted. (b) Object between the centre of curvature and the focal point. (c) Object closer than the focal point

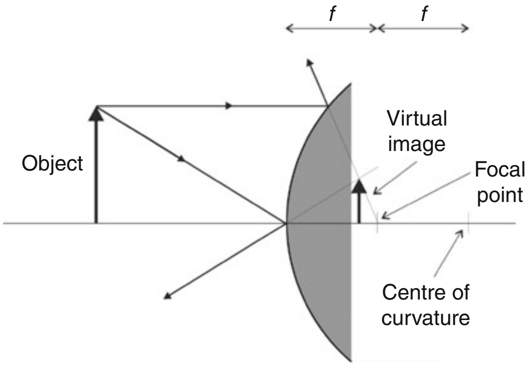

Fig. 5.50

Image formation by a convex mirror. The image is always virtual, upright and smaller than the object

These two equations can be combined to yield information about the image distance and image height if the object distance, object height, and focal length are known.

Using a spherical mirror with a wide aperture always produces some spherical aberration, resulting in blurred images. Incident rays travelling parallel to but a long way from the optical axis of a concave mirror are focussed closer to the reflecting surface than those near the optical axis (➋ *Fig. 5.51*). As with lenses, restricting the aperture reduces the aberration and improves focussing. Spherical aberration can be reduced by using a mirror with a parabolic reflecting surface. This creates sharper, clearer images than those produced by a spherical mirror. First-surface mirrors do not introduce any chromatic aberration.

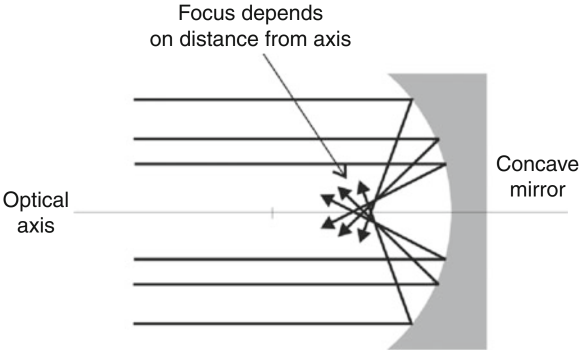

Fig. 5.51
Spherical aberration in a concave mirror. Rays that are parallel to but a long way from the optical axis are focussed closer than those that are near to it. The effect can be reduced by placing a small aperture in front of the mirror

5.5.7 Anamorphic Mirrors

An anamorphic mirror is a device that distorts the image geometry. While the curved mirrors discussed above are often made with spherical reflecting surfaces, only a small proportion of the total area of the sphere is actually used. As a result, the image suffers only a small degree of geometric warping. On the other hand, a full spherical mirror introduces quite severe distortion. Many forms of anamorphic mirror are available and have a variety of specialised uses:

- A cylindrical mirror can be used to adjust the aspect ratio of an image.
- A conical mirror can provide an all-round view of (part of) the internal surface a pipe.
- A complete sphere can provide an all-round view of a room. (The mirrors discussed earlier in this section are formed from small sections of a sphere and do not introduce much geometric distortion. A full sphere reflector does.)
- An elliptical mirror projects all of the light passing through one focus of the ellipse onto its other focus.
- A paraboidal mirror focuses a parallel beam onto a single point. Conversely, it projects all light passing through the focus of the parabola to create a parallel beam
- A concave toroidal mirror can be used to focus a narrow ring of light around (i.e., almost 180°) a cylindrical surface.

It is tempting to dismiss anamorphic mirrors as expensive playthings that serve no useful purpose. This is not the case! Using modern production methods, they are not particularly expensive to manufacture, even on a bespoke basis. First, a high quality master is made, possibly by employing computer-controlled machining methods. This master must then be polished so that its surface is smooth and free of pits, gouges, scratches and protrusions. A mirror surface is then created on it, using electrolytic deposition of a reflecting film, such as nickel. This is, in turn, coated electrolytically, with a highly reflective, hard and durable film. Rhodium reflects well throughout the ultraviolet, visible, and infrared wavebands. It also resists tarnish and oxidation, even at elevated temperatures (i.e., over 200°). Replicated reflectors made in this fashion are comparable in performance to conventional ground and polished

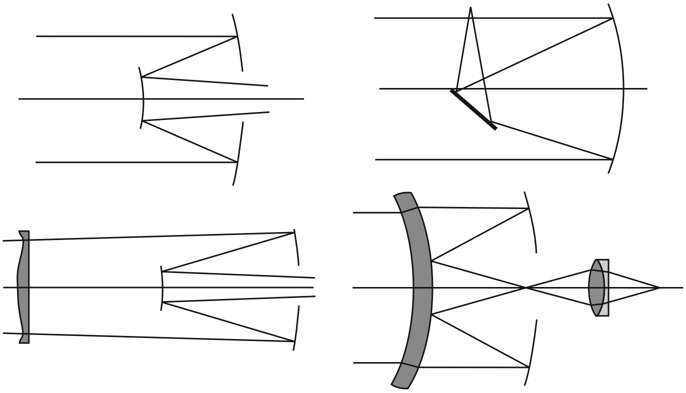

Fig. 5.52

Mirror-based optical systems. (a) Schwarzchild microscope/Cassegrain telescope. (The Gregory telescope is similar but uses a concave secondary mirror.) (b) Newton telescope. (c) Schmidt-Cassegrain telescope. (d) Cassegrain-Matsutov telescope

rhodium-coated mirrors. If the reader still remains unconvinced, remember that the cost of a vision system may actually be reduced by employing one relatively expensive optical component that reduces digital image processing costs/complexity!

Very large anamorphic mirrors (several metres across) can be made by stretching metallised mylar film over a box with a partial vacuum inside and numerous fine holes over its shaped surface. The taut film stretches to form a smooth surface that acts as a tolerably good reflector (Lighting Viewing Method 111 in Chap. 40).

Further examples of anamorphic mirrors are part of our everyday experience; they can be found on silver hollow-ware, brass musical instruments, chrome finish on automobile bumpers (fenders), kitchen equipment (e.g., chrome-plated kettles) and of course, in the fair-ground "Hall of Mirrors."

Photographers have long been familiar with the term *Catadioptric Lens*. This is a combination of one, or more, curved mirrors and a lens assembly. (*Figure 5.52* shows four typical designs for a catadioptric telescope.) It is possible to build a short, light-weight catadioptric device that has a very long focal length. While catadioptric systems use both lenses and mirrors for image formation, *catoptric* systems which use only mirrors. The term *dioptric* is used when referring to optical systems that use only lenses.

5.5.7.1 Spherical Mirror ("Witch Ball")

See *Figs. 5.53* and *5.54*. Prior to the introduction of CCTV surveillance, it was common to find hemi-spherical mirrors in shops, allowing the shop-keeper to monitor suspected thieves. Mirrors of this type are often placed at hazardous junctions on minor country roads to allow drivers to see oncoming traffic. By placing an hemi-spherical mirror above a camera looking upwards, it is possible to obtain an all-round (360°) view of a room. Mobile robots often use this arrangement, enabling them to navigate around obstacles. The geometric

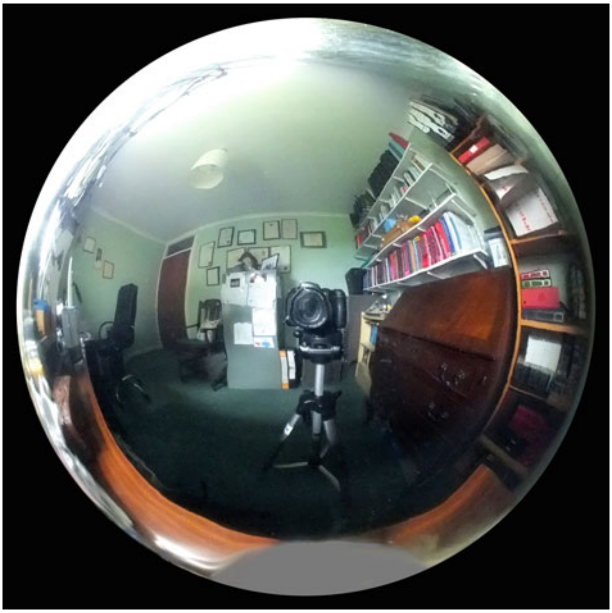

Fig. 5.53
Image warping using a spherical mirror ("Witch Ball")

distortion produced by a spherical mirror is evident in *Fig. 5.53* (Look at the shape of the reflections of the brown table-top and shelving on the right.) Notice that it is possible to locate the light sources: the window and the electric light. This provides the basis for a useful way of characterising the positions and shapes of light source(s) within an Automated Visual Inspection cell [3]. In order to do so, it is necessary to translate the Cartesian address of each point in the image detected by the camera into spherical coordinates, bearing and azimuth. The formulae for doing this are well known [4].

5.5.7.2 Cylindrical Mirrors

Cylindrical mirrors can magnify/minify one axis of an image, while leaving the orthogonal axis unaltered. Both convex and concave versions are available. The cross-section may be circular, elliptical, parabolic, hyperbolic, or polygonal. Within the plane of maximum curvature (YZ in *Fig. 5.55*), a cylindrical mirror with a circular cross-section behaves like a standard curved mirror; Eqs. 5.26 and 5.27 apply close to the X-axis. Within the orthogonal plane (XZ), the curvature is zero and it behaves like a plane mirror.

An example of the warping effect of a convex cylindrical mirror (circular cross-section) is shown in *Fig. 5.56*. Also see [5]. These mirrors were popular in Scotland after the Jacobite Rebellion, when possession of an image of Charles Stewart was illegal. However, his ingenious supporters realised that it was possible to circumvent the law by keeping a warped image of him. When this was viewed via a cylindrical mirror, an undistorted image of the Scottish hero/outlaw appeared [6]. A convex cylindrical mirror would be useful on a mobile robot, to

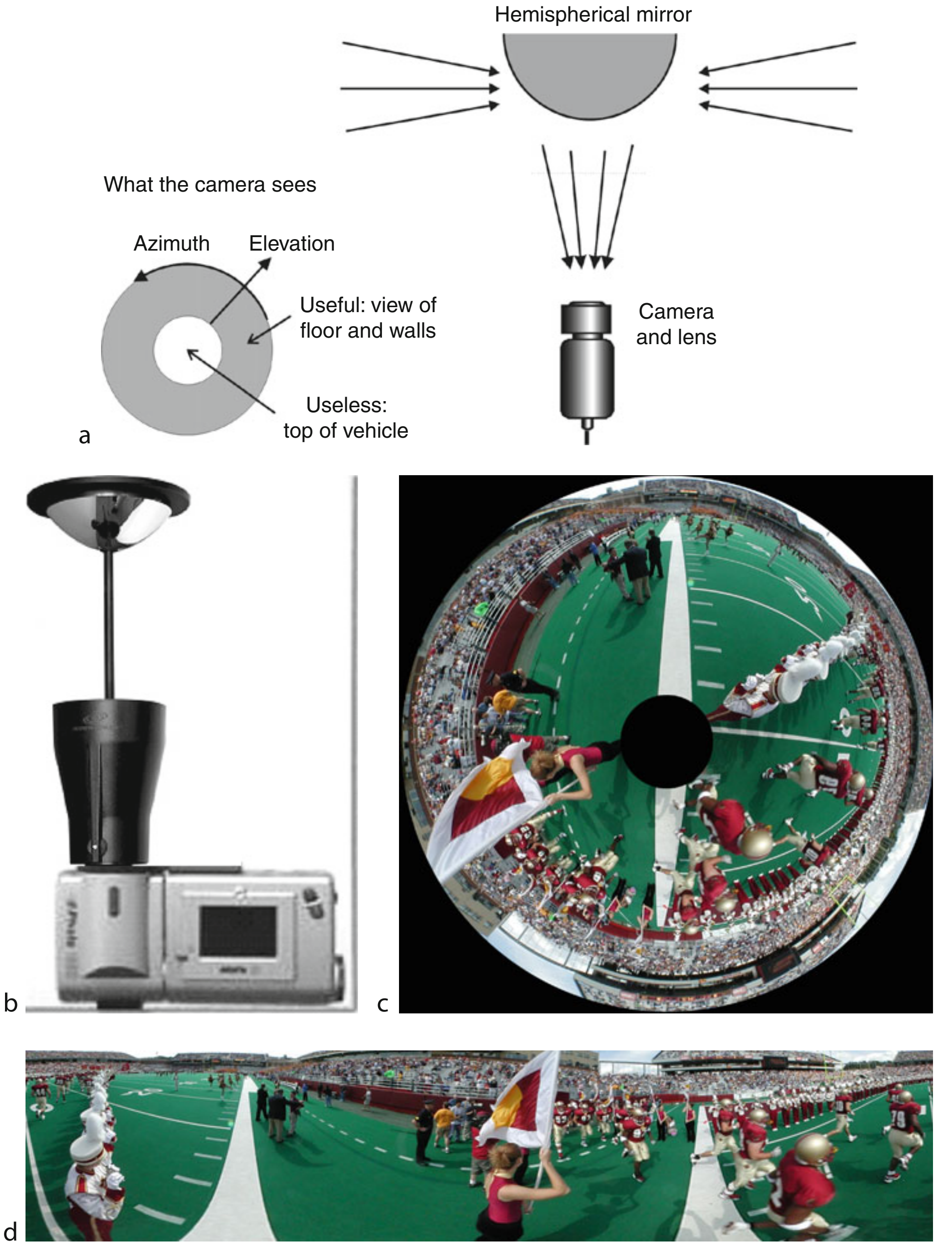

Fig. 5.54

An hemispherical or parabolic mirror can be mounted above a camera to provides a 360° view. Other mirror types (hyperbolic and conical mirrors) can used instead, depending on the range of azimuthal angles to be viewed. (a) Arrangement of the optical system. (b) ''Oneshot'' camera fitted with a parabolic mirror. (c) Image obtained from the ''oneshot'' camera. obtain a wide-angle view of the scene ahead, and could also be used for surveillance of a long thin scene, such as a conveyor belt, walk-way or staircase. Concave cylindrical mirrors with a parabolic cross-section are used in laser scanners. Here, they have two possible uses: ensuring that the projected beam is always paraxial and for gathering light. A concave cylindrical mirror could be used for focussing an elongated linear light source (e.g., a long fluorescent tube) to form a narrow line that could, for example be projected across conveyor belt. The field of view of a line-scan camera can also be broadened using a mirror of this type. Very large cylindrical mirrors are relatively easy to make. It should therefore be borne in mind that a 2-dimensional imaging system can be constructed with two such mirrors. It is therefore possible to build large telecentric optical systems (➋ Chap. 6) that would be prohibitively expensive, if not impossible, using lenses.

5.5.7.3 Parabolic Mirrors

A set of parallel rays can be focussed to a single point by a parabolic mirror (➋ *Fig. 5.57a*). For this reason, a parabolic mirror is often used as the primary (objective) element in an

b

Fig. 5.57
Parabolic mirror. (a) Paraxial rays are focussed to a single point. (b) A point source placed at the focal point generates a parallel beam

astronomical telescope. Conversely, a small light source placed at the focus of a parabolic mirror will form a beam whose rays are nearly parallel (➋ *Fig. 5.57b*). It is often much easier/ cheaper to generate a collimated beam of light with a single paraboidal mirror than with an array of lenses. This arrangement is particularly useful if the scene to be illuminated is far away, or if it is necessary to project a spot of light with a well-defined diameter, without illuminating its neighbourhood. Using a parabolic mirror, it is possible to illuminate the bottom of a deep well, without placing any optical or lighting equipment inside it.

By placing a small camera with a wide field of view at the focal point of a concave parabolic mirror, it is possible to make a telecentric imaging system. Notice however, that the camera "sees" a small image of itself.

Since it is relatively easy to manufacture a parabolic mirror, it is likely to be much cheaper than a lens assembly for any task involving the inspection of objects bigger than about 100 mm. Making a large objective lens can be very expensive.

5.5.7.4 Elliptical Mirrors

Elliptical reflectors have various applications in condensing and illumination systems. A single concave elliptical mirror can replace a complete multi-element condenser system. Elliptical mirrors possess one very valuable property: any light passing through one of the focal points of the ellipse (F_1, ➋ *Fig. 5.58*) will also pass through the other focal point (F_2). Hence, by placing a small light source at focal point F_1, it is possible to project a lot of light onto a small area centred on focal point F_2.

5.5.7.5 Conical Mirrors

A conical mirror was used for inspecting the internal surfaces of pipes as early as 1924 [10]. Also see [11] (➋ *Fig. 5.59*). Conical mirrors have also been used to provide a mobile robot with a panoramic (360°) view of it surroundings. (Cylindrical, spherical, hyperbolic and toroidal mirrors have also been used for this purpose. [12]).

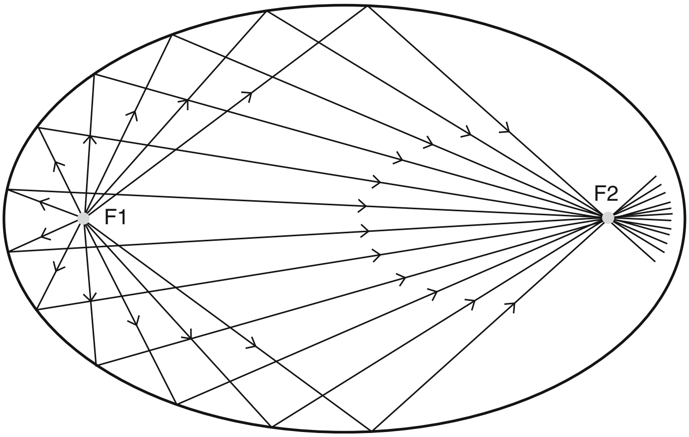

Fig. 5.58
Elliptical mirror. All rays emanating from focus F1 pass through F2

5.5.7.6 Toroidal Mirrors

The flared end of a trumpet indicates some of the possibilities for image formation provided by toroidal mirrors. Since it is rotationally symmetrical, a toroidal mirror is quite easy to form and polish. Like cylindrical mirrors, toroidal mirrors can be made with a variety of cross sections: circular, elliptical, parabolic, hyperbolic or polygonal. Again, both concave and convex versions are possible. A toroidal mirror can be either converging (i.e., directing light towards the central axis of symmetry) or diverging (directing light away from it). Hence it is possible to illuminate/view a rod-like object placed at the centre of the torus, or the inside of a pipe. Convex toroidal mirrors with various cross sections have been used to provide all-round viewing for mobile robots: the camera is placed coaxially with the mirror and "looks" upwards. A concave toroidal mirror can focus a hollow cylinder of light to form a bright ring of light all round a cylinder. The main point to note is that toroidal mirrors offer numerous possibilities for both image acquisition and light projection; the vision system designer simply needs to exercise his/her imagination a little!

5.6 Filters

Optical colour filters can provide significant improvement in contrast. For example, in *Fig. 5.60* the red and blue regions are more easily distinguished from each other if either a long-pass or short-pass filter is inserted in the optical path. In this case, the filter was placed in the illumination path-way, as this avoids distorting the image.

Two types of colour filter are in widespread use. These employ either the bulk properties of coloured materials (e.g., glass or gelatine), or interference effects in a multi-layer dielectric film. Interference filters enable rapid and accurate measurement of the optical energy within a well-defined spectral band. Narrow-band filters provide a means of isolating, or blocking, wave-bands just a few nanometres wide, sometimes even less. This is achieved without the use of

prisms or gratings. For example, a single line in the emission spectrum of a flame, a sodium or mercury lamp can be monitored without confusion from other nearby lines. The light from a diode laser line-projector (used for 3D shape measurement) can be detected even when the scene is in bright sunlight. Coloured-glass and gelatine filters are incapable of such fine discrimination as this. Interference filters are based on multi-layer (thin-film) devices. They are often termed “dielectric devices” but may contain metallic layers as well. Indeed, broad-band filters almost always contain a metallic layer in their spacers. Interference filters come in three types:

(a) Band-pass filters transmit over a defined wave-band while rejecting longer and shorter wavelengths.

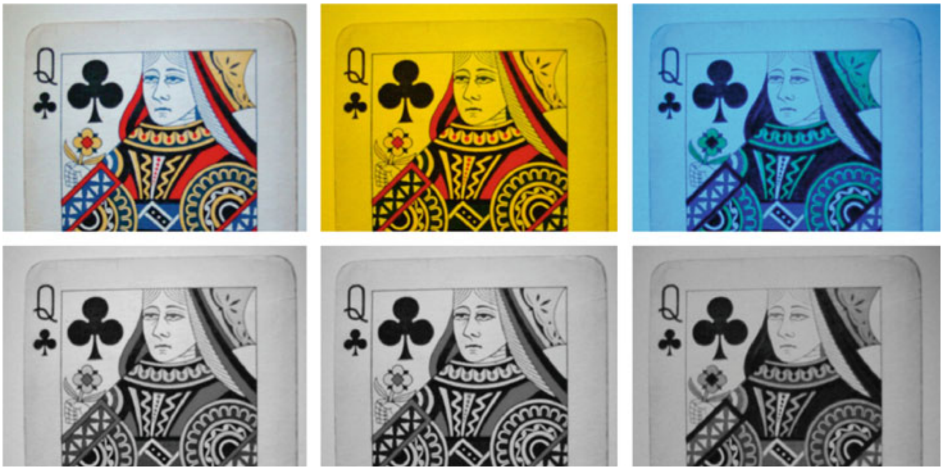

Fig. 5.60

(c) Short-pass interference filter placed in the illumination path. Cut-off 0.550 µm. (d) Intensity component of (a). (e) Intensity component of (b). (f) Intensity component of (c)

(b) Band-stop block light within a defined wave-band while passing longer and shorter wavelengths.
(c) Long-pass transmit light with wavelengths *above* a certain critical value and block others.
(d) Short-pass transmit light with wavelengths *below* a certain critical value and block others.

5.6.1 Interference Filters

Narrow-band interference filters operate on the same principle as the Fabry-Perot interferometer; they both rely on the interference of multiple reflected beams (➋ *Fig. 5.61*). Incident light undergoes multiple reflections. When there is no phase difference between emerging wavefronts, constructive interference occurs; each transmitted wave-front has undergone an even number of reflections. The air gap of the Fabry-Perot interferometer is replaced by a thin layer of dielectric material with a half-wave optical thickness corresponding to the wavelength of the desired transmission peak. By analogy with interferometers, the simplest band-pass interference filters are sometimes called cavities. Two, or more, band-pass filters can be deposited, to form a multiple-cavity filter (➋ *Fig. 5.61*). Increasing the number of cavities has a significant effect on the shape of the passband. The resulting overall pass-band transmittance is given approximately by the product of the pass-bands of individual cavities. By using multiple-cavity filters, it is possible to obtain sharp cut-off, improved near-band rejection, and “square” pass-band peaks.

5.6.2 Points to Note

The spectral transmission characteristics of several different types of interference filters are shown in ➋ *Figs. 5.62–5.69*.

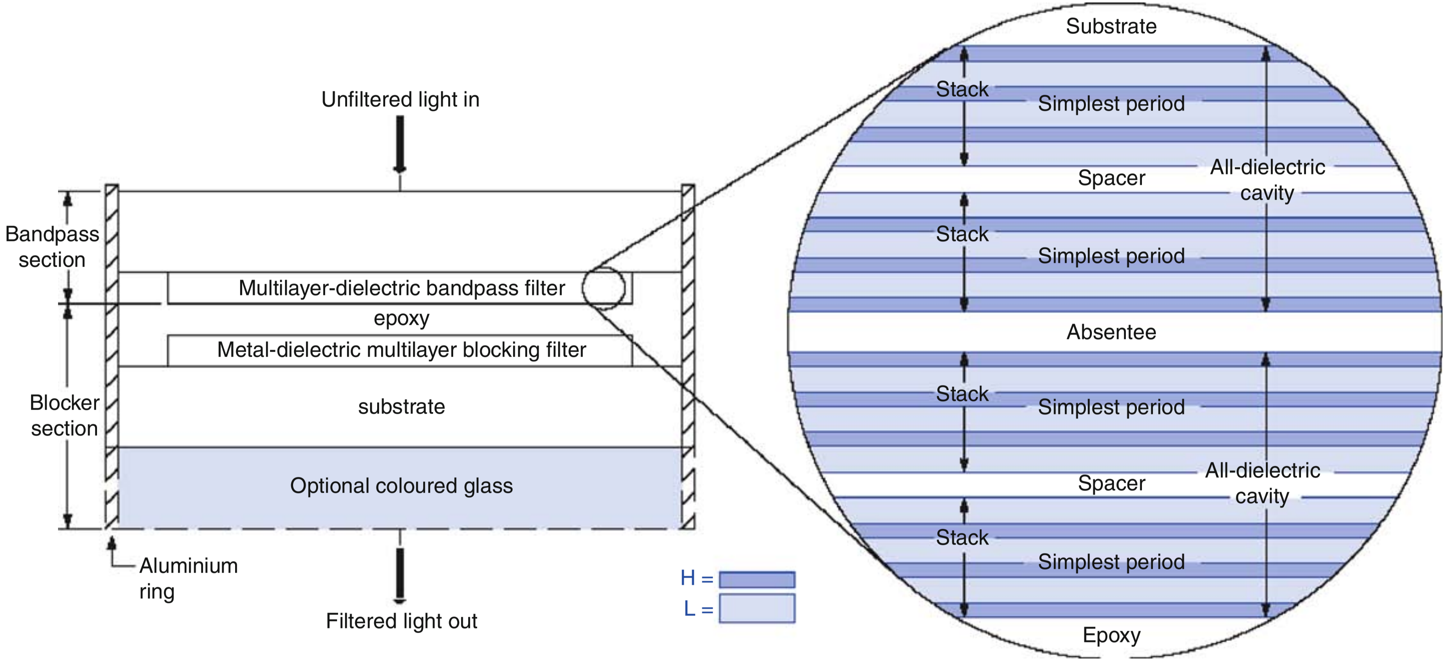

Fig. 5.61
Construction of a band-pass interference filter

5.6.2.1 Dichroic Filters/Mirrors

A dichroic filter, or dichroic mirror, passes light within one part of the spectrum, while reflecting others. Dichroic mirrors are usually characterized by the colour(s) that they reflect, rather than those that they transmit. These devices operate using interference in a multi-layer thin film and hence can have sharp cut-off characteristics. Many quartz-halogen lamps have an integral dichroic reflector. They were incorporated into slide projectors to avoid melting the slides. They are now widely used in domestic "mood" lighting and to illuminate product and poster displays. So-called *hot mirrors* reflect wavelengths in the infra-red wave-band and transmit visible light. (*Cold mirrors* reflect VIS and transmit IR.) Since they absorb very little energy, a hot mirror does not become as hot as a conventional IR-absorbing filter. Dichroic filters are also widely used in multi-sensor colour cameras to separate the RGB channels optically. Dichroic and Trichroic filters in the form of solid-glass prisms are discussed in ❯ Sect. 5.8.

5.6.2.2 Tilting a Filter Alters Its Cut-Off Wave-Length

A useful characteristic of interference filters is that transmittance spectrum shifts to shorter wavelengths as they are tilted from normal to oblique incidence. This applies to long-pass, short-pass and band-pass filters. (As the angle of tilt is increased in filters constructed with metallic layers, the transmittance peak splits into two orthogonally polarised peaks which shift to shorter wavelengths at different rates. However, filters made with all-dielectric multilayers do not suffer from this disadvantage.) This shift in the cut-off wave-length is very useful in fine tuning band-pass filters to suit the application requirements.

5.6.2.3 Filter Orientation

A good rule of thumb, especially important if there is a risk of overheating, is that interference filters should be oriented with the shiniest (metallic) and nearly colourless side toward the light source. This will minimize thermal load on the component. Notice, however, that reversing the orientation of a filter will have no effect on its transmittance near, or within, the pass-band.

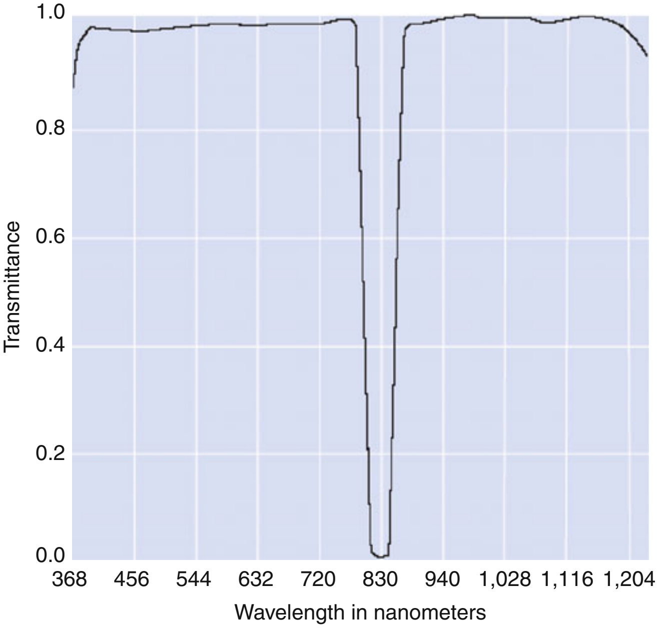

Fig. 5.69
Typical band-stop filter characteristics ("notch filter"). Notch filters are useful for blocking a single wavelength, such as a laser line, while allowing a wide spectral band on both sides of the blocked wavelength to pass with little attenuation. High rejection at the blocked wavelength allows these filters to be used in applications such as laser-induced fluorescence. The wavelength that is blocked can be shifted to a shorter wavelength by tilting the filter so that the angle of incidence is not 0°. Typically, a shift of up to 1% of the nominal wavelength can be achieved with a tilt of 10–15°

5.6.2.4 Temperature Effects and Thermal Shock

The transmittance spectrum of an interference filter is slightly temperature dependent. As temperature increases, all layer thicknesses increase. At the same time, all of their refractive indices change. These effects combine in such a way that the transmittance spectrum shifts slightly to longer wavelengths with increasing temperature. The thermal coefficient is a function of wavelength, as shown in the following table. Interference filters are typically designed for use at or near 20°C. Unless band-pass filters with extremely narrow pass-bands are used at very different temperatures, the transmittance shifts are negligible; standard interference filters can be used at temperatures down to −50°C. Thermal contraction will result in permanent filter damage below this temperature. High-temperature limits depend on filter design: 70°C is a safe and conservative limit for filters of this type, although some can tolerate temperatures up to 125°C. As a general rule, it is unwise to subject interference filters to thermal shock, especially close to the lower limit of −50°C. Temperature change rates should not exceed 5°C/min.

5.6.3 Coloured-Glass Filters

To improve stability and reliability, use high-grade glass (e.g., Schott glass) filters in preference to gelatine filters. The spectral properties of coloured-glass filters are uniform over their entire aperture and are invariant with temperature below 250°C (482°F). Unlike interference filters, their spectral properties are insensitive to the angle of incidence (➲ *Figs. 5.70* and ➲ *5.71*).

At any specific wavelength the external transmittance, *T*, of a coloured-glass filter is given by the approximate formula

$$T = t_1 t_2 T_\mathrm{i} \tag{5.28}$$

where t_1 is the transmittance of the first air-glass interface, t_2 is the transmittance of the second airglass interface, and T_i is the internal transmittance. T_i is proportional to the width of the filter material. This formula neglects possible multiple reflections that may occur between interfaces. The interface transmittances t_1 and t_2 are equal, and their product $t_1 t_2$ is called the correction factor. This is related to the refractive index n of the glass by the following formula

$$t_1 t_2 = 1 - 2\left(\frac{n-1}{n+1}\right)^2 + \left(\frac{n-1}{n+1}\right)^4 \tag{5.29}$$

5.7 Neutral Density Filters (ND Filters)

The purpose of a neutral density filter (ND filter) is to reduce the intensity of the light passing through it. Ideally, it attenuates all wavelengths within the working spectrum equally. Neutral density filters allow greater flexibility of aperture settings when working in extremely bright conditions. (Recall that the depth of field of a lens is dependent on the size of its aperture.) An ND filter allows the aperture to be opened in a bright environment, while keeping the depth of field small. In some situations, having a small depth of field is an advantage; back-ground detail does not produce sharp edges. Neutral density filters are particularly useful when catadioptric devices are to be employed.

5.7.1 Graduated ND Filters

The attenuation varies across the face of a graduated ND filter. This type of device is useful when one region of the scene being viewed is very bright, compared to the remainder.

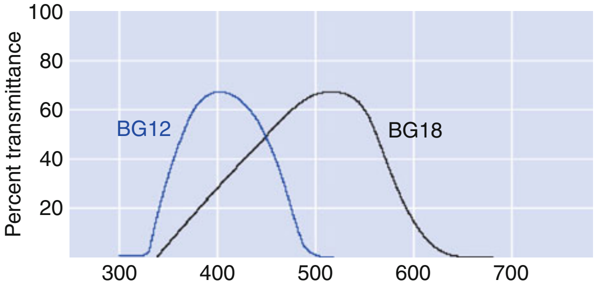

Fig. 5.70
Typical coloured glass filter characteristics (band-pass) for two different types of material

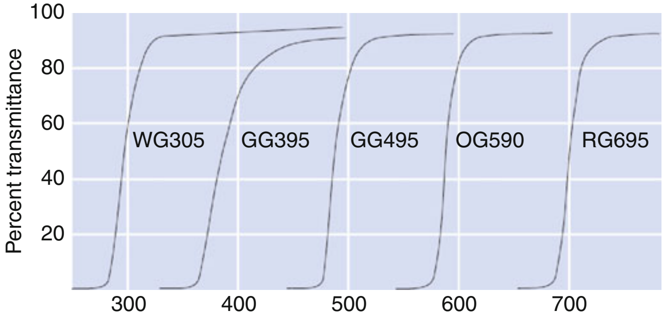

Fig. 5.71
Typical coloured glass filter characteristics (long-pass) for five different types of material

Photographers have long used graduated ND filters when trying to capture sunset images. The attenuation profile may be abrupt (*hard edge ND filter*), or smooth. in which case it may vary linearly, logarithmically, or otherwise non-linearly with position. Using a graduated ND filter effectively allows the camera's dynamic range to be increased. This is useful when the position, or size, of a very bright object is to found relative to a much darker one, using a single camera. Graduated neutral density filters might have two or more step-like transitions between regions of constant attenuation. They are also made with the intensity varying with angular position, or as a function of distance from the central point. Again, the transitions may be smooth or abrupt. Stepped ND filters are useful for checking the linearity of the intensity scale of a camera, since they have well-defined attenuation values.

5.7.2 Metallic ND Filters

Metallic ND filters are made with annealed glass, or optical-quality synthetic fused silica substrates. Vacuum deposition is used to apply a thin film of several special metallic alloys to the substrate. These alloys are chosen to create a spectral-density curve that is flatter over a wider range than the curves of most pure metals. Substrate materials are chosen for homogeneity, transmittance uniformity, finishing characteristics, and (in the case of synthetic fused silica) ultraviolet transmittance. Substrates are polished to minimize light scattering. Metallic ND filters can be used at any wavelength between 0.20 and 2.50 μm (fused silica), or between 0.350 and 2.50 μm (BK7 glass). Their operation depends on absorption in, and reflection from the thin metallic film. When used in high-intensity (laser) beams, ND filters should be oriented with the metallic film facing toward the source to minimize substrate absorption and heating. Alloy films are corrosion resistant and do not age at normal temperatures. Adhesion of alloy films to their substrates is tenacious and unaffected by moisture and most solvents from −73°C to 150°C. Exposure to higher temperatures should be avoided because it causes film oxidation and increased transmittance. These filters are not suitable for use with high-power lasers.

5.7.3 Absorptive ND Filters

Absorptive ND filters provide an alternative to metallic ND filters. The light attenuating characteristics of this type of filter is a function of its material properties and the filter thickness. Since there can be large variations between glass melts, actual thickness and glass material may vary in order to guarantee optical density. These filters are recommended for low-power applications only, because of their absorbing properties.

Despite their inherent simplicity, neutral density filters are not perfect. Like any other thin glass plate, they introduce some aberrations, they scatter light and do not have a perfect spectral response. However, these are minor effects and do not cause serious problems for most applications. More importantly, they do not respond well outside the visible waveband and it may be necessary to add UV- and/or IR-blocking filters.

5.8 Prisms

Prisms are blocks of glass, or some other transparent optical material, with flat polished sides, arranged at precisely defined angles. They are used in four principal ways:

(a) To decompose light into its constituent wavelengths.
(b) To deflect/invert/rotate a light beam.
(c) To split a light beam into two secondary beams, while preserving its image structure.
(d) To separate light rays according to their polarisation.

5.8.1 Aberrations

Prisms introduce aberrations when used with convergent or divergent beams of light. Using prisms with collimated, or nearly collimated light, will reduce aberrations to a minimum. Since light of different wavelengths is dispersed by a prism it may be necessary, in some applications, to use monochromatic or narrow-band lighting.

5.8.2 Total Internal Reflection

Rays that are internally incident upon an air/glass boundary at angles greater than the critical angle are reflected with 100% efficiency, regardless of polarisation. The critical angle is given by θ_{critical} where

$$\theta_{\text{critical}} = \sin^{-1}\left(\mu_{\text{air}}(\lambda) \Big/ \mu_{\text{glass}}(\lambda)\right) \tag{5.30}$$

Note that the refractive index of glass, μ_{glass}, is a function of wavelength. (μ_{air} does not vary significantly, over the visible waveband.) Reflectance decreases rapidly at angles of incidence less than the critical angle. This effect is used in prismatic beam-splitters to select rays with different polarisations. (See ➤ Sect. 5.8.5)

5.8.3 Equilateral Dispersing Prism

Dispersive prisms are able to decompose light into its constituent wavelengths. These are seen by human beings as having different colours. The refractive index of glass differs slightly for different

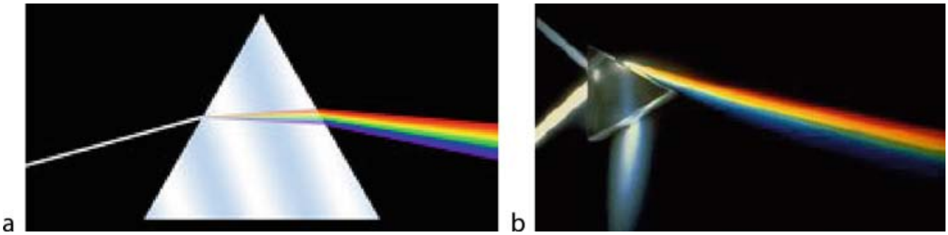

Fig. 5.72
Standard equilateral triangle (i.e., 60°/60°/60°) prism. (a) Idealised schematic. (b) In practice, the incoming light beam is partially reflected at the first and second surfaces, as well as producing a dispersed beam

wavelengths of light (strictly, optical frequencies). Rays with different wavelengths are diverted through different angles; blue light is slowed down more than red light and is therefore diverted more than red light. In his famous experiment, Isaac Newton used a prism to disperse a beam of sun-light, creating a rainbow-like spectrum (➲ *Fig. 5.72*). He then used a second prism to reconstitute white light from a rainbow-like spectrum, thereby allowing him to study the physics of colour. Reflection losses are minimized for unpolarised rays travelling parallel to the base of the prism. This is called the *minimum deviation condition* and occurs when the angles of the entrant and emergent rays, relative to their respective surface normals, are equal.

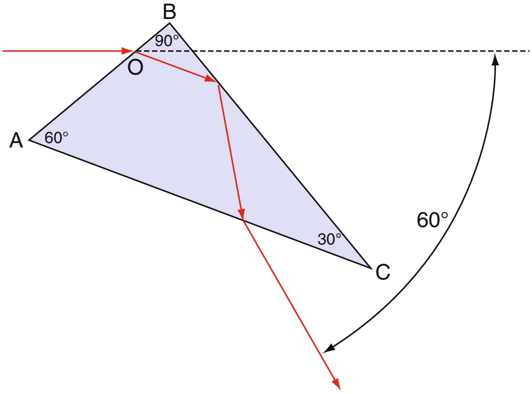
Dispersive prisms are used exclusively for spectral analysis and do not have any direct role in image formation. While a prism can be used for performing spectral analysis, the same function can often be achieved better by a fine grating.

5.8.4 Abbe and Pellin-Broca Prisms

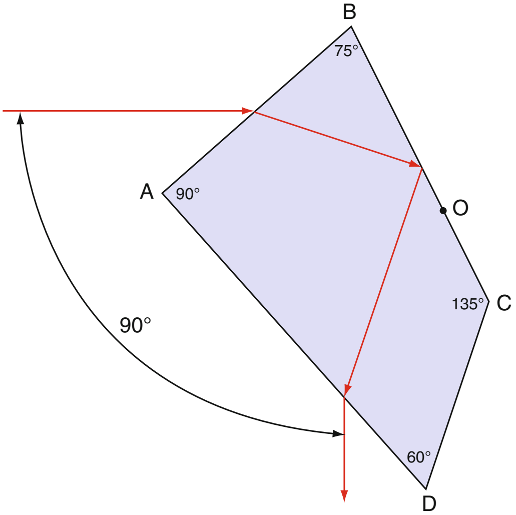
An Abbe prism has angles of 30°, 60° and 90° (➲ *Fig. 5.73*). The light beam undergoes total internal reflection from the hypotenuse face. One particular wavelength of light is deviated by exactly 60°. (This is the minimum possible angular deviation; all other wavelengths are deviated by greater angles.) By rotating the prism about the point O, the wavelength of the emergent ray that is deviated by 60° can be altered. The Pellin-Broca prism is shown in ➲ *Fig. 5.74*.

5.8.5 Dichroic and Trichroic Prisms

A *dichroic* prism splits light into two beams of differing wavelength (colour) and consists of one or more glass prisms with dichroic optical coatings on certain faces. These act as wavelength-sensitive beam-splitters and are often used in camcorders and good quality digital cameras. A *trichroic* prism assembly is a combination of two dichroic prisms and is typically used to decompose an image into three components: red, green and blue. A trichroic prism can be used in reverse to combine three monochromatic beams (e.g., from LEDs) to form a single beam and has potential application in a programmable projector that allows different mixtures of red green and blue light to be created (➲ *Fig. 5.75*).



■ **Fig. 5.73**
Abbe prism



■ **Fig. 5.74**
Pellin-Broca prism. Rotating the prism about point O (BO = 2OC) causes a ray with a different wavelength to emerge with a deviation of 90°

5.8.6 Reflecting Prisms

A right-angle prism can be used to deflect a beam of light by 90°, or to retroreflect it (➲ *Fig. 5.76*). Little light is lost, since total internal reflection occurs at the hypotenuse face. To improve the performance, antireflection coatings should be used on the entrance and exit faces. Two prisms can be used to rotate an image by 180°. If the hypotenuse face is given a metallic (“silvered”) coating, the prism may be used as an external front-surface mirror.

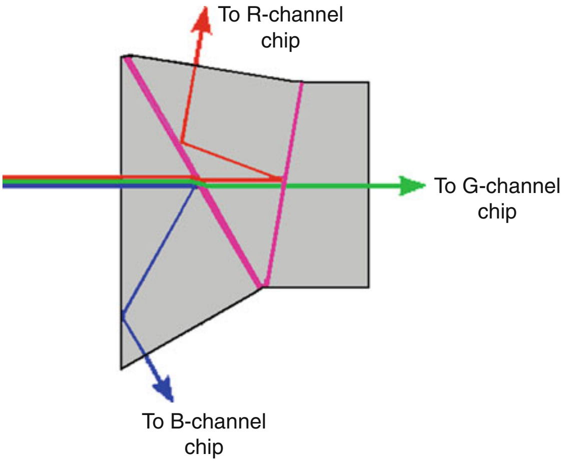


Fig. 5.75
Trichroic prism

5.8.7 Amici Roof Prism

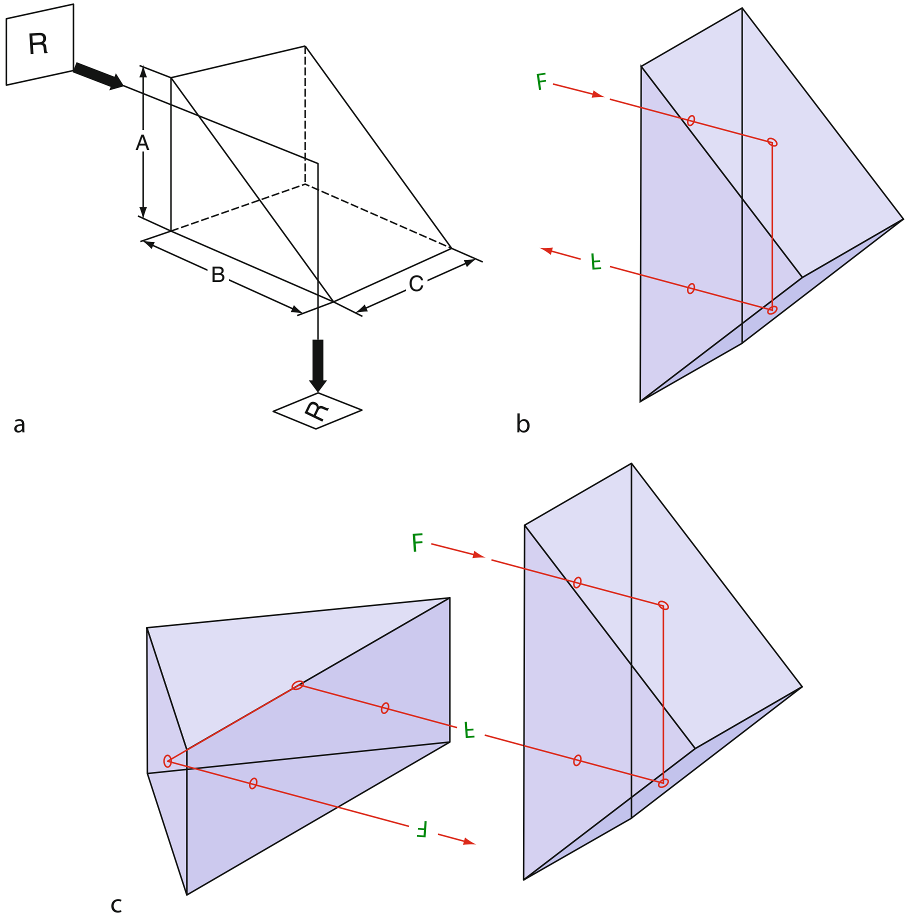
An Amici roof prism is a right-angle prism whose hypotenuse has been replaced by a 90° totally internally reflecting "roof," two faces inclined at 90° to each other (➲ *Fig. 5.77*). This prism deflects the light beam through an angle of 90° and performs left-to-right axis inversion. Amici prisms are available with antireflection coated entrance and exit faces. Any imperfections, such as chips, along the ridge of the roof, spoil the centre-line of the image. This may cause problems in some applications.

5.8.8 Pentaprism and Roof Pentaprism

A pentaprism is a five-sided reflecting prism and is able to deflect a light beam by 90° without inverting it (➲ *Fig. 5.78*). This type of prism does not rely on total internal reflection. Hence, the two reflecting faces must be coated, to provide mirror surfaces. The two transmitting faces are often coated to reduce spurious reflections. The fifth face is not used optically. In the roof pentaprism one of the reflective faces of a normal pentaprism is replaced by "roof" section (two surfaces angled at a 90° to each other). This inverts the image. However, chips in the "ridge top" of the roof spoil the centre of the image, which may make the roof pentaprism unsuitable for certain applications.

5.8.9 Dove Prism

A Dove prism is used to rotate an image; if a Dove prism is turned through an angle θ, the image is rotated by 2θ. It is a truncated 90°/45°/45° prism. The beam undergoes total internal reflection at the hypotenuse face, which need not be aluminized (➲ *Fig. 5.79*).



◘ **Fig. 5.76**

Right angle prism. (a) A single prism used as an internal mirror. (b) A single prism used as a retroreflector. (c) Two prisms used to rotate an image by 180°

However, the entrance and exit faces may be coated to reduce reflections Dove prisms are normally used with parallel, collimated beams. Since it disperses white light into its spectral components, a Dove prism should be used with monochromatic (or narrow-band) light.

5.8.10 Anamorphic (Beam Expanding) Prisms

Anamorphic prisms are used in pairs to magnify beam size along one axis, while leaving the beam unchanged along the orthogonal axis (➲ *Fig. 5.80*). They can typically achieve magnification ranging from 2× to 6× (or if reversed 0.17–0.5). These prisms

- Minimize reflection losses
- Maintain the polarisation state of the radiated beam

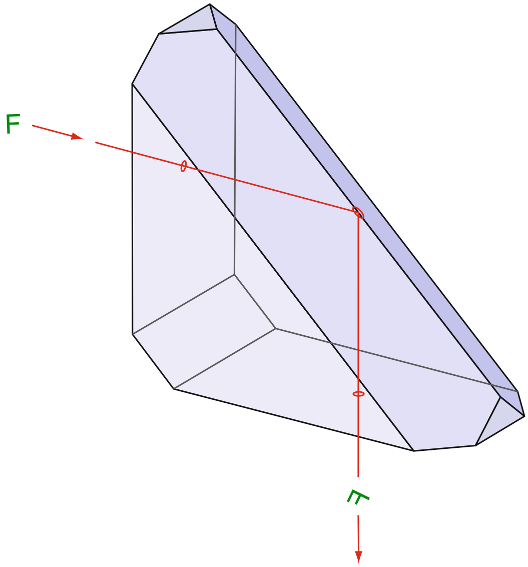


Fig. 5.77
Amici roof prism

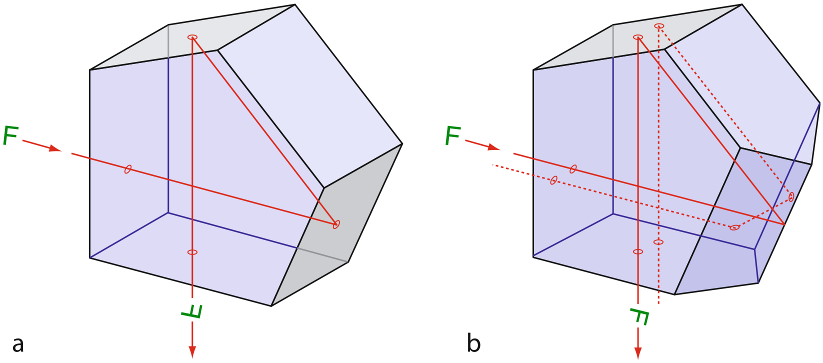

Fig. 5.78
Pentaprism. (a) Standard pentaprism. (b) Roof pentaprism

- Displace the transmitted beam by only a small lateral amount
- Typically deviates the beam by a very small angle (less than 1°)

5.9 Polarisation and Polarisers

Polarising sunglasses provide a clue as to the benefits of using polarisers for Machine Vision. Polarisers include the ability to

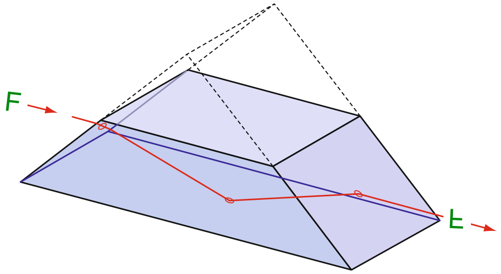

Fig. 5.79
Dove prism

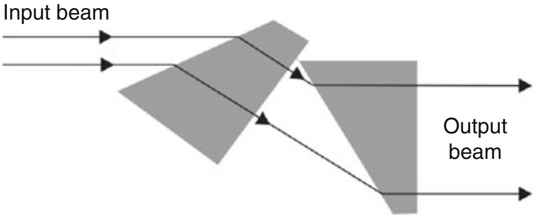

Fig. 5.80
Beam expanding prisms (This can be used in reverse, to reduce the input beam)

(a) Suppress glinting from smooth dielectric materials
(b) Visualise stress patterns in glass, plastics and other clear materials (Recall the stripes that appear on automobile wind-screens when wearing polarising sunglasses, *Fig. 5.81*.)

Several different types of polarisers are in common use and are reviewed below. Their relative merits should be considered carefully before deciding which one to use in an industrial vision system.

5.9.1 Physics of Polarisation

Consider light as a wave: the electric field (**E**) and magnetic field (**H**) are orthogonal to one another and to its direction of travel (*Fig. 5.82*). We can describe polarisation by considering the E-vector alone. If all rays travelling along a given path have their E-vectors aligned in the same direction, the beam is said to be polarised. This can be achieved by passing it through an array of fine parallel conductors. The rays whose E-vectors are parallel to the conductors are blocked, while those whose E-vectors are normal to the array can traverse unhindered. To understand how rays with E-vectors at other orientations behave, we must first decompose the ray into two orthogonal components (*Fig. 5.82c*), parallel and normal and to the conductor array. The former is blocked, while the latter is able to pass through the array unattenuated. As a result, the E-vector of the emergent ray is normal to the conductors but its amplitude is lower than that of the incident ray. What we have described thus far is called *linear polarisation*.

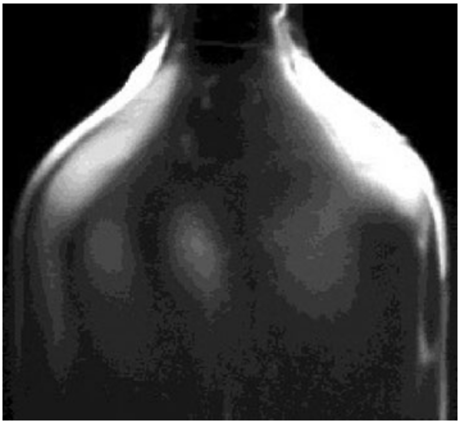

Fig. 5.81

Stress patterns in glass are made visible using two crossed linear polarisers

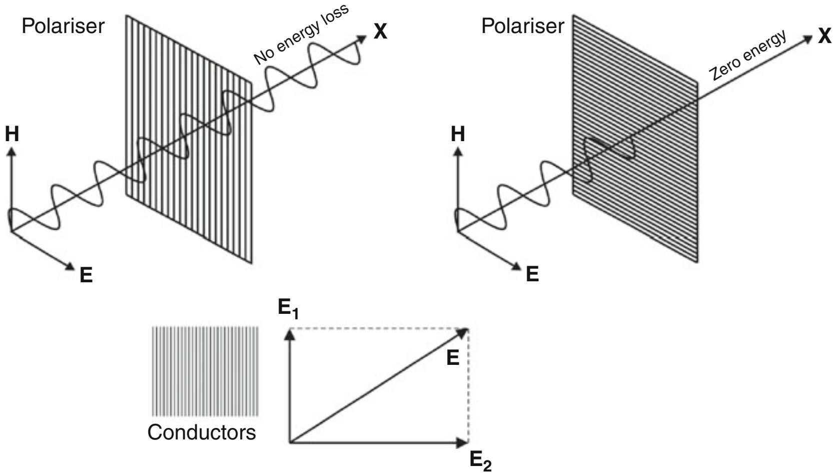

Fig. 5.82

Linearly polarised light. Polarising light using an array of very fine conductors. (a) A wave whose E-vector is normal to the conductors is transmitted unattenuated through the array. (b) A wave whose E-vector is parallel to the conductors is blocked by the array. (c) A wave with E-vector E resolved into two components: E_1 and E_2 where $E = E_1 + E_2$. The polariser blocks E_1 and passes E_2

Let us now consider a slightly more complicated situation (➲ *Fig. 5.83*). Two waves travelling along the same path have orthogonal E-vectors, have the same wavelength but have different phases. Their amplitudes may not be the same. Since their E-vectors are additive, the result is a ray whose E-vector rotates in both time and along the direction of travel. This is called *elliptical polarisation*. If the amplitudes of the two waves are the same, the ray is *circularly polarised*. A circular polariser may be constructed by combining a linear polariser with

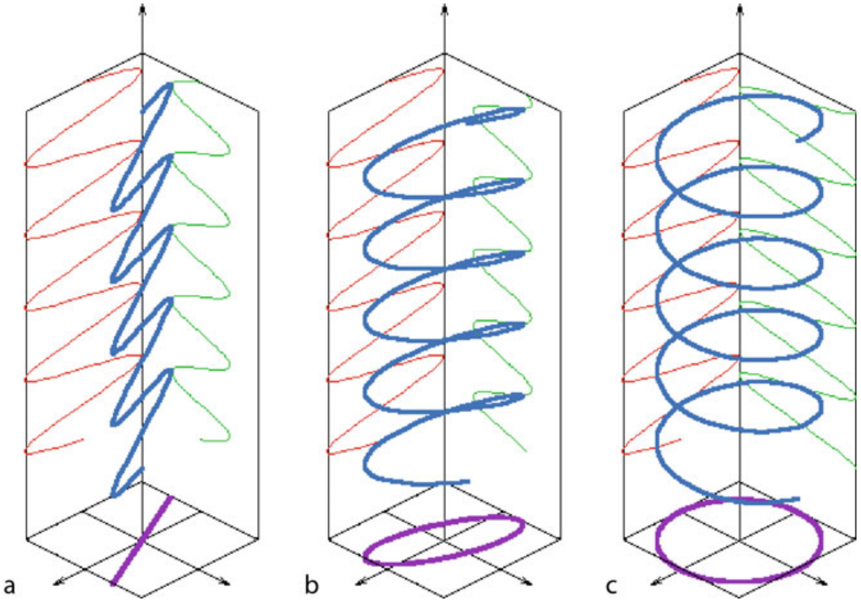

Fig. 5.83
Polarisation states. (a) Linear. Sinusoidal components, projected onto orthogonal axes, are in phase. (b) Elliptical. Sinusoidal components are not in phase and their amplitudes are unequal. (c) Circular. Sinusoidal components are not in phase and their amplitudes are equal

a quarter-wave plate. Circularly polarised light can be used to suppress glinting, while reducing the effect of changing the angle of illumination. At normal incidence, we cannot distinguish between vertical and horizontal polarisation in which case using polarisers will not help us.

Note the distinction between *randomly polarised light* and *unpolarised light*. Light from a standard source, such as an incandescent filament, or fluorescent tube, is unpolarised. A linear polariser placed in the beam will pass the same amount of light, whatever its orientation. On the other hand, light from a laser is usually polarised, although its polarisation at any instant may be unknown and may vary with time. Reflections from non-metal surfaces are often polarisation sensitive. Hence, if a polarised source is to be used for illumination, it is best to know what the polarisation is and hold it constant.

When a perfect polariser is placed in a linearly polarised beam of light of intensity I_0, the intensity of the light passing through it is given by *Malus's law:*

$$I = I_0 \cos^2(\theta) \tag{5.31}$$

where θ is the angle between the initial plane of polarisation and the axis of the polariser. A beam of unpolarised light contains a uniform mixture of linear polarisations at all possible angles. The average value of $\cos^2\theta$ is 0.5, so the transmission coefficient becomes

$$I = I_0/2 \tag{5.32}$$

In practice, some light is lost in the polariser. A Polaroid-type sheet polariser transmits about 38% of the incident light, while some birefringent prism types achieve transmission coefficients of over 49.9%.

If two polarisers are placed in tandem, and the angle between their polarising axes is θ in Malus's law, the transmission coefficient is

$$I = I_0 \cos^2(\theta)/2 \tag{5.33}$$

If $\theta = 90^\circ$ (the two axes are orthogonal), the polarisers are said to be *crossed*. In theory no light is transmitted. In practice, however, the transmission is not exactly zero. For example, when a room light is viewed through two crossed sheets of Polaroid material, a dark blue spot is seen. The ratio of the transmission of the unwanted component to the wanted component is called the *extinction ratio*. It varies from about 1:500 for Polaroid sheet polariser, to about 1:10^6 for a Glan-Taylor prism polarisers.

Any polarisation effects produced by a transparent material placed between two crossed polarisers increases the transmission. This principle is used to visualise the shear stress in glassware and clear plastics. Applying Malus's Law three times explains this. Imagine three perfect polarisers with axes at 0°, θ and 90°, placed in tandem. An unpolarised light source of intensity I_0 is used as a back-light. The light transmitted has intensity

$$I = I_0\cos^2(\theta)\sin^2(\theta)/2 \tag{5.34}$$

This has a maximum value of 0.125 when $\theta = 45^\circ$. When θ is either 0° or 90°, I is zero; no light is transmitted.

5.9.2 Brewster's Angle

Consider a light ray travelling across a boundary where there is a step change of refractive index. Some light will be reflected and some will enter the new medium. At one particular angle of incidence, called Brewster's angle the reflected ray will be strongly polarised (➜ *Figs. 5.84* and

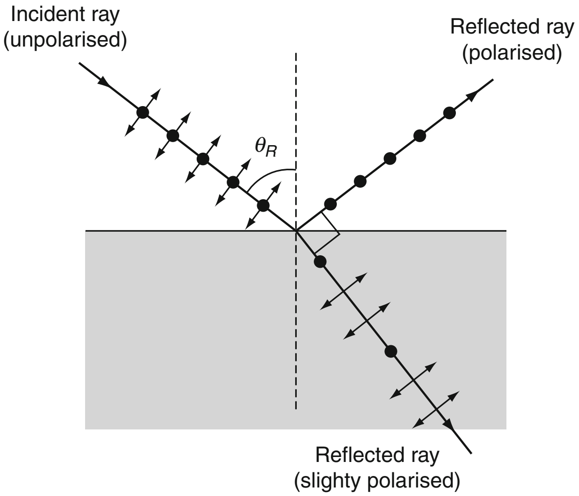

Fig. 5.84
Brewster angle. Notice that the angle between the refracted and reflected rays is 90°

➋ 5.5). The polarisation of the reflected ray is such that its **E**-vector lies in the same plane as the incident ray and the surface normal. Light with this polarisation is said to be *p-polarised*. Light with the orthogonal polarisation is said to be *s-polarised*. When unpolarised light strikes a surface at Brewster's angle, the reflected ray is always s-polarised. The value of Brewster's angle, θ_B, is given by

$$\theta_B = \tan^{-1}(n_1/n_2) \tag{5.35}$$

where n_1 and n_2 are the refractive indices of the two media. Brewster's angle for an air-glass interface is approximately 56°. (For glass, $n_2 \approx 1.5$; for air, $n_1 \approx 1$. For water, $n_2 \approx 1.33$.) Brewster's angle is approximately 53°. Since the refractive index depends on wavelength, Brewster's angle varies with wavelength. For angles of incidence close to Brewster's angle, the reflected ray is strongly but not completely polarised. By placing a suitably orientated polariser in the path of the reflected (or incident) ray; we can greatly reduce the intensity of the reflected beam. This is the principle upon which polarising sunglasses operate.

5.9.3 Birefringence

In a birefringent material, such as calcite, the velocity of light, and hence its refractive index, changes slightly, depending on the orientation of the E-vector. Again, decompose the ray of light into two separate rays whose E-vectors are orthogonal to one another. Passing light through a birefringent medium alters the phase relationship between these components. Calcite and other birefringent materials exhibit this behaviour because the distribution of free charge carriers (electrons) in the crystal structure is anisotropic. The orientation of the E-vector for rays travelling along the fastest path defines the *optic axis*, or *fast axis*, of the material. Such a ray is called the *o-ray*, or *ordinary wave*. The orthogonal wave is called the *e-ray*, or *extraordinary wave*. The o-ray sees the lowest refractive index of the birefringent material and the e-ray the highest. In calcite ($CaCO_3$), a birefringent material commonly used in optical components, the refractive indices are 1.658 (o-ray) and 1.486 (e-ray) at 0.59 µm. Birefringent materials can be used to separate the *o*- and *e*-rays; a prism made of calcite will separate a (monochromatic) unpolarised beam into two beams that are both polarised. Many glasses and plastics, especially when stressed, exhibit birefringence, as do ice, quartz, mica and several gem-stones.

5.9.4 Dichroism

The term *dichroic* is used in two ways in optics, to refer to the property of a material that either

(a) Separates light rays with different wavelengths, by transmitting some and reflecting others. (This is the way that the word was used in ➋ Sect. 5.6.)
(b) Absorbs light rays with certain polarisation states more strongly than others. In some materials, such as tourmaline, the polarising effect is wavelength dependent, in which case the material appears to have different colours depending on the polarisation of the light used to view it.

It is the second meaning that is relevant in this section.

5.9.5 Polarising Components

Polarisers can take various forms: plastic sheets, prisms, stacked plates, or optical coatings. The choice depends upon the polarisation purity needed, cost, robustness, physical size, weight and the working waveband.

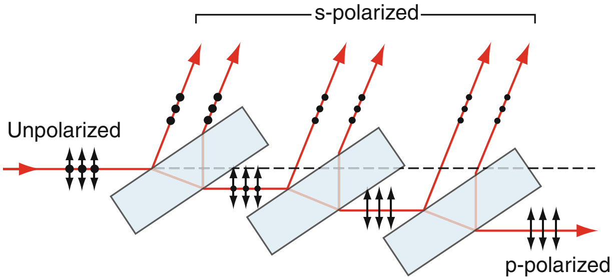
5.9.6 Polaroid Film

Polaroid is the generic name given to a range of synthetic plastic sheets containing needle-like crystals. These are aligned during manufacture, by stretching the film, or by applying an electric or magnetic field. The film absorbs light that is polarised so that the **E**-vector is parallel to the direction of the crystal alignment, but transmits light which is polarised perpendicular to it. The needle crystals act as the conductor array mentioned above. Both linear and circular polarising material is available in large sheets. The polarisation purity is not as good as the prismatic devices based on birefringence but Polaroid sheeting allows a shorter optical system to be built, that is lighter and considerably cheaper. The film can be damaged by scratching and high temperatures. Moreover, it does not polarise infra-red radiation, so this should be removed, by filtering.

5.9.7 Brewster Polariser

A polariser can be built using a stack of glass plates inclined at Brewster's angle to the incident beam. (For visible light in air and for a typical optical glass, Brewster's angle is about 57°, ➔ *Fig 5.85*.) Some of the *s*-polarised light is reflected from both surfaces of each plate. In a typical case, about 16% of the *s*-polarised light is reflected for each air-to-glass or glass-to-air interface. If there are *N* glass plates, the polarisation purity of the emergent beam is approximately

$$(1 - 0.16)2N \tag{5.36}$$



■ **Fig. 5.85**

Polariser consisting of a set of glass plates inclined at Brewster's angle (about 57°) to the optical axis. At each air–glass or glass–air interface, about 16% of the s-polarised light is reflected, leaving a greater proportion of the p-polarised light in the transmitted beam. Both the reflected and transmitted beams can be used for illumination but only the latter is useful for imaging applications

Hence, many plates are required to achieve even modest levels of polarisation purity. The reflected beam is strongly polarised but represents $2N$ spatially separated images of the light source and hence is unlikely to be useful in practice.

5.9.8 Thin Film Polarisers

A simple film polariser consists of a glass plate with a multilayer optical coating. In another method of construction, the coating is applied to the hypotenuse of a 90°/45°/45° glass prism. A similar prism is then cemented to it. (Do not confuse this with the Glan-type polarisers which also have the form of a cubic but rely on birefringence, not interference.) In both cases, optical interference within the coating film separates the polarised components. Since interference is sensitive to the wavelength of the light, this type of polariser is only able to operate over a narrow waveband. The cube-type polarisers generally perform better than the plate polarisers. Thin-film polarisers generally do not perform as well as Glan-type polarisers but are cheaper and provide two beams that are about equally well polarised.

5.9.9 Wollaston Prism

A Wollaston prism consists of two 90° calcite prisms, with perpendicular optic axes, cemented together on their hypotenuse faces to form a cuboid (➲ *Fig. 5.86*). Outgoing light beams diverge from the prism, giving two polarised rays, with the angle of divergence determined by the prisms' wedge angle and the wavelength of the light. Commercially available prisms are available with divergence angles from about 15° to 45°. The work well over a wide spectral range: 0.35–2.3 µm.

5.9.10 Nicol Prism

The Nicol prism polariser consists of a crystal of birefringent calcite that has been cut diagonally into two prisms and then cemented together again using Canada balsam (➲ *Fig. 5.87*). The crystal is cut such that the *o*- and *e*-rays are in orthogonal linear polarisation states. Total internal reflection of the *o*-ray occurs at the balsam interface which is therefore

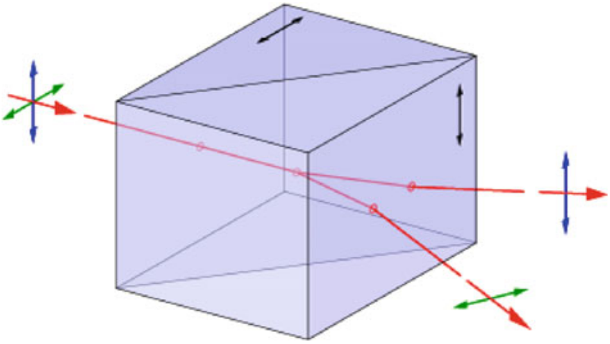


Fig. 5.86
Wollaston prism

deflected to the side of the cube. (The refractive index is larger in calcite than in balsam.) The *e*-ray, which experiences a smaller refractive index in the calcite, is transmitted directly across the balsam interface into the second prism. Nicol prisms produce very pure polarised light and are not wavelength sensitive.

5.9.11 Glan-Thompson Prism

A Glan-Thompson prism consists of two right-angled calcite prisms cemented together at their hypotenuse faces. (The optical axes of the crystals are both aligned perpendicular to the plane of reflection, ➋ *Fig. 5.88*.) The *o*-ray undergoes total internal reflection at the calcite–Balsam cement interface; only the *e*-ray is able to cross that interface. Notice that some of the e-ray energy is lost due to reflection, so the light deflected by the prism is not purely polarised. The Glan-Thompson polariser has a wider acceptance angle than the Glan-Foucault prism and works over a wide range of wavelengths: 0.35–2.30 µm. The linearly polarised e-ray is not deviated from its initial path.

5.9.12 Glan-Foucault Prism

The Glan-Foucault prism (or Glan-air prism) differs from the Glan-Thompson prism, in that two 90° calcite prisms are separated by a narrow air-gap (➋ *Fig. 5.89*). Total internal reflection

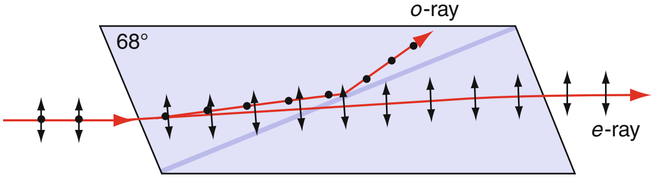

Fig. 5.87
Nicol prism polariser

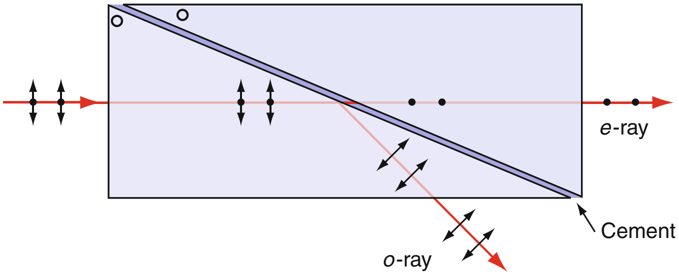

Fig. 5.88
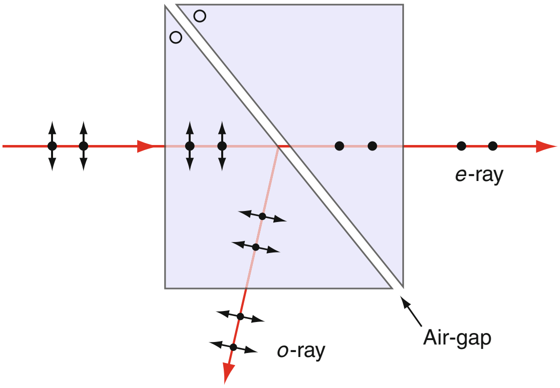
A Glan-Thompson prism deflects the o-ray whilst transmitting e-ray. The two halves of the prism are joined with optical cement, and the crystal axes are perpendicular to the plane of the diagram

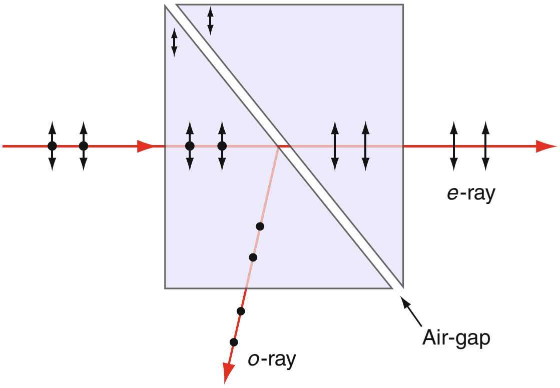
of the *o-ray* occurs at the calcite-air interface, so only *the e-ray* is transmitted straight through the prism. The reflected beam is not purely polarised. Compared to the Glan-Thompson prism, the Glan-Foucault device has a narrower acceptance angle. For this and other reasons, Glan-Foucault prisms are rarely used nowadays.

5.9.13 Glan-Taylor Prism

The Glan-Taylor prism is a polarising beam splitter and consists of two 90° prisms of calcite. Their hypotenuse faces are separated by a narrow air gap (➋ *Fig. 5.90*). The optical axes of the



◘ Fig. 5.89
Glan-Foucault prism deflects the o-ray and light, transmits the e-ray. Notice that the calcite prisms are separated by a narrow air gap. The optical axis of the calcite is perpendicular to the plane of the diagram



◘ Fig. 5.90
Glan-Taylor prism reflects the o-ray at the air-gap, transmitting only the e-ray. The reflected light is not purely polarised. The length-to-aperture ratio is 0.85

calcite crystals are aligned parallel to the plane of reflection. Total internal reflection of the *o-ray* occurs at the air-gap, so only the e-ray is able to cross it. The device is efficient, losing only a small proportion of the e-ray energy due to reflection at the second air-calcite interface. Although the transmitted beam is purely polarised, the reflected beam is not. Glan-Taylor polarising prisms are recommended for applications requiring a high degree of polarisation purity and high total transmission. They transmit well over a wide spectral range (0.35–2.3 µm) and the linearly polarised e-ray is not deviated significantly from its initial path.

5.10 Beamsplitters

A beam splitter is an optical device that divides the energy within a beam of light between two secondary beams, whilst maintaining the spatial distribution in each one. Beamsplitters can also be used to merge beams from two light sources, or superimpose two images. For example, it is possible to superimpose a calibration grid onto the view of a scene. Beamsplitters can also be used to allow two cameras to view the same scene in different ways, perhaps via different colour filters or polarisers.

5.10.1 Cube Beamsplitter

One of the most common forms of beamsplitter is a cube, made from two 90° triangular glass prisms that are cemented together at their hypotenuse faces (➋ *Fig. 5.91*). The hypotenuse face of one of the prisms is coated to provide a partially reflecting mirror. Light should enter this prism first. Normally, the coating thickness is adjusted so that the light intensity emerging from the two exit faces of the cube is approximately the same. Both entrant and exit faces should have antireflection coatings. Cube beamsplitters should be used with normally incident, collimated, or nearly collimated light, to avoid producing ghosting, spherical aberration and dispersion with varying wavelength. A cube beamsplitter is easy to mount, is physically robust and does not suffer from problems due to vibration. The coating is sealed inside the cube, so it is less susceptible to degradation due to chemical attack than plate or pellicle beamsplitters.

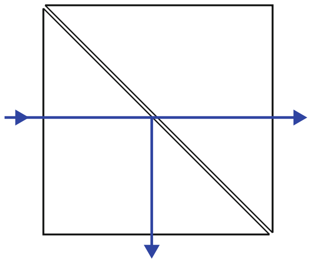


Fig. 5.91
Cube beamsplitter

5.10.2 Plate Beamsplitter

Another popular beamsplitter uses a half-silvered mirror, inclined at 45° to the path of the light beam. The beam should be collimated (i.e., all rays are parallel). This type of beamsplitter commonly consists of a plate of glass with a thin uniform coating of metal (e.g., aluminium or Inconel) deposited on one face. The thickness of the metal layer is normally adjusted so that 50% is of the light is transmitted and 50% is reflected. Other ratios can be produced. A plate beamsplitter is efficient but can produce ghost images as a result of reflections from the non-metallised surface (➔ *Fig. 5.92*). Simple geometric optical analysis shows that the spacing between ghost images is as follows:

$$\text{Adjacent to the transmitted beam}: \quad 2W\tan(\theta')/\sin(\theta) \tag{5.37}$$

$$\text{Adjacent to the reflected beam}: \quad 2W\tan(\theta')/\cos(\theta) \tag{5.38}$$

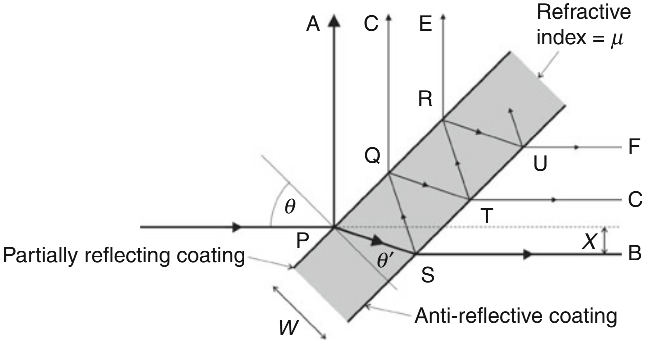
When $\theta = 45°$, both of these expressions reduce to

$$2\sqrt{2}W\tan(\theta') \tag{5.39}$$

For crown glass, the refractive index is 1.6. So, for a plate inclined at 45° to the incident beam, $\theta' = 26.2°$ and ➔ Eq. 5.39 reduces to

$$5.43W \tag{5.40}$$

Notice that the transmitted beam is offset slightly from the incident ray. Using the notation of ➔ *Fig. 5.92*, the displacement is equal to



Displacement of the transmitted beam:
$X = W\sin(\theta)(1\text{-}\cos(\theta)/\mu\cos(\theta'))$

Fig. 5.92

Beam-splitter based on a partially reflective coating. The input beam is split into two main components: A and B. In addition, low intensity beams emerge after multiple reflections within the substrate: C, E, F and G. Notice that beam B is offset slightly from the input beam by an amount X, W. If W is small, beams A, C and E are close together, as are B, F and G. Hence to avoid producing ghost images, it is important keep W small. In a pellicle beamsplitter, the substrate width (W) is very small, so ghosting and spherical and chromatic aberration are all negligible

$$\mathrm{W}\sin(\theta)(1 - \cos(\theta)/(\mu\cos(\theta')) \tag{5.41}$$

Again, letting $\theta = 45°$, $\mu = 1.6$, we find that $\theta' = 26.2°$ and the displacement is equal to

$$0.3616\mathrm{W} \tag{5.42}$$

5.10.3 Coatings

Two types of partially reflecting metal coating can be produced:

(a) *Spatially uniform coating*, deposited on the substrate by condensing metal from a vapour. The thickness of the metal film determines the transmission:reflection ratio.

(b) *Polka dot coating*, consists of a large number of small dots of metal deposited on the substrate. Each of these acts as a tiny mirror that reflects all of the light it receives. Of course, the clear spaces between these small mirrors allow light to travel through the substrate. Provided the reflective dots are small enough, the overall effect is to produce a beamsplitter that has a well defined transmission:reflection ratio. If the dots are positioned on a regular grid pattern, strobing may occur with the photo-sensor array. If they are too small, the dots will cause diffraction effects. For these reasons, it may be difficult to use a Polka dot beamsplitter in an imaging application. It is possible to manufacture a graded Polka Dot beamsplitter, so that the transmission:reflection ratio varies in a controlled way across the device.

A dielectric coating is normally applied to the non-metallised side of the plate, to reduce the intensity of the ghost images. In addition, a transparent coating may be used to protect the metallised surface from physical damage. It should be noted that plate beamsplitters are sensitive to the polarisation of the entrant beam. This can be a nuisance, or an advantage, depending on the application requirements.

For operation at a fixed wavelength, a mutli-layer dielectric coating can be used instead of metal for the reflecting film. This also offers scope for building a dichroic device that reflects wavelengths above/below a certain critical value and transmits wavelengths below/above that value. These were discussed in ❯ Sect. 5.6.

5.10.4 Pellicle Beamsplitter

A third design, called a pellicle beamsplitter, uses a thin, high tensile-strength elastic membrane (e.g., nitrocellulose), stretched tightly, like the skin of a drum, and coated on one side with a partially reflecting film. Pellicles are manufactured with two different coatings. Again, dielectric coatings are useful when working at one specific wavelength. However, a metal coating, containing a mixture of nickel, chromium, cobalt, and iron, can be made to produce a device that is almost independent of wavelength. Aluminium also allows operation over a wide spectrum.

A pellicle does not produce a ghost image of any significance, because the thin membrane provides a separation between the primary and ghost images of only a few microns.

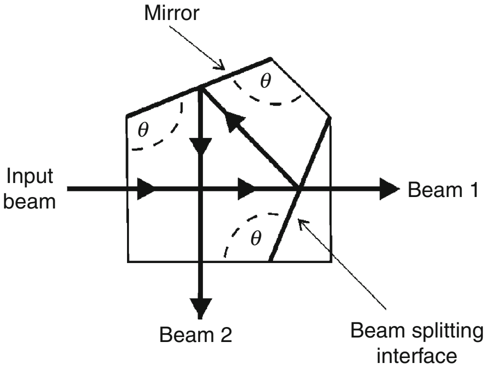


Fig. 5.93
Pentaprism beamsplitter. All angles marked θ are 112.5°

(The variable W in Eqs. 5.37 and 5.38 is very small.) In addition, chromatic and spherical aberrations are negligible in converging beams. The membrane normally provides low absorption across the visible spectrum but may attenuate other wavelengths. The thickness of the metal film can be adjusted during manufacture, to provide 50:50%, or other splitting ratios.

Pellicles suffer from two major disadvantages

(a) The membrane is very delicate; it must never be touched by fingers. A pellicle should be cleaned only with a gentle flow of clean, dry air.
(b) Acoustic noise and vibration can be troublesome, since the film resonates at certain frequencies.

5.10.5 Prism Beamsplitters

It is possible to build a robust, broadband beamsplitter using a pentaprism with one face coated with a partially reflecting metal film (*Fig. 5.93*). Such a device is heavier and more bulky than a plate or pellicle beamsplitter but it defines the angular separation of the reflected and transmitted beams precisely at 90°. Ghost images are eliminated and there is no offset for the direct beam (Beam 1 in *Fig. 5.93*) Neither beam is flipped horizontally nor vertically. There is no separation of rays with different wavelengths.

The use of prisms for separating rays according to their wavelength and polarisation has been discussed in Sect. 5.8.

5.11 Optical Windows

Optical windows are used to isolate one operating environment from another while allowing light to pass. A closed box is sometimes used to protect the camera, in which case an optical window allows the camera to "see" the outside world. (See *Fig. 5.94*.) An important point to note is that the optical window should be regarded as a sacrificial element; it is the one optical component that must face the hostile factory environment.

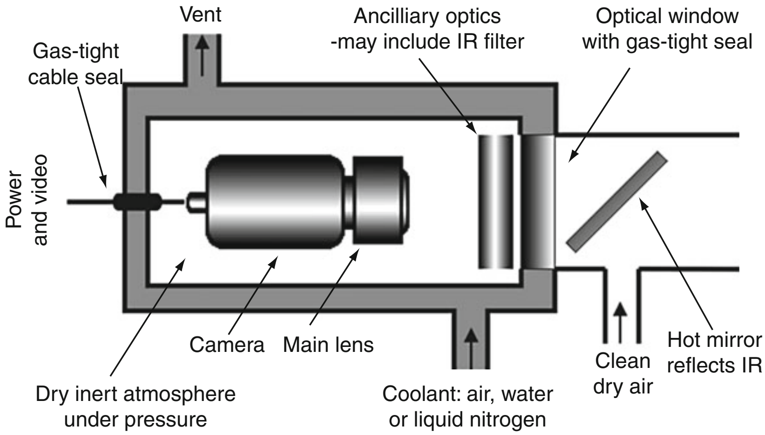

Fig. 5.94
Protecting a camera and optics in a hostile environment

When choosing a suitable window material, the following points should be should be borne in mind:

- There should be very little attenuation of light over the working spectrum
- There should be a minimal change to the spectrum
- There should be very little scattering of light
- Wavefront distortion should be minimal
- The window should be resistant to damage by
  - Water
  - Oil
  - Acids
  - Other chemicals used in the manufacturing process
  - Nuclear radiation
  - Scratching (The window may be rubbed vigorously during over-zealous cleaning.)
  - Flying debris
  - Extremes of temperature
  - Thermal shock due to rapid temperature changes
  - Large temperature gradients

In Sect. 5.2, we pointed out that, for many purposes, sapphire is an ideal material for this function. A synthetic sapphire window can be provided with a thin metal coating, which allows it to be heated electrically so that condensation is eliminated. The spectral transmission characteristic of sapphire is vey flat over the visible waveband. (See *Fig. 5.17*.) However, it should not be forgotten that other window materials may be more suitable for some applications.

5.12 Practical Issues

We conclude this chapter with some advice about building and maintaining optical systems in good working order. Adhering to a few simple rules will improve overall system performance and reliability. Failure to do so will result in disappointment, which may, in turn, lead to frustration and exasperation with the whole of Machine Vision technology. Do not forget that cleaning optical surfaces properly is just as important as making sure that computers remain virus free, or that cameras are not overheated.

5.12.1 Cleaning Optical Components

Optical components must be kept clean, to ensure that they perform properly. Failure to do so will result in a general and/or local reduction of light levels, a change in the spectral composition and polarisation, as well as an unpredictable scattering effect. Optical surfaces can be contaminated in many ways, for example by water (condensation, splashes drops or streaks), saliva (from sneezing or coughing), oil, dust, fumes from the manufacturing process – and fingerprints. Contamination can be kept to a minimum by returning unused optical components to their cases immediately after use, fitting lens caps and using a protective enclosure (➋ *Fig. 5.94*). A jet of clean dry air can also help to keep dust away. However, even with these precautions, the optics will almost inevitably accumulate dust, stains or other form of contamination.

5.12.1.1 General Advice

- Keep optical components in their protective cases when they are not in use.
- Fit lens caps whenever possible. Be careful to avoid touching the lens when doing so.
- If possible, place optical components, including lights within protective enclosure.
- Do not touch optical surfaces with bare fingers; always wear powder-free gloves, or finger cots.

5.12.1.2 Cleaning Methods

The six cleaning methods described below are suitable for different types of optical components and surfaces (➋ *Table 5.3*).

1. *Blowing* The first step in cleaning any kind of optical device is to remove dust, grit, lint or other loosely held particles using a dry, dust-free air blast. This reduces the chance of scratching the optical surfaces. Blowing is specifically recommended for bare metal, soft coatings, and membrane beamsplitters (pellicles). These types of surfaces should never be touched with bare fingers.
2. *Drop-and-drag* It may be necessary to remove the optical component from its mount. When wiping optical surfaces, be careful not to drag any dirt across it, as this could result in scratching. (Use blowing first.) To eliminate streaks, the following procedure should be followed two to three times, wiping in different directions each time.
   1. Place a drop of solvent, such as methanol, on a lens tissue paper.
   2. Place the wet area of the tissue onto the optical surface to be cleaned.
   3. Slowly drag the tissue across the surface until the lens tissue is dry.
3. *Wiping* If the optical component cannot be taken out of its mount, or if more stringent cleaning is required, use the following procedure.
   1. Fold a piece of lens tissue paper, creating a folded edge.
   2. Wet the folded edge with acetone.

   3. Wipe the optic with the lens tissue paper with one continuous motion. If necessary, carefully apply light pressure. When repeating this process, always use a new lens tissue, to avoid redepositing dirt.
   4. Apply final wipe with methanol, as this does not leave streaks on the surface. Acetone and isopropyl alcohol are also effective but can leave streaks.

      If the device is very small, cotton buds can be used instead of lens tissue.

4. *Bathing* Small and lightly contaminated optical components can be cleaned by immersing them in solvent. Do not use this method with cemented components, or mounted optics, both of which are likely to be damaged.
   1. Line a shallow dish with lens tissue and fill it with methanol.
   2. Place the optical element in the dish, clean its surfaces gently with a piece of soaked cotton wool.
   3. Agitate the solvent for a few minutes.

Table 5.3

Methods for cleaning optics

	Cleaning method					
Component/surface/coating	1	2	3	4	5	6
Aluminium, bare metal	✓					
Bare substrate	✓	✓	✓	✓	✓	✓
Coloured filters and heat absorbing filters	✓	✓	✓	✓	✓	
Compound camera lens (Assembly cannot be dismantled. Usually no need to clean the rear surface as this is well protected)	✓		✓			
Cube beamsplitters, polarising prisms, other compound prisms	✓	✓	✓			
Fibre optic bundles (illumination and imaging)	✓	✓	✓		✓	
Gold, bare metal	✓					
Half-silvered plate beamsplitters	As reflective coating					
Interference filters (short-, long-, band-pass)	✓	✓	✓	✓	✓	
Mirrors	As reflective coating					
Multi-layer dielectric anti-reflective coating (E.g., HEBBAR™, Melles Griot, Inc.)	✓	✓	✓	✓	✓	
Multi-layer dielectric reflective coating (E.g., MAXBRite™, Melles Griot, Inc.)	✓	✓	✓	✓		
Neutral density filters	✓	✓	✓			
Pellicle beamsplitters	✓					
Prisms (some prisms also have reflective coating)	As anti-reflective coating					
Protected and enhanced aluminium coatings	✓	✓	✓	✓		
Protected silver and gold	✓	✓	✓	✓		
Silver, bare metal	✓					
Simple lens	As anti-reflective coating					
Single-layer MgF_2 coating	✓	✓	✓	✓	✓	

   4. Repeat steps 1–3 with acetone.
   5. Remove the component from and blow until it is dry.
   6. If stains remain, apply the drop-and-drag method.
5. *Soap Solution Bathing* Surfaces contaminated by fingerprints, oil or grease, cannot be cleaned properly using methanol, or acetone, which simply re-distribute the pollution. In this case, a soap solution can be used instead. Mild, non-abrasive soap without additives (green soap), should be used.
   1. Using a soap solution, apply either the Methods 3 (Wiping) or 4 (Bathing).
   2. Rinse thoroughly with de-ionized water.
   3. Repeat method 3/4, using methanol or acetone.
   4. Blow dry to remove water.
6. *Ultrasonic Cleaning* The component is placed in an ultrasonic bath for about 1 min. Notice that this method may damage dielectric coatings.

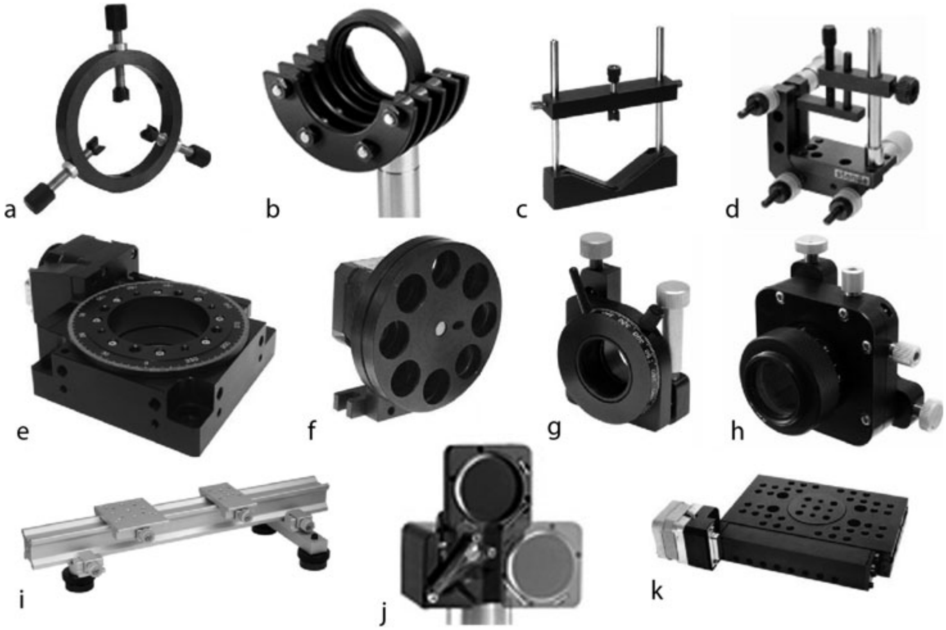
5.12.2 Protecting Optical Systems and Sensors

Following the maxim that protection is better than cure, it is worthwhile discussing methods by which fragile and delicate optical components can be made more secure. Small lighting devices, optical components and cameras can be enclosed in an air-tight box, with only a small tough viewing window. Sapphire is an ideal material for this window, which has to face the full hazards of the work-place. To maintain good visibility, the window must be cleaned regularly, either automatically or as part of a disciplined maintenance schedule. It must also be accepted that this window is a sacrificial element in a vision system. If anything in the optical sub-system breaks as a result of an accident, the window will! A well designed enclosure will protect the optics from dust, flying grit, steam, water and oil splashes and hot air. If necessary, the enclosure can be water-cooled and in extreme circumstances, liquid nitrogen could be used as a coolant instead. IR blocking filters and/or hot mirrors can be used can be used to protect the camera. IR absorbing filters get hot and can be cooled with an air purge. An air jet can also be used to protect the window. A tube placed around the window will keep much of the flying debris away from it. Again, an air jet injected into the tube will help to keep the window clean. These ideas are summarised in ➜ *Fig. 5.94*.

5.12.3 Mounting Optical Components

Providing proper mountings for optical components is likely to be regarded as a mere detail to be left to the very last moment during the design of a vision system. The system may well fail to fulfil its intended function if the lenses and/or mirrors are not held rigidly in their appropriate places. The mechanical fixtures that hold them are just as important as the optical elements themselves, or the camera and the image processing algorithms. A casual attitude to the mounting of optical components will almost invariably lead to disappointment! Mounting the components in an optical system requires just as much care as choosing the elements in it! Failure to give proper attention to optical mountings will result in blurred images, low image contrast and inconsistent overall performance by the vision system. The task of building a robust optical system has been made easier, because manufacturers have devised specialist holding devices for holding lenses, mirrors, filters, prisms, polarisers, beam-splitters, lamps and cameras. The prime requirements for any optical mounting system are that it must be stable with varying temperature and free from vibration. Each optical component, including the lamp(s) and camera(s), must be held in such a way that it does not move relative to the other components. In some harsh environments, this may require the use of a heavy optical bench, with sophisticated pneumatic damping on each of its supporting pillars. In less demanding applications, a much lighter and far less expensive mounting rail will suffice. The reader is warned that optical mounting devices are not cheap and may even be more expensive than the bits of glass that they hold. Buying good mechanical fixtures is well worth the investment, since failure to mount the optical components solidly in place will result in serious deterioration of the image quality. Making a safe, stable mounting for optical components requires careful design and precise machining; it is unlikely that a non-specialist designer and general machine-tool operator can produce better, cheaper fixtures than the commercial equipment.

It is not our intention here to describe in detail the range of fixtures that have been devised for even standard optical devices. A few are illustrated in ➲ *Fig. 5.95*. A variety of lens mounting



◘ Fig. 5.95

Optical mounting and precision translation devices. (a) Lens holder, manual centring. (b) Multiple filter holder. (c) Single lens/filter holder. (d) Cylindrical lens holder. (e) Universal prism holder. (e) Motorised rotation stage. (f) Motorised filter wheels. (Two wheels can be rotated independently) (g) Precision polariser holder, with calibrated rotation scale. (h) Multi-axis position device with manual controls. (i) Mounting rail. Notice the anti-vibration feet and that the saddles by repositioned and locked in place easily (j) Filter holder with motorised flipping in/out of optical path. (k) Motorised linear translation stage (Reproduced with permission from Standa, Vilnius, Lithuania, http://www.standa.lt/. Accessed 23rd April 2008)

rings, not shown, have been designed specifically for certain types/sizes of lenses. Bespoke designs for this function would probably do little more than replicate what is already available in off-the-shelf products and would very likely be less accurate and more expensive. A variety of precision motorised devices exists for adjusting optical systems. These include rotary, linear and multi-axis translation stages, filter wheels, filter flippers. The last two can insert/remove colour filters, neutral density filters or polarisers from the optical path.

5.12.4 Centration

The mechanical axis and optical axis exactly coincide in a perfectly centred lens. For a simple lens, the optical axis is defined as a straight line that joins the centres of lens curvature. For a plano-convex or plano-concave lens, the optical axis is the line through the centre of curvature and perpendicular to the plane surface. The mechanical axis is determined by the way in which the lens will be mounted during use. There are typically two types of mounting configurations: edge mounting and surface mounting. With edge mounting, the mechanical axis is the centreline of the lens mechanical edge. Surface mounting uses one surface of the lens as the primary stability reference for the lens tip and then encompasses the lens diameter for centring. The mechanical axis for this type of mounting is a line perpendicular to the mounting surface and centred on the entrapment diameter. The tolerance on centration is the allowable amount of radial separation of these two axes, measured at the focal point of the lens. Centration error is measured by rotating the lens on its mechanical axis and observing the orbit of the focal point.

5.12.5 Alignment and Calibration

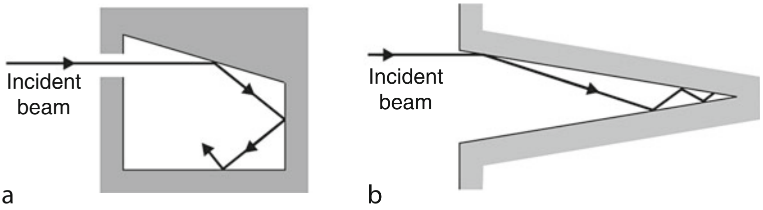
It is important that all of the components in an optical system are aligned accurately. To do this properly requires a clear understanding of the way that each component works. Much can be achieved using simple tools and ingenuity based on a good general appreciation of optical principles:

(a) A small, low power (diode) laser
(b) A single low power LED mounted on a wand
(c) Two opaque diaphragms with tiny pinhole apertures
(d) Micrometer mounts for the pinholes/laser can be useful when aiming for precise alignment
(e) A calibration target consisting of a board with an array of high-contrast horizontal and vertical lines. A higher contrast target can be made with a back-lit board with an array of holes. The same effect can be produced using an array of LEDS
(f) As in (e) but with the holes/LEDs arranged around a series of concentric circles

A useful ploy, in some situations, is to replace the camera temporarily with a "point" light source: a laser or a single LED. A narrow beam of light is then projected backwards through the optical system during alignment. Beam steering components (mirrors, prisms, beamsplitters and lenses) should be aligned first; filters and polarisers, can be removed from the system during the initial phases of alignment. A laser beam can be used to define the optical axes. Systems with mirrors and prisms have non-linear optical axes, while those containing beam splitters have more than one. After alignment, the behaviour of the system should be investigated with the "point" light source placed both on and off the optical axis. To do this properly requires precise position control, hence the inclusion of micrometer mounts (d) in the list above. This allows the origin and destination of stray light to be determined.

5.12.6 Light Absorbing Materials and Structures

When a 50:50 beamsplitter is used in the illumination path of a vision system, half of the light it receives from the lamps is immediately discarded and must be disposed of properly. To absorb the large quantities of unwanted light that this type of system produces requires that special techniques be used. The naïve approach to producing a light absorbing surface is to use commercially available matt black paint. However, this still reflects a significant amount of light. Black velvet provides an efficient light absorbing surface but this is hardly practical for use in a dirty factory environment. Although amorphous carbon (soot) is a good absorber, it is friable. A standard approach to improving matters in photographic lens hoods, is to use rifling on the inside surface. A closed box with a small aperture in its side wall and painted matt black inside is a good absorber. A deep hollow cone is too (➲ *Fig. 5.96*). Any light reflected by the inside surface of the cone is reflected deeper into it, where more of the unwanted light will be aborbed. This leads to the idea of building a surface consisting of a series of small conical depressions. A similar idea is to use a stack of razor blades; the side of the stack is a good light absorber. Creating a sponge-like structure from a material that itself has a low reflection coefficient seems to offer the best approach to building a really efficient light absorber. One recently announced coating material aborbs 10–20 times more less light than conventional techniques [8]. (It is claimed by its inventors to be 25 times blacker than conventional black paint.) This coating consists of an alloy of nickel and phosphorus. The surface is pitted, with tiny craters. Another type of very black surface ha been constructed using an array of carbon nano-tubes aligned with the path of the incoming light. These work on the same principle as illustrated in ➲ *Fig. 5.96b*. Absorption is claimed to be better that 99.99%. At the time of writing (April 2008) these materials are still expensive.



▣ Fig. 5.96

Light absorbing structures. In both cases, the internal surface is coated with absorbent material, such as matt black paint. (a) Box (b) Deep conical pit

6 Telecentric, Fresnel and Micro Lenses

Spencer D. Luster[1] · *Bruce G. Batchelor*[2]
[1]Light Works, LLC, Toledo, OH, USA
[2]Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_6,

Abstract: Telecentric lenses provide constant perspective and large magnification depth of field. For this reason, they are often well suited for gauging and a variety of other demanding Machine Vision applications. This is especially true when viewing objects that have variable depth and/or lateral position. Lighting issues relating to the use of telecentric optics for viewing and lighting are discussed, together with their ability to provide sensitive detection of defects in clear or flat and shiny materials. Telecentric lenses can view objects, with constant perspective, anywhere within a cylindrical volume. On the other hand, hypercentric lenses can view objects within a conical region, whose apex is in front of the lens. (A fish-eye lens views objects within a conical region, whose apex is behind the lens.) As a result, hypercentric lenses are able to view the top and sides of an a cylinder simultaneously.

By adding a spacer between certain types of hypercentric lens and the camera, it is possible to view inside a bore, even when the viewing aperture, at the camera end of the bore, is very small. Both telecentric and hypercentric lenses are only able to work effectively if the front refracting element is larger than the object being viewed. Manufacturing large conventional (i.e. curved-surface) lenses is very expensive. Fresnel lenses provide a convenient alternative. There are three common types of optical component made by forming numerous very small grooves and/or mounds on a plane surface. *Fresnel* lenses employ very fine prismatic surface features on a thin plane plate. *Micro-lens arrays* consist of numerous small lenses (lenslets) placed close together on a plane substrate. In both of these cases, the optical formulae explained in ➲ Chap. 5 are applicable, because the surface features, while small, are still much larger than the wavelength of light. On the other hand, *Diffraction (or Binary)* optical components have such small surface features that they cause interference due to diffraction; refraction usually plays no significant part in the operation of these devices. Some hybrid refractive-diffractive lenses are made but these are uncommon.

6.1 Telecentric Lenses

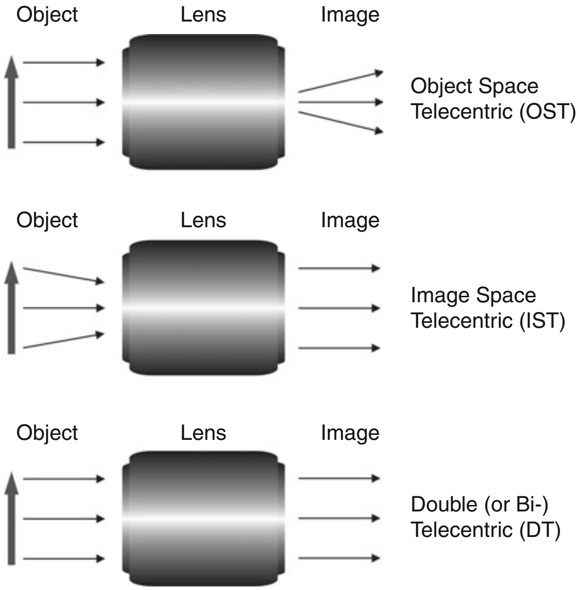
The term *telecentric lens* is used to refer to one of the following:

1. A lens that receives mostly parallel rays of light from the object being inspected. This is called an *Object Space Telecentric (OST)* lens.
2. A lens that projects mostly parallel rays of light onto the camera's photo-detector array. This is called an *Image Space Telecentric (IST)* lens.
3. A lens that does both of the above. This is called a *Double Telecentric (DI)* or *Bi-telecentric* lens.

➲ *Figure 6.1* shows all three types. There are very few cases in Machine Vision applications where IST lenses are useful, so we won't discuss them here. Most commercial telecentric lenses are of the OST variety, with a few vendors providing DT lenses. There are advantages to the latter, which will be discussed below.

6.1.1 Advantages of Telecentric Lenses

Telecentric lenses offer several important advantages for Machine Vision and frequently transform what would otherwise be difficult applications into much simpler ones. They often



Object

Object
Lens
Image
Image Space Telecentric (IST)
Object
Lens
Image
Double (or Bi-) Telecentric (DT)

Fig. 6.1
Three types of telecentric lenses

make the processing of images in software much simpler, faster and less expensive. Indeed, it might reasonably be claimed that telecentric lenses form one of the major pillars that has made Machine Vision successful in practice!

6.1.1.1 Constant Magnification

A telecentric lens is able to provide a nearly constant magnification, irrespective of object-camera distance. Everyday experience teaches that a conventional lens, including that in the human eye, produces an image that becomes larger as the subject approaches the observer/ camera (➋ *Fig. 6.2*). The size of an image, and information about the type of object that produced it, are combined in the brain, so that the object-eye distance can be estimated. Human beings are relatively insensitive to image size. To most people, a dog seen at a range of 10 m appears very little different from the same animal at 5 m. Size constancy, as this is called, is a useful feature of human vision. It can, however, easily mislead us when building a vision system, as it gives false expectations. Varying image size is a nuisance! Automatic compensation for image size variation is possible using a vision system. If the absolute size of the object is known, it is possible to estimate its range from the size of its image and vice versa. However, measuring image size does not always lead to estimates of distance that are acceptable for precise gauging applications. In many applications, it is necessary to measure the size, irrespective of object-camera distance. Varying image size has the disadvantage that it complicates the image processing and can introduce many "wasted" pixels. The near-constant magnification of a telecentric lens is therefore of great practical value.

While it is always desirable to constrain the presentation of objects for inspection, this is not always possible. Variation of object-camera distance occurs naturally in the industrial context

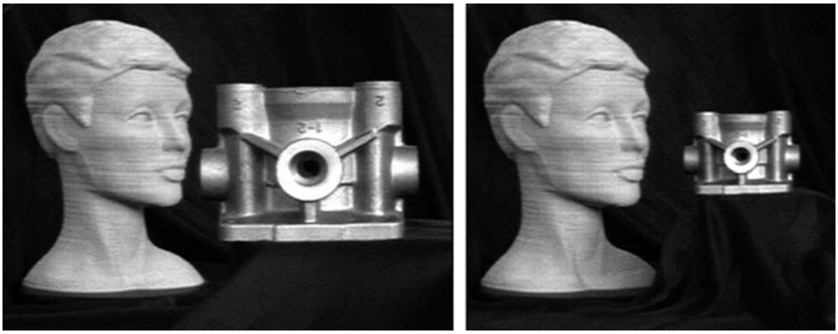

Fig. 6.2
Size variation in a conventional lens occurs when objects are moved along the camera's optical axis. Which object is larger? Size variation, like this, that are due to movement along the optical axis are greatly reduced using a telecentric lens

and we are fortunate if it can be limited by the clever use of mechanical handling. Two situations where this is not possible are described below:

- Bottles on a conveyor may arrive for inspection at a wide range of positions across a conveyor belt. Hence, a side-view camera views them at different distances.
- Components on circuit boards might be mounted at different heights. A low-altitude overhead camera fitted with a conventional lens will therefore see large size variations.

In absolute terms, these variations in the object-camera distance might seem insignificant, but when trying to obtain high-precision measurements of object size or distance, the resulting errors might be totally unacceptable.

When using structured lighting (laser-line triangulation) for height measurement, it is important to use a lens that provides constant magnification. Failure to do so will require significantly more complicated algorithms to estimate surface height.

Many objects must be viewed with the camera close to one face and a long way from others (➋ *Fig. 6.3*). When viewed using a conventional lens, these different faces will each be viewed with a different magnification.

Good telecentric lenses, especially of the Double Telecentric variety, overcome these problems; the image size does not vary significantly over a large distance along the optical axis. How far an object can change its distance and still appear to be the same size is called *Magnification Depth of Field*. This term is completely different from image-sharpness depth of field, which is what most people refer to when using the simple term "*Depth of field*."

6.1.1.2 Constant Perspective

Unlike conventional lenses, OST and DT lenses view the object from nearly the same angle across the whole field of view (➋ *Fig. 6.3*). The effect is the same as viewing the object from an infinite distance using a conventional lens. This can be very important for gauging applications, especially for non-flat objects, or for applications in which it is necessary to look down the bore of a tube, or pipe, to check for obstructions (➋ *Figs. 6.4* and ➋ *6.5*). Like a pair of calipers, these lenses are capable of providing accurate diameter, or width, measurements.

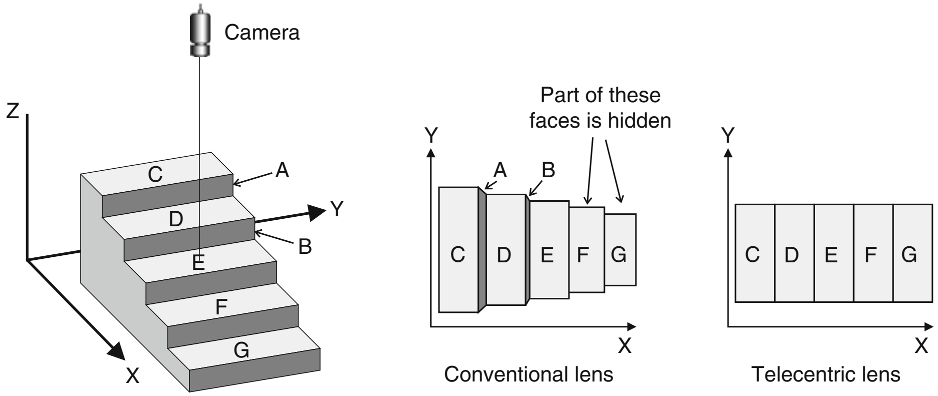

Fig. 6.3
Size constancy in telecentric lenses is not shared by conventional lenses. (a) Scene (b) Image created by a conventional lens (Geometric distortion introduced by the lens has been ignored) (c) Image created by a telecentric lens. Notice that faces A and B are not visible but that C, D, E, F and G are fully visible

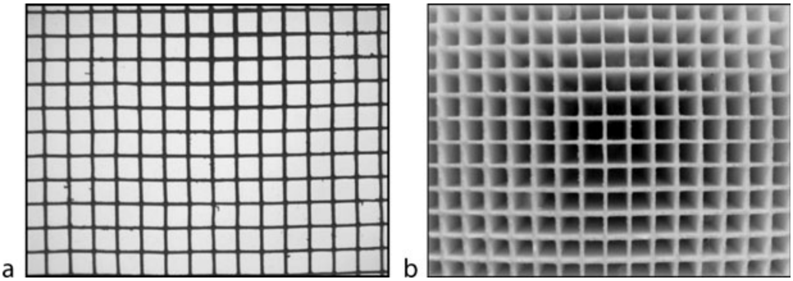

Fig. 6.4
Constant perspective across the whole visual field. (a) Catalytic converter element imaged with a telecentric lens. This object consists of a "honeycomb" structure, containing square tubes, 6 × 6 × 100 mm^3 (b) A conventional lens does not provide constant perspective. Notice the apparent barrel distortion, which is just perspective error

6.1.1.3 Small Angular Acceptance Range

Any lens can be "stopped down," to reduce its entrance pupil diameter. As the *f-number* (*f*/#) increases, the aperture *inside* the lens is made smaller. The cone enclosing the light rays from a given object point passing through the lens becomes narrower. The center axis of every little cone of light emanating, from every point on the object, converges toward the entrance pupil of the lens. There can be large angles between the central axes of these cones. For OST and DT lenses, the axes of all these cones are parallel, since the lens will not accept non-parallel rays. Such a lens can be useful for detecting certain types of subtle defects in transparent, or reflective, flat material. This feature of telecentric lenses is often overlooked, but we will provide a good example later (➋ *Fig. 6.6*).

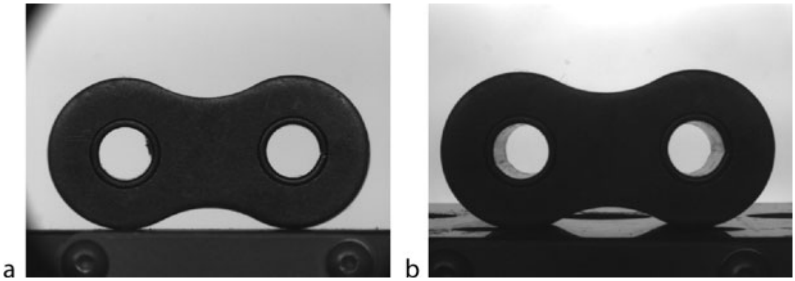

Fig. 6.5
Link of a motorcycle chain, with a blocking defect (a) Telecentric lens (b) Conventional lens

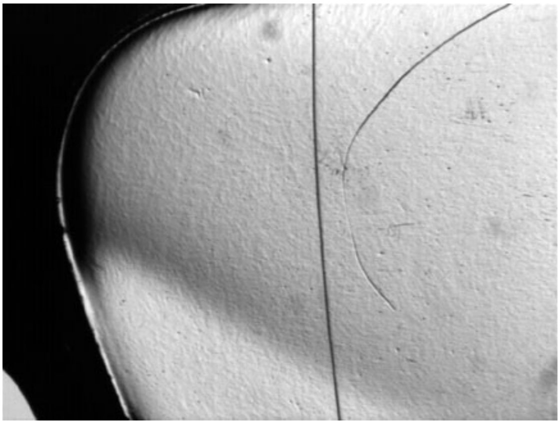

Fig. 6.6
Lens for a pair of plastic safety spectacles, imaged with a telecentric lens and collimated light

Telecentric lenses, of whatever kind, do not have larger image-sharpness depth-of-field than conventional lenses; this kind of depth-of-field is only a function of magnification and f-number. (This assumes that the lens is has been designed properly and is of a high quality of manufacture.)

6.1.2 Disadvantages of Telecentric Lenses

One of the most serious problems with telecentric lenses is that the first (i.e., objective) element must be at least as large as the object being inspected. Refer again to *Figs. 6.2* and *6.3*, which show that this must be the case, since the lens only accepts rays of light that are nearly parallel. This is not the case, of course, with conventional lenses, which are very often smaller than the objects they view. The cost of a large telecentric lens can be quite high. However, there are other solutions:

- A Fresnel lens may be used as the front element. This will reduce the cost and weight. Telecentric lenses with Fresnel front elements of 1.5 m diameter, are perfectly feasible.

However, the image quality is reduced (often considerably) compared to a conventional lens. (Fresnel lenses are discussed later in this chapter, ➋ Sect 6.3)

- A catadioptric (mirror based) telecentric system may be used instead. Again, this can reduce the cost and weight, compared to a telecentric lens using a large refractive front element. (The reader who is unfamiliar with Fresnel lenses may be reassured that they are commonplace devices. A Fresnel lens usually forms the main optical element in an overhead projector. They are also used in visual displays and rear-view mirrors in automobiles).
- If a line-scan sensor is being used, the cost of a telecentric lens incorporating a very large Fresnel or catadioptric front element, may be reduced very significantly.

For many commercial telecentric lenses, especially of the OST variety, it is difficult to provide good telecentric imaging with long working distance. This is less of a problem for DT lenses.

A DT lens may be constructed around a pin-hole aperture, located at the focal points of two simple lenses. (➋ *Fig. 6.7*) The aperture must be very small to make sure that only parallel rays are accepted. However, this greatly reduces the brightness of images produced by the lens. In many Machine Vision applications, this may not be a serious disadvantage, since lighting a small area is normally sufficient. (The area that needs illumination is only a little large than that of the front aperture of the telecentric lens).

6.1.3 Applications of Telecentric Lenses

6.1.3.1 Gauging

The large magnification depth-of-field of a telecentric lens makes it ideal for a great variety of dimensional gauging applications. It is possible to think of a telecentric lens as forming an optical caliper with very long jaws. Typical gauging applications include measuring threaded fasteners, machined parts, the geometry of bottles, and component placement on PCBs.

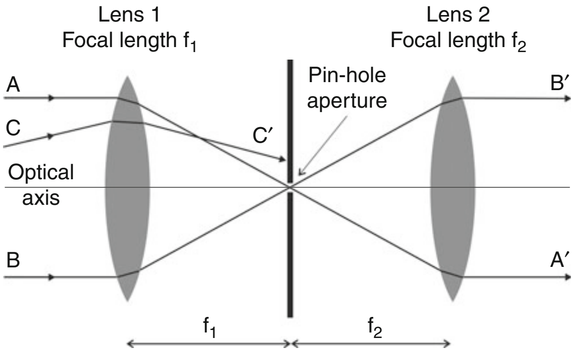

Fig. 6.7

Constructing a telecentric lens with a pin-hole aperture. Rays AA′ and BB′ travel through the aperture, while ray CC′ does not. In practice, several lens elements may be used on each side of the aperture, to ensure a bright image without serious aberrations (The pin-hole inevitably blocks much of the light, thereby reducing the image brightness)

Any application that requires the measurement of an object with little or no perspective error, or with varying distance, is suitable for a telecentric lens.

6.1.3.2 Constant Perspective

Non-gauging applications that make use of the constant perspective property of telecentric lenses include inspection of tubes, pipe bores, gun barrels and the verification of hole clearance. An extreme case of this is shown in *Fig. 6.4*. This image of a catalytic converter element was captured using a telecentric lens with a very large field-of-view. It would not be possible to view more than a few of the cells (nine at the most) with a conventional lens.

Figure 6.5 compares the diverging field of view of a conventional lens with that of a telecentric lens. The defect (surplus material in the left-most hole) can only be seen with a telecentric view.

6.1.3.3 Defect Detection in Transparent or Flat Materials

A telecentric lens collects rays of light that are very nearly parallel. Hence, it is possible to detect defects that divert light away from a parallel path. Nominally flat transparent and reflective sheet materials, such as glass, plastic, polycarbonate (optical discs), or simple plastic packaging can be inspected very effectively with a telecentric lens. Scratches, cracks, pits, blisters, pimples, embossing, inclusions, bubbles, water/oil droplets, etc., and local variations in refractive index all divert light and hence are able to produce high contrast images with a telecentric lens. These can be difficult to see using conventional lenses and lighting, In addition, telecentric lenses can often make subtle defects clear on mirror-like surfaces (e.g., CDs, DVDs, silicon wafers, optical components) *Fig. 6.6* shows an example of imaging part of a pair of plastic safety glasses. With a conventional lens, the defects are barely visible, even to the human eye. With a telecentric lens and collimated back lighting (parallel beam), the defects are sharply defined.

6.1.4 Lighting

As often stated in this book, illumination can be critically important. Poor lighting can seriously affect the performance of a vision system, even in seemingly straightforward applications such as back-lit gauging. For example, difficulties may arise when measuring bright shiny objects. *Figure 6.8* illustrates this point by showing a shiny sphere with a presumed large, diffuse back light.

One solution to this problem is to mask off the diffuse light source so that it is only just larger than the object being inspected. An equivalent approach is to move the light source far behind the object. Either case reduces the angular range of the light rays that approach the object. Sometimes, however, this technique is impractical. The object may move around too much to allow effective masking, or there may be no room for a distant diffuse light source in the inspection station.

A more expensive, but technically superior solution is to use a collimated back light such as shown in *Fig. 6.9*. A small light source placed at the back focus of an appropriate lens will produce nearly parallel or collimated rays of light as an output. Such a light provides a close

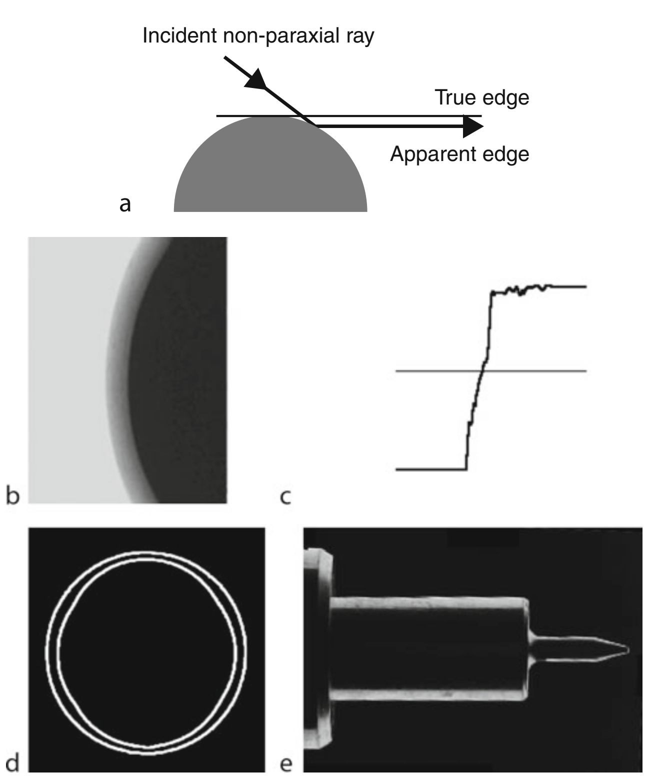

Fig. 6.8
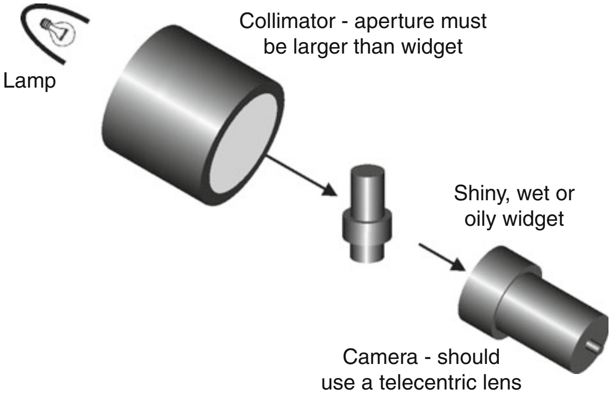
Large-area diffuse back lighting of a shiny object allows non-paraxial rays causes reflections that could be avoided by using telecentric lens (a) Ray optics explains why this happens. (b) Sample image, derived from a brightly polished metal sphere in front of a large "light box." Ordinary back-illumination like this produces a light grey annulus around a very much darker disc. The grey band is caused by reflections of non-parallel rays. (c)Intensity profile shows the gradual change of intensity within this grey band. (d) True contour (*outer curve*) and the apparent edge contour (inner curve). Clearly, it is easy to under-estimate the diameter of the sphere. (e) The effects of non-paraxial illumination angles are emphasised in dark-field illumination. The non-paraxial rays which illuminated the object (a carburretor needle) to produce the bright edge would be eliminated by a telecentric collimator

source that allows the object to move about during inspection. Furthermore, this is a much more efficient use of light. When well-aligned, all the rays of light from the collimator enter the telecentric lens and contribute to the image. Where a diffuse light source may require many watts of power to provide enough light for high-speed applications, a collimated source may operate at a tenth to a hundredth of the power.

6.1.5 Comparison of Telecentric and Conventional Lenses

Telecentric lenses have better magnification depth-of-field than do conventional lenses. Furthermore, Double Telecentric lenses are better than Object Space Telecentric lenses in this



Lamp
Collimator - aperture must be larger than widget
Shiny, wet or oily widget
Camera - should use a telecentric lens

Fig. 6.9

Collimated light source for improved telecentric imaging of shiny objects. In practice a very small, intense light source would be used. The beam generated by the collimator contains rays that are almost all, very nearly paraxial

Table 6.1

Comparing magnification depth-of-field for conventional, OST and DT lenses

Object distance change (mm) centred on 100mm stand-off	Magnification (Theoretical)		
	Conventional (20mm fl.)	OST (100mm fl.)	DT (afocal)
0 mm	0.25	0.250	0.250
4 mm	0.238	0.248	0.250
8 mm	0.227	0.245	0.250
12 mm	0.217	0.243	0.250
Max. change	13.2%	2.8%	0.0%

respect. ❯ *Table 6.1* quantifies this, by comparing the changes in magnification versus object distance for these three types of lenses. In each case, it is assumed that the nominal optical magnification is 0.25X, and that the nominal stand-off distance (lens to object) is 100mm. If we ignore the limiting factor of image sharpness depth-of-field, a double telecentric lens could theoretically have perfectly constant magnification over an infinite range of object distances. In practice, real lenses with finite manufacturing tolerances cannot meet this ideal. A DT lens will have a greater magnification depth-of-field than will an OST lens, and much greater than the equivalent stand-off distance for a conventional lens.

❯ *Table 6.2* compares the merits of telecentric and conventional lenses. In many cases, with a little thought and care, telecentric lenses used at the “front end” of a Machine Vision system can make the “back end” engineering much easier and more cost-effective. Do not be put off by the increased price compared to conventional lenses; investing in a telecentric lens can often reduce the *system cost* significantly.

Table 6.2

Comparing telecentric and conventional lenses

Feature	Type of lens	
	Conventional (CL)	Telecentric (TL)
Advantages	Low cost Greater availability, compared to TL Greater flexibility, compared to TL	Constant magnification (little change with varying object-lens distance) No perspective error Narrow acceptance angle
Disadvantages	Magnification varies with object-lens distance Perspective Error	Darker images than CL Heavy Higher cost than CL Requires large first element (refractive lens, Fresnel lens or mirror)
Applications	Colour checking Counting objects/features Detecting foreign bodies Existential inspection Grading & sorting Inspecting large objects Inspecting textured surfaces	Inspecting deep holes, pipes, tubes, etc. Inspecting plain surfaces Inspecting transparent film Metrology Object/feature alignment

6.2 Hypercentric Lenses

Inspection tasks often require seeing a lot more of an object than a single view can achieve. The usual solution is to rotate the object, which is often time-consuming, or use multiple cameras. Sometimes, employing an optical view-splitter works very well. Other times, however, a preferred solution would be to capture a continuous view all around the object. Hypercentric lenses offer one such solution. A hypercentric, or pericentric, lens provides a converging view of an object, so that its top and sides can be viewed simultaneously. It has the reverse effect of the more familiar fish-eye lens. The operation of a hypercentric lens is explained in *Fig. 6.10*.

In normal mode, hypercentric lenses provide a converging view, as if aimed at a single point, called the Convergence Point (CP). The volume that can be well-imaged is contained within an imaginary truncated cone, called the Near View Cone (*NVC*). This is the blue hatched region in *Fig. 6.10a*. The dimensions of this region are *T*, *B* and *Max WD*. For standard Hyper-Eye lenses, *T* varies from 15.2 mm to 25.6 mm, *B* from 35.3 mm to 51.2 mm, and *MaxWD* from 28 mm to 42 mm. Other options are available.

Some hypercentric lenses can also serve as a long stand-off borescope, by simply adding a short spacer (typically 0.5–1.5 mm) between the lens and camera. Although counter-intuitive, this increases the focus distance beyond the CPD. The lens can therefore view the inside of a bore, even those with very small openings (*Fig. 6.11*). Unlike standard borescopes, this arrangement provides a large working distance between the lens and the object being viewed. This reduces the risk of parts crashing into the lens, makes it easier to arrange for suitable illumination within the bore.

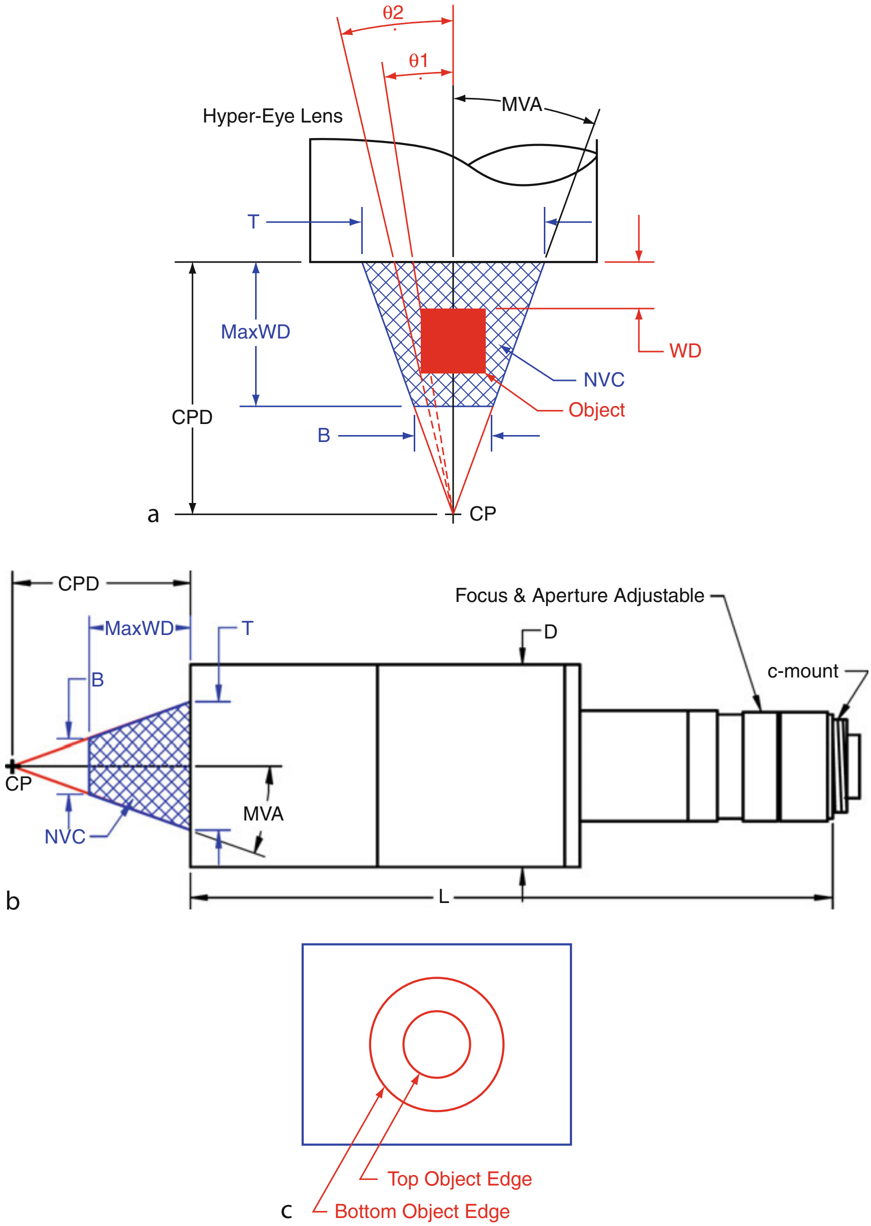


Fig. 6.10

Hypercentric lens. (a) The lens receives rays of light as if they all originate from a single Convergence Point (CP). The distance from the front of the lens to CP is the Convergence Point Distance (CPD). Any object that is within the Near Viewing Cone (NVC) can be focused onto the camera detector. Rays of light that are collected at smaller angles (1) are imaged closer to the center of the detector. Those collected at higher angles (2) are imaged farther out. (b) Hypercentric lens with a C-mount fitting, plus focus and aperture controls. (c) A hypercentric lens used to view a cylindrical object end on can see its top and sides

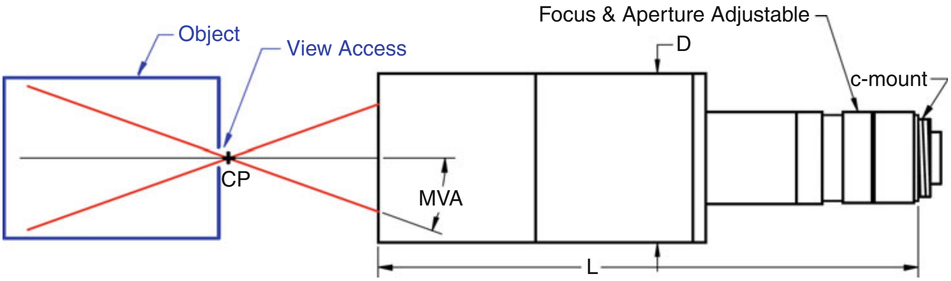

Fig. 6.11

Using a hypercentric lens as a borescope. A small spacer (not shown) is inserted on the C-mount between the lens and camera on the C-mount

Table 6.3

➋ *Tables 6.3* and ➋ *6.4* summarise the properties of a range of commercially available hypercentric lenses. ➋ *Figure 6.12* shows a sample of images produced using a this type of device.

6.3 Fresnel and Micro Optics

The term "*Micro-optics*" may refer to the very small conventional optical components employed in fibre-optic communications systems, and medical imaging instruments such as needle endoscopes. There is however, another meaning for this term and is the one that we use here. There are three common types of optical component made by forming numerous very small valleys and/or mounds on a plane surface. *Fresnel* lenses employ very fine prismatic surface features on a thin plane plate. *Micro-lens arrays* consist of numerous small lenses (lenslets) placed close together on a plane substrate. In both of these cases, the optical formulae explained in ➋ Chap. 5 are applicable, because the surface features, while small, are still much larger than the wavelength of light. On the other hand, *Diffraction (or Binary)* optical components have such small surface features that they cause interference due to diffraction; refraction plays no significant part in the operation of these devices.

Table 6.4
Showing how the ray angles from the CP correspond to the detector at the image plane. This relates to the Hyper-Eye™ range of lenses produced by Light Works LLC, http://www.lw4u.com/] The table indicates that the HE-5012A2 lens is best used with a 1/2" format or larger detector. The image radius at 20.5° is 2.35mm (diameter 4.7mm) The standard 1/2" format detector is 4.8mm x 6.4 mm, therefore the image circle will just fit inside it. A 1/3" format detector (3.6 mm × 4.8 mm) would not be a good match.The HE-5008A3 and HE-7508A3lenses are typically for use with 1/3" format or larger cameras, while the HE-5012A3 and HE-7512A3 are suitable for use with 1/2" format or larger cameras

HE-5008A2		HE-5012A2		HE-7508A3		HE-7512A3

21	1.57 mm	21.5	2.45 mm				

6.3.1 Fresnel Lens

A Fresnel lens consists of a thin sheet of transparent material, such as Polymethyl Methacrylate (acrylic resin), with a series of fine grooves impressed on one, or both, of its sides. (One surface is usually plane with no grooves.) The grooves act like tiny prisms see (➋ *Figs 6.13* and ➋ *6.14*). The angles of their inclined surfaces vary across the face of the lens and are chosen so that a parallel coaxial beam is focussed to a very small spot. Little light is lost by absorption, since the plastic sheet is thin. This also reduces the weight of the lens. Fresnel lenses with a high groove density can produce good quality images, whereas a low groove density improves efficiency, which is important in light-gathering applications. The prismatic grooves disperse light, making Fresnel lenses prone to chromatic aberration. (Of course, in many Machine Vision applications, monochromatic illumination can be used, which will eliminate this aberration.) Fresnel equivalents of aspheric, convex, concave, fish-eye and cylindrical refracting surfaces are all available. Using two "crossed" Fresnel cylindrical lenses, it is a simple task to perform anamorphic warping in which the two image axes are magnified by different amounts. These axes are not necessarily orthogonal. Fresnel lenses that operate in the infrared waveband are also manufactured.

Fresnel lenses are usually made by moulding, stamping or rolling and can be manufactured in bulk, cheaply and easily. Very large Fresnel lenses can be made for a modest cost that would not be possible with conventional lenses. For example a Fresnel lens with a diameter of 1.65m costs under €220. (US $300, January 2010) A Fresnel lens for an overhead projector costs about €40, while a wide-angle automobile rear-window lenses costs about €5.

It is, of course, possible to make reflecting surfaces on the same principle. (*Figs 6.15* and *6.16*) Fresnel reflectors are sometimes used in overhead projectors and illumination optics.

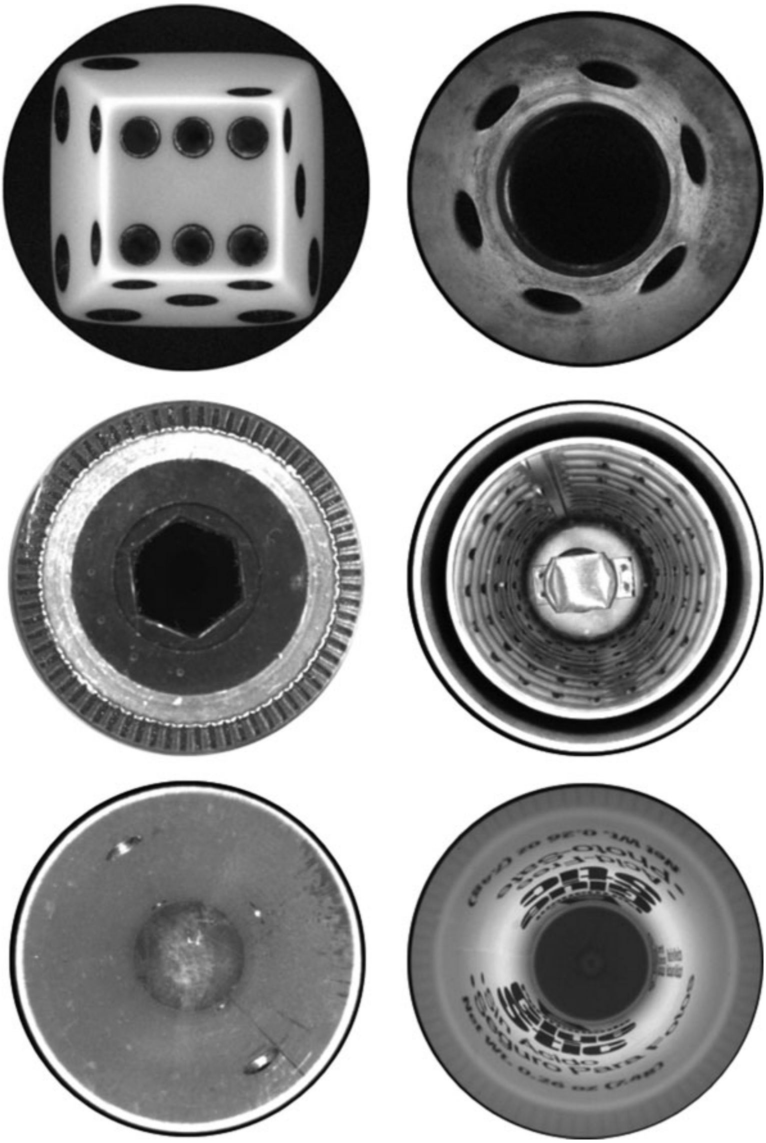

Fig. 6.12
(Continued)

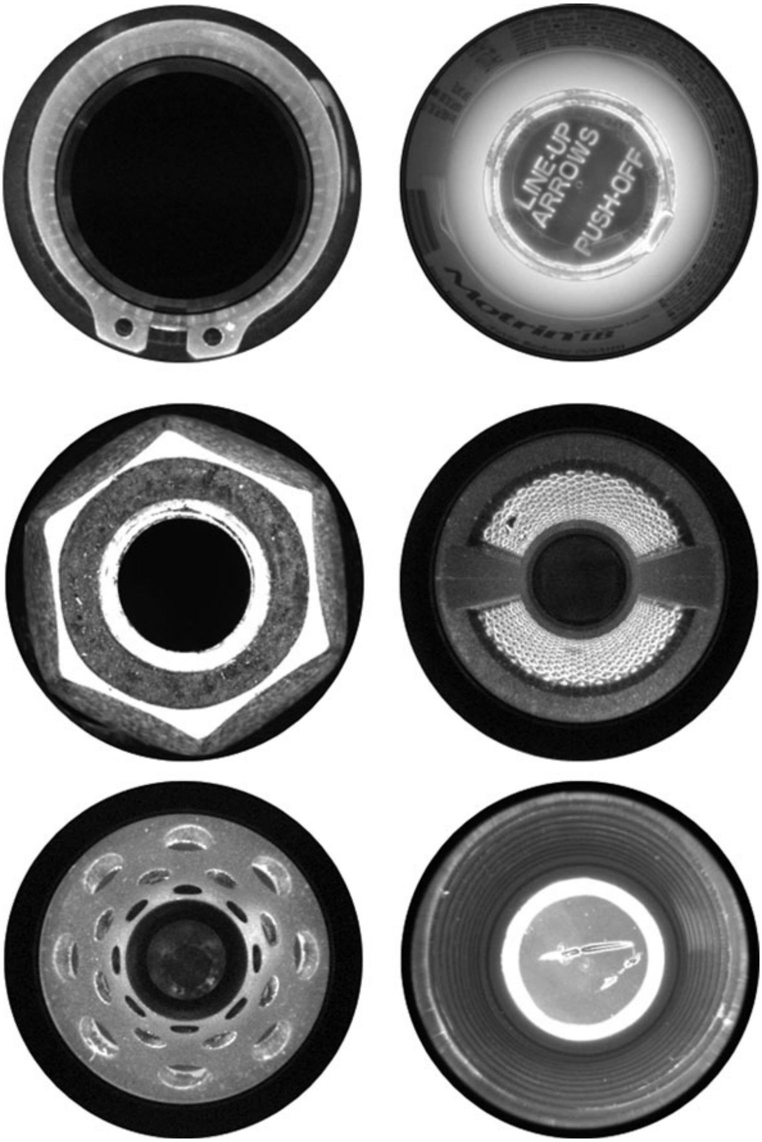

Fig. 6.12

Images obtained using a hypercentric lens. (a) Cube, gaming die. (b) Cylinder with six side ports, diameter approximately 16mm. (c) Screw head with a defect. (d) Car oil filter, viewed through a hole of approximately 19mm diameter. (e) Pipe, 35mm diameter, 100mm deep. (f) Medicine bottle. (g) Hexagonal nut (h) Cylindrical filter screen with a defect. (i) Cylinder with 24 side ports. (j) Pipe cap, internal diameter 25mm

Since they are flat, they occupy less space and are easier to mount than conventional curved mirrors. Unlike Fresnel lenses, they do not introduce any chromatic aberrration at all. The facets of a Fresnel mirror can be coated individually to construct a mirror that provides different deflection angles, or variable focal lengths, for different parts of the spectrum.

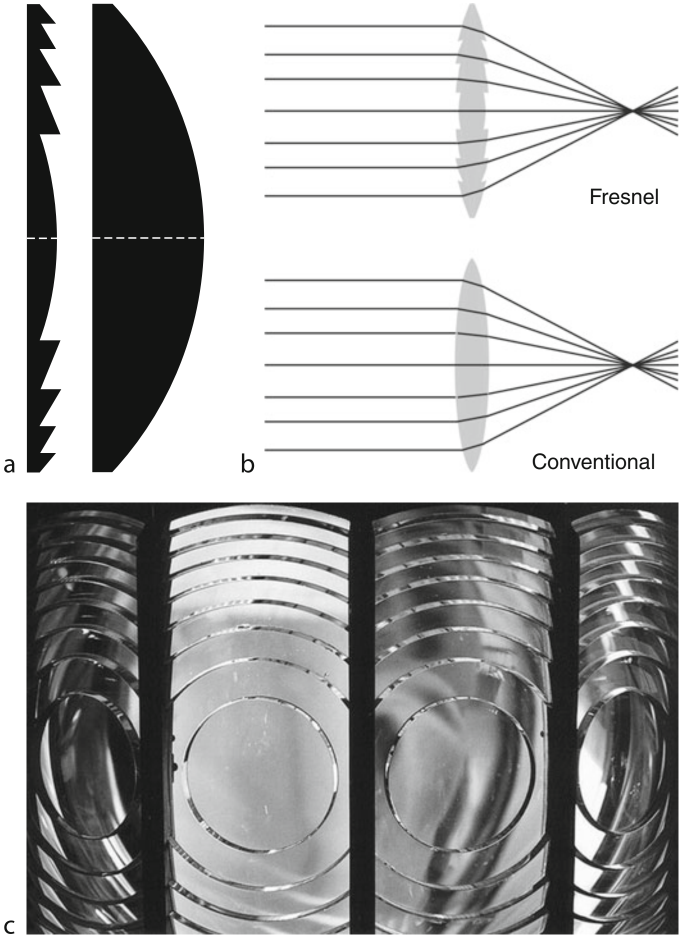

Fig. 6.13

Fresnel lens (a) Cross section, compared to that of a conventional lens. In most cases, the grooves are far smaller and more numerous than shown here. (b) Focussing in a Fresnel lens. Each groove acts a small prism, (c) Light-house Fresnel lens. Such a Fresnel lens may be a metre tall. An equivalent conventional lens would be extremely expensive and very heavy

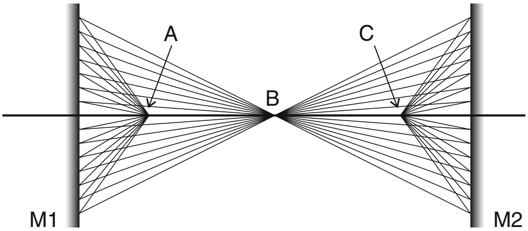

Fig. 6.14

Typical microlens structures. (a) The lenslet diameter is about 20μ. Closer packing and aspherical form are sometimes used. (b) Lenticular (1-dimensional) array

Fresnel lenses are used in domestic and commercial luminaires, traffic lights, maritime light-houses, navigation and automobile lights (➋ *Fig. 6.16*). They are used in overhead and video projectors, for image formation and are sometimes used to magnify the picture on small LCD displays. They are employed for light gathering, in devices such as solar cookers and furnaces. They are ideal in this type of application as a large low-cost Fresnel component can greatly increase the effective light-capture area of a photo-electric energy converter. Since they are light in weight and can be made to have considerable optical power, Fresnel lenses are suitable for making spectacles for people with certain vision defects including strabismus. Computer cameras, webcams and photocopiers all frequently employ them. Adjustable Fresnel

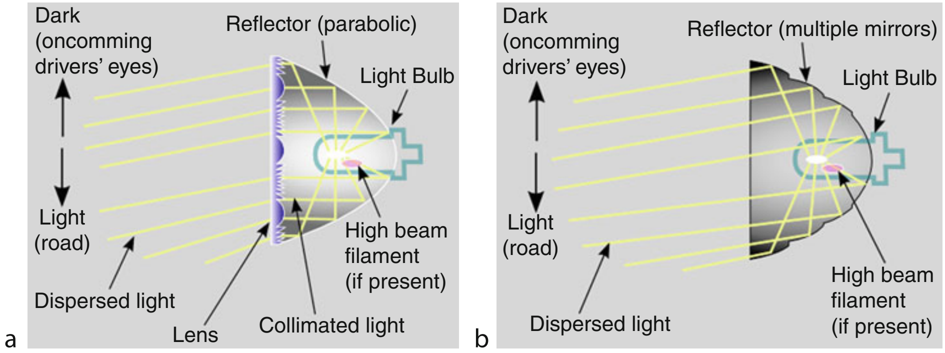

Fig. 6.15
Using two identical Fresnel mirrors (M1 and M2) to focus light from a "point" source (A), to another point (C). (For the sake of simplicity, the facets of the Fresnel reflectors are not shown.) An object placed at C will be illuminated at its side furthest from A. (Compare this to an elliptical mirror.) The distribution of light falling on point C is identical to that emitted by the source A. A pinhole placed at B will block most of the "stray" light coming directly from A (Compare this to a telecentric lens)

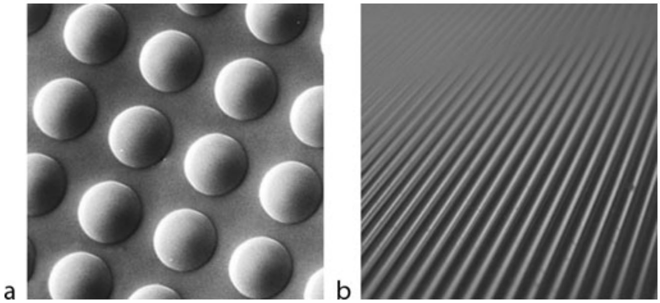

Fig. 6.16
Automobile headlamp designs. (European standard) (a) Fresnel lens. (b) Multi-facet Fresnel mirror. Reproduced under the GNU Free Documentation License, from [Headlamp, Wikipedia, URL http://en.wikipedia.org/wiki/Headlamp, Accessed 27th October 2010]

lenses have been made using piezo-electric crystals to control the focal length of the lens. The lens is heated when making the adjustment and then cooled to room temperature for use. Since very large Fresnel lenses can be made without incurring enormous cost, they are frequently used as objective elements in a telecentric-lens assemblies. (The objective element must be at least as large as the object being viewed.)

6.3.2 Microlens Arrays

A *microlens array* (also referred to as *microlenticular array* or *lenslet array*) is similar to a Fresnel lens, except that its surface consists of numerous tiny lenses, rather than prisms (➋ *Fig. 6.14*). The size, profile and transmission characteristics of these lenslets may vary across the array. Low quality arrays can be manufactured cheaply, by moulding materials such as Polymethyl Methacrylate (acrylic resin) or epoxy. Microlens arrays are available in sheet form. More precise arrays are constructed from high-grade optical materials, such as fused silica, using standard semiconductor manufacturing methods. This provides good uniform transmission over a wide range of wavelengths (0.19–3.0 μm) Silicon is sometimes used instead and transmits well over the NIR waveband (1.2–5μm). The shape, position and alignment of each individual lenslet can be controlled within close limits. Other commonly used materials are Gallium Phosphide and Calcium Fluoride. Appropriate optical coatings can be applied to control the transmission over selected ranges of wavelength. *Graded index* (*GRIN*) arrays depend not on the 3D shape of the lenslets but variations of the refractive index within a plate that has smooth parallel sides. M*icro-Fresnel lenses* are devices in which individual lenslets have Fresnel refracting surfaces. They can be made very thin and light in weight.

Single microlenses are used in communications systems, to couple light to individual optical fibres, LEDs and lasers. Arrays of microlenses can form excellent diffusers, providing a way to homogenise beams precisely and efficiently from a variety of sources including high-power LEDs and lasers, LED arrays and fibre-optic illumination bundles (➋ *Fig. 6.17*).

Microlens arrays are used in some digital projectors, to focus light to the active areas of an LCD spatial light-modulator. Combinations of microlens arrays have been designed that have novel imaging properties, such as the ability to form an image at unit magnification without inverting it. This is not nearly so convenient with conventional lenses. Microlens arrays are used in photocopiers and mobile-phone cameras. They can form several "copies" of an image, acting as a multi-way beam-splitter. Of course, they can act in the reverse direction, enabling two or more beams to be merged by interlacing them. Interlacing two images can be achieved with an array of alternating transmitting and opaque strips and is useful in 3D stereoscopy. These strips can be replaced by an array of cylindrical microlenses, forming what is known as a *lenticular screen* that is able to make efficient use of the illumination. A microlens array can provide variable magnification over its field of view. Such a device provides the basis for building a variable-resolution sensor akin to the eye and can be used in a projector to generate complex patterns of light from a simple "point" source.

Microlens arrays are used to increase the sensitivity of CCD image sensors, particularly interline-transfer devices, that suffer from reduced aperture due to metal shielding. One lenslet is placed over each photodetector, where it can collect and focus light that would otherwise have fallen on non-sensitive areas of the detector array (➋ *Fig. 6.18*). This increases its sensitivity, by making better use of the available light. The optical fill-factor can be improved significantly; the optical fill-factor of interline CCDs can be increased from below 20% to

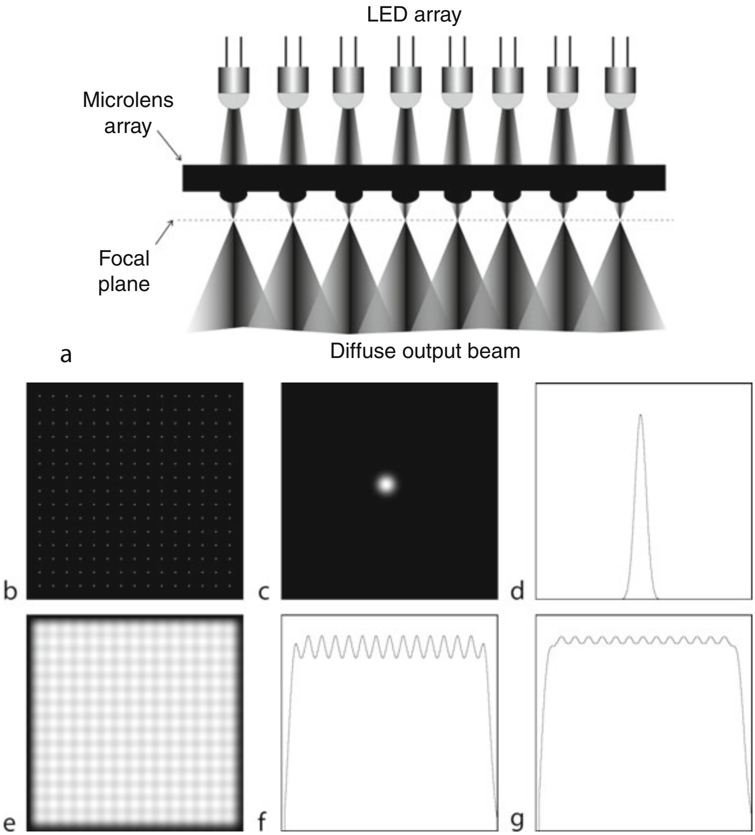

Fig. 6.17

Using a microlens array as a diffuser. (a) Layout, using one lenslet for each LED. The LED beams overlap beyond the microlens focal plane, thereby reducing local variations in the brightness of the illumination field. (b) Test pattern consisting of a series of "point sources". (The spots have been slightly dilated, for the sake of clarity.) (c) 2d microlens point-spread function. (d) 1D microlens point-spread function. (e) Illumination pattern. (f) Intensity profile across the centre of the illummination pattern. (g) Making the point-spread function wider (33%), reduces local variations in intensity (These are simulated results)

nearly 100% by placing a lenslet in front of each photosite. Moreover, the microlenses reduce the amount of stray light that might otherwise spoil the image quality. By controlling the incoming light better, fewer photons "spill over" into a neighbouring photo-receptor, to blur the image. The resemblance of the arrangement shown in ❯ *Fig. 6.18c* to an insect eye is obvious. One drawback of such an arrangement is that large variations in detector illumination angle can produce large variations in received image brightness.

The quality of the lenlets that can be fabricated using modern electronic manufacturing techniques (photolithography) is comparable to that of a standard ground lens. The diameter of an individual lenslet might be anywhere in the range 10–800 μm. There is no reason why all of the lenslets in an array should be all be same size, or have their optical axes all parallel to one another. Round lenslets may be packed hexagonally, while square lenslets can be packed more

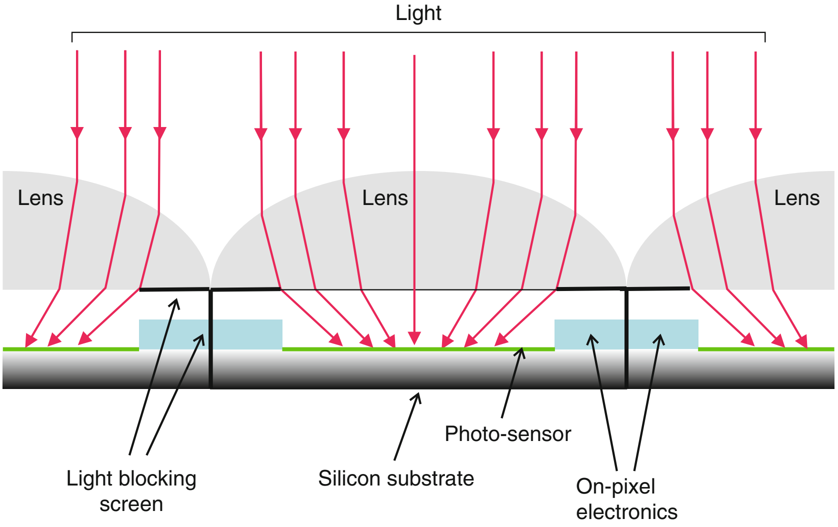

Fig. 6.18
Microlens array placed over a CCD image sensor. One lenslet is fitted to each photosensor to concentrate light on the light-sensitive area and away from the other electronic elements. Without a microlens, the detector would collect a significantly lower proportion of incoming photons. As a result, the fill factor is greater than it would be without the lens

closely together. When the lenslets are small than about 10 microns diffraction effects can become troublesome. The microlens array discussed so far rely on refraction. There is another type of device in which diffraction is deliberately exploited and these are discussed in the next section.

6.3.3 Binary Optics (Diffractive Optics)

Binary optics focus light by diffraction, not refraction. For ease of manufacturing, they are made with stepped, or multilevel micro-groove surfaces. Familar examples of the type of surface structure to be found on diffractive optics are to be found on CDs, DVDs, butterfly wings, fish scales and beetles. Binary optical devices have a range of specialised applications, principally being used in conjunction with coherent optical (laser) systems:

- Homogenising laser beam intensity
- Randomising beam phase
- Beam Splitting
- Kaleidoscope lens, creating several identical images from one image.
- Beam shaping
- Generating illumination patterns, such as gratings, cross hairs, multiple stripes, multiple spots, concentric circles, etc.
- Correcting for aberration in combination with refractive lenses
- Building Fresnel zone lenses
- Generating wavefronts of given shape
- Colour-selective filtering

6.4 Conclusions

The conventional optical devices described in the previous chapter are well known. The ability of telecentric lenses to produce images without perspective error, or parallax, has solved many critical inspection applications, especially those involving gauging. Controlling the direction of view is important but so is the ability to direct light at given angles onto an object. Again, telecentric lenses are able to help. Hypercentric lenses can produce a conical viewing/lighting volume., which enables them to see features that would otherwise require physical movement, multiple cameras, or a complex arrangement of beam-splitters and mirrors. The physical size of both telecentric and hypercentric lenses is limited by that of the front refracting element. Very large Fresnel lenses can be made at a modest cost, thereby enabling the benefits of telecentric and hypercentric lenses to be enjoyed over a much wider range of applications than would be the case with conventional lenses. A technology similar to that used for manufacturing Fresnel lenses is able to produce interesting and useful effects in microlens arrays. A wide variety of transformations is possible, including: field splitting, merging multiple beams to form a single image, polar-to-Cartesian axis mapping, correcting barrel or pin-cushion warping, etc. By making the features on the lens even smaller, diffractive effects dominate, enabling yet more interesting functions to be performed optically. It is well to remember that any operation that can be accomplished using optics is very much faster than the equivalent process performed in software, or even dedicated electronic hardware.

7 Illumination Sources

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_7,

Abstract: Our everyday experience does not alert us to the need to choose lamps for Machine Vision carefully. The human eye-brain complex is able to compensate for slow variations in both the colour and intensity of ambient lighting, without our ever becoming aware that any change has taken place. As a result, people often remark with surprise how bright the room suddenly appears when a light bulb has been changed. Unlike people, machines are very sensitive to variations in both colour and brightness. Incandescent filament bulbs and fluorescent tubes are used in the home and office, while mercury and sodium discharge lamps are commonly employed in street lighting and in factories and warehouses. For many years, advertising has relied heavily on "neon" displays. In addition, there is a new variety of lamps available, including a wide range of LED-based lighting units, cold cathode tubes, compact fluorescent bulbs and plasma panels. Arc lamps have been used in specialised scientific and industrial applications. For Machine Vision, the following properties of lamps are important:

- 3D radiation pattern
- Ability to control the lamp brightness
- Brightness, including long-term variations due to lamp ageing
- Driver (AC /DC, frequency, closed-loop control)
- Efficiency, measured by the ratio of the optical emission power to the electrical power consumed
- Electrical noise generated
- Heat produced
- Infra-red content of the beam
- Life-time, measured simply by how long before the lamp becomes so dim as to be useless, or stops emitting altogether
- Long-term degradation of emitted power
- Power-line ripple
- Shape
- Short-tem stability of emitted power
- Spectrum (This requires a much more detailed analysis than simply stating the "colour".)
- Ultra-violet content

The features of the major types of lamp are discussed. LEDs are almost ideal for many industrial applications and in recent years, there have been major advances in the design of LED arrays for Machine Vision. It is possible to build arrays in a variety of shapes. An array may contain LEDs of many different and precisely known colours. LEDs are efficient and stable over a long period. The lighting pattern can be adjusted dynamically, under software control.

7.1 Introduction

Success in Machine Vision begins with good lighting! A well-designed illumination sub-system enhances the features being inspected, whereas a poor one will obscure them. Here is a universal truth: successful Machine Vision systems do not rely on environmental lighting. To build a reliable Machine Vision System, the lighting must be specially designed for each application. Simply pointing the first available light source, such as a hand-held torch or a desk light, at the object to be inspected is simply not good enough. (This comment does not, in any way, diminish the case for experimenting with lighting during prototype development.)

A poorly designed illumination system may produce glare (thereby saturating the camera), shadows (hiding defects or other important features), and/or low contrast images. Uneven illumination forces the vision engineer to use image processing algorithms that are slower, more expensive and less reliable than they need be. It always pays to optimise the lighting before proceeding with the rest of the design.

7.1.1 Measuring Light

It is important, first, to distinguish between photometric and radiometric measurements of light.

- *Radiometry* is concerned with the physical measurement of electromagnetic radiation within the range of wavelengths 10^{-2} to 10^{3} μm (i.e., frequency range 3×10^{11} to 3×10^{16} Hz). This includes ultraviolet (UV), visible (VIS) and infrared (IR) wavebands.
- *Photometry* is concerned with the measurement of light as perceived by the human eye (wavelength range 0.360–0.830 μm).

Photometric and radiometric concepts are similar, except that for the former, emission/reflection spectra are weighted by a luminosity function representing the spectral response of the eye of a standard observer (➔ *Fig. 7.1*) [1]. If the radiometric spectrum is represented by R(λ), the photometric spectrum by P(λ) and the standard luminosity function by L(λ), then

$$P(\lambda) = R(\lambda).\ L(\lambda)$$

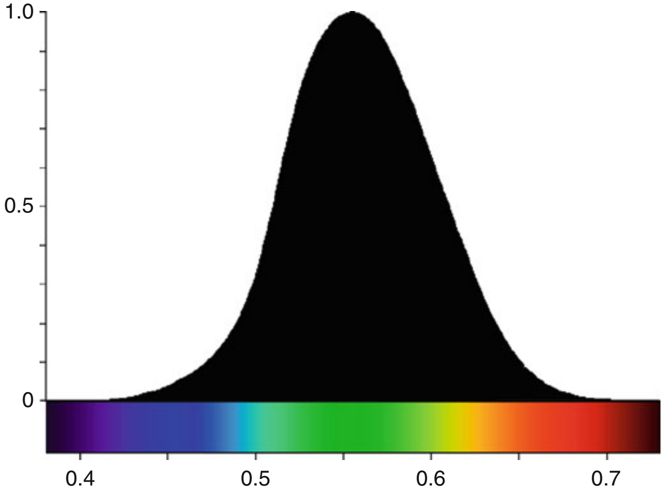

Fig. 7.1
The 1931 CIE standard luminosity function describing the average sensitivity of the human eye to different wavelengths. The photopic curve, shown here, relates to day-time light levels and is the basis for the definition of the 1931 CIE Colour Space. It can be used to convert radiometric spectra into photometric spectra. For low light levels (scotopic vision), the luminosity function has a similar shape but the peak is shifted towards the shorter wavelengths

$$P(\lambda) = R(\lambda) \cdot L(\lambda) \tag{7.1}$$

We are now able to define several measurements of light. Also see ➲ *Table 7.1*.

- *Candela* (cd) is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of wavelength 0.555 μm (mid-green, frequency 5.40 × 10^{14} Hz) and has a radiant intensity in that direction of 1/683 W per steradian. (A common candle emits roughly 1 cd and a 100 W incandescent lamp emits about 120 cd.)
- *Lumen* (lm) is the SI unit of luminous flux. If a light source has a luminous intensity of 1.0 cd, the total luminous flux emitted into a solid angle of one steradian, the total luminous flux emitted is 1 lm. An isotropic 1 cd source emits a total luminous flux of 4π lumens.
- *Lux* (lx) is the SI unit of illuminance and measures the intensity of light weighted according to the *Luminosity Function* (➲ *Fig. 7.1*). The illuminance levels commonly encountered in everyday life are summarised in ➲ *Table 7.2*.

Table 7.1
Units of illumination

Quantity	SI unit	Abbreviation
Luminous intensity (SI base unit)	candela	cd
Luminous energy	lumen second	lm s
Luminous flux/luminous power	lumen (= cd sr)	lm
Luminance	candela per square metre	cd m^{-2}
Illuminance (light incident on a surface)	lux	lx = lm m^{-2}
Luminous emittance (light emitted from a surface)	lux	lx = lm m^{-2}
Luminous efficacy of a lamp (maximum is 683.002)	lumen per watt	lm W^{-1}

Table 7.2
Relating photometric illuminance to everyday experience

Illuminance (lux)	Example
5×10^{-5}	Starlight
10^{-3}	Moonless clear night sky (no city lights)
10^{-2}	Quarter Moon
2.5×10^{-1}	Full Moon, clear sky
10	Candle, 300 mm away
5×10^{1}	Household living space
4×10^{2}	Brightly lit office
10^{3}	Television studio lighting
3×10^{4}–10^{5}	Sunlight, average day

Colour rendering index (CRI) is a measure of how well balanced the different spectral components of nominally white light are. A black body radiator, such as an incandescent lamp has a CRI of nearly 100, while fluorescent tubes have CRIs of 50–99%. Colour temperature is another measure of the whiteness of a light source. Typical incandescent lighting has a colour temperature of 2,700 K (yellowish-white). Quartz halogen lighting is 3,000 K. “Warm-white” fluorescent lamps have a colour temperature of 2,700 K and are therefore widely accepted for domestic lighting. “Daylight” fluorescent lamps have a colour temperature of 5,000–6,500 K, which appears bluish-white.

7.2 Light Sources and Their Features

When considering a new application, the vision engineer must first decide what type of light source is most appropriate. This requires that we consider a broad range of features, not just how much light it emits.

7.2.1 General Remarks

Several types of light source are commonly used in Machine Vision and will be reviewed in this chapter:

- Incandescent filament lamps
- Fluorescent lamps (linear)
- Compact fluorescent lamps (These are simply “folded” fluorescent tubes.)
- Discharge lamps
- Light Emitting Diodes (LEDs)

In this chapter, we review these four major families of light source. Before then, we highlight some of the features that are likely to affect the choice. (For a summary of the salient features, see ➋ *Table 7.3*.)

Coherent and non-coherent light Human beings live in a world flooded with non-coherent light and normally encounter coherent light only when working with lasers. The light emitted by the Sun, flames, incandescent filament lamps, fluorescent tubes and other discharge lamps are non-coherent, as are computer screens and LEDs. On the other hand, lasers are able to generate almost pure monochromatic beams in which all rays are in phase. It is possible to produce very narrow and very intense beams from a laser. (The total light flux may, however, be quite small.) While phase coherence is important for holography, it normally provides little benefit for Machine Vision. In structured-light range finders, it is not an essential requirement; it simply has to be tolerated. Speckle patterns can be produced by projecting a phase coherent beam onto a surface. This will create a textured effect, even on a plain surface and may give a false impression of its physical structure and visual appearance with ordinary lighting. Speckle effectively produces a random noise-like effect and hence complicates the image processing required.

Imaging Optics Many light sources are large compared to the objects they are used to illuminate. This fact must be taken into account when designing the illumination optics. The latter are just as important as the imaging optics but are often neglected when designing the optical sub-system. The application may require a “point” or “line” source, while the light is generated by a large lamp, probably producing a completely different beam shape from

Table 7.3

Factors influencing the choice of light source for machine vision

Main feature	Category	Factors to be considered
Light characteristics	Intensity	Overall brightness
	Spectrum	Emulating day-light (black body source)
		Monochromatic
		Multiple peaks
		Smooth panchromatic with/without spiky peaks
		Ultra-violet
		Infra-red
	Beam shape	Omni-directional
		Directed
		Linear
		Rectangular
		Circular
		Beam uniformity
	Coherence	Coherent (Lasers)
		Non-coherent (Other sources)
	Temporal variation of intensity	Ageing
		Strobing
		Light fluctuating with AC power cycle
		Start-up
Use, implementation and operation	Cost	Installation
		Running
		Replacement
		Special electronic driver
	Electrical	Voltage
		Power
		AC or DC?
	Physical	Size of luminaire
		Maintenance (cleaning)
		Heat generated
	Sensitive operating environment	Operating temperature
		Vibration
Other	Failure mode	Slow degradation
		Sudden catastrophic failure
	Safety	Toxic chemicals (particularly mercury)
		Flashing lights (migraine & epilepsy)
		Broken glass
		Electric shock
		Eye & skin damage

that required. The apparent size of a light source can be reduced by the use of focussing optics. Notice, however, that the focussed image of the source limits the minimum size of the light spot. Light can be collected from the lamp and then focussed by a combination of lenses, mirrors and fibre optic devices. So called *condenser lenses* are designed specifically for this purpose. Since these have to be at least as large as the lamp, it may be necessary to use Fresnel (prismatic) lenses. An example of lenses of this type is to be found in maritime warning lights (light-houses). Sometimes, a concave mirror, with a parabolic, elliptical or similar form, is used as the primary light collector. Examples of this type are, of course, found in automobile head-lights, navigation lights, projectors and photographic enlargers. Some lamps incorporate their own light collecting/focussing optics: small quartz halogen lamps, used for spot-lights in retail displays, often incorporate a dichroic filter. The filter focusses visible light into a narrow beam but does not focus infra-red, which is therefore dispersed over a much wider solid angle.

Stray light Most light sources, except some lasers and LEDs, emit radiation over a large solid angle. Hence, it may not be possible to collect all of the light emitted by the lamp and project it in the correct direction. We must be careful to stop stray light from reaching the object being inspected. If stray light is allowed to illuminate the scene being viewed from the wrong direction, the image contrast light may be greatly reduced, perhaps disastrously. Stray light and ambient light must both be regarded as creating optical “noise” in the optical system and should be deflected, or blocked by baffles with light-absorbent surfaces.

Ambient light For a similar reason, ambient light should be blocked by opaque screens, or curtains. In some rare situations, it may be possible to project so much light onto the object being inspected that environmental lighting is insignificant. However, it is always good practice to eliminate ambient light by shrouding the inspection area, if only to reduce energy costs.

Keeping optics clean To ensure reliable performance, it is imperative that all optical surfaces be kept clean. This may not be easy for a large source working in a dirty atmosphere. Baffles used to block stray/ambient light make the luminaire larger and more complicated and may inhibit cleaning. Where possible, the whole illumination sub-system should be enclosed in a dust-proof protective box. A regular cleaning regime should also be established. If total enclosure is not possible, regular cleaning of all optical surfaces is vital.

Heat Infra-red and waste heat can damage some products/materials, such as chocolate. Many light sources require significant amounts of electrical power and then waste much of it by generating large amounts of heat. Incandescent filament lamps generate a great deal of waste heat, which is carried away by conduction and convection. The end caps of fluorescent and other discharge lamps can become quite hot. Some high-power, multi-LED assemblies generate enough heat to require cooling fins. Special precautions may be needed, in some circumstances, to remove waste heat and/or eliminate IR radiation from the beam. The light source may need no more than simple convection cooling. On other occasions, a fan might be needed. In really difficult situations, a circulating liquid coolant can be used. It may be necessary to block infra-red radiation using a hot mirror, or an IR-blocking filter.

Beam Profile The emission profile for many lamps is irregular. This is not surprising in the case of incandescent lamps whose filaments have complex shapes (e.g., C- or W-shaped). Moreover, the support wires cool the filament locally, causing dark spots (➋ *Fig. 7.2*). Linear fluorescent tubes do not emit uniformly along their whole length, particularly near the ends, which are usually darker than elsewhere. Compact fluorescent lamps often have convoluted tubes. (➋ *Figure 7.3* shows a tube in the form of a helix. Other lamps of this type have the form of a series of 2, 3 or more U-shaped tubes.) LED devices may be far from simple “point” sources; there may be several separate LEDs within a single housing. Whatever their origin,

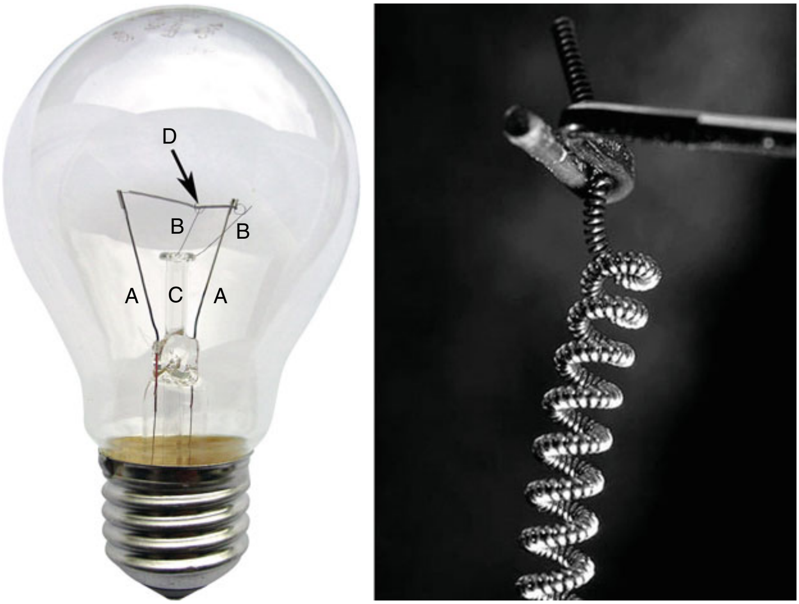

Fig. 7.2
Incandescent lamp filaments. (a) Structure of the traditional light bulb, which is now ''outlawed'' in many countries [2]. A – current-carrying wires. B – support wires. C – glass support column. D – local cold spot, due to conduction of heat away from the filament by the support wire. The shape of the filament leads to an uneven light distribution. A variety of other filament forms is illustrated in [3] (b) Coiled-coil filament and support wire in detail. The coiled-coil allows a very long wire to be used in a compact space (up to 2 m for 60 W lamp). Variable spacing of either the primary or secondary helix leads to uneven temperature distribution and uneven light output

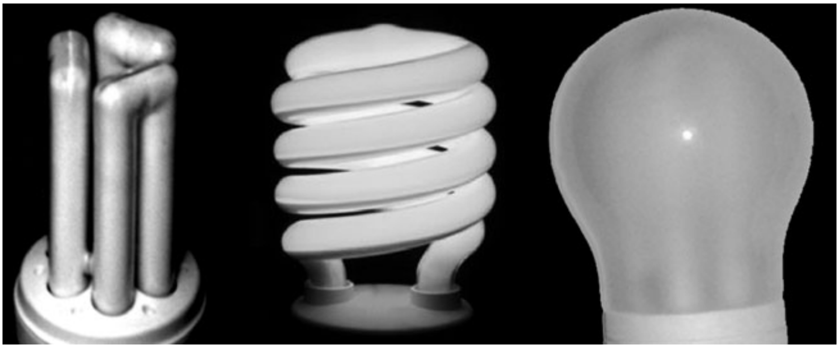

Fig. 7.3
Compact fluorescent lamps used for ambient lighting. In each case, the physical structure of the lamp causes uneven distribution of the emitted light. The internal structure of the lamp on the right is just visible. This consists of a folded tube inside a ''spherical'' diffuser

irregularities in the lamp emission profile have to be reduced to a minimum, using specially designed illumination optics and diffusers. The latter may be simple embossed glass/polycarbonate sheeting, thin ceramic plates, stippled metal reflectors, or for superior performance diffractive optics.

Lamp Ageing and Control The change in the light output from a lamp during its working life is a major factor which the designer of a vision system must always bear in mind. The brightness of a standard incandescent lamps falls as tungsten that has evaporated from the hot filament condenses on the inside of the glass bulb. It is not uncommon for the light output to fall by over 50% during a bulb's working life. Quartz halogen lamps overcome this problem to some extent, by redepositing metallic tungsten on the filament. (Tungsten halide forms in the cooler part of the bulb and then decomposes when it reaches the hot filament.) Fluorescent tubes also darken as they get older, as anyone who has ever replaced a tube at home will have noticed. Again a 50% reduction in the light output over the life-time of the tube is not unusual. LEDs also become darker as a result of ageing, although the change is not as great; a 30% reduction over a working life of 1,00,000 h is often quoted by suppliers.

Since the output light level changes significantly during the life of a lamp, it is often advisable to employ feedback control. Placing a photo-sensor in the periphery of the output beam would seem to be appropriate for maintaining a constant light output. The output of a differential amplifier would then be used to vary the drive current to the lamp. In principle, this seems straightforward but there are several points to bear in mind. Altering the current through an incandescent lamp changes the filament temperature and hence the colour of the light emitted. It is possible to adjust the brightness of fluorescent and discharge lamps using pulse-width modulation. This requires a fairly sophisticated controller but the colour of the light emitted does not change. Changing the current through LEDs does not alter their colour either A multi-LED assembly does not have an homogenous beam but the short-term variations among individual LEDs are not likely to be significant. Furthermore, the effect of any one LED is small in a large array. However the light is generated, it is a good idea to check the beam profile of multi-lamp sources regularly, using the camera and a plain calibration surface.

Efficacy Efficacy measures the ratio of the total light output for a lamp to the electrical power that it requires. The efficacy of various light sources are compared in ➔ Table 7.4.

Table 7.4

Comparing the efficacy of various light sources [4]

		Percent of input energy			
Type of lamp	Efficacy (lmW^{-1})	UV	Visible	IR	Heat
Incandescent filament	12.6	0.25	5.75	75	19
Xenon (2 kW)	35	2	15	58	25
Low pressure sodium	125	0.5	22	36	41.5
High pressure mercury	49	9	11	52	28
Low pressure mercury	6.4	56	5	15	24
Fluorescent (linear tube)	62	2.4	22	30	45.6
LED (white, space lighting)	26–70	0	26–70	0	

The values given for low pressure mercury lamps does not take into account the possibility of converting the UV radiation to visible light by a phosphor coating

7.3 Incandescent Filament Lamps

When a body is sufficiently hot, it radiates in the visible wave-band (➋ *Fig. 7.4*). This fact has been exploited for centuries to generate light. Material can be heated in a flame (e.g., lime lights used in nineteenth century theatres), chemically (e.g., by combustion and fire-flies), or by ohmic resistance to an electric current. (Eddy current, microwave and radiation heating are also possible ways to raise the temperature of a material to incandescence.)

In a domestic electric light bulb, an electric current passes through a thin tungsten wire raising its temperature (typically around 2,500–2,800 K). This causes it to release thermally generated photons. The enclosing glass bulb simply prevents air from reaching the hot filament, which would otherwise be quickly destroyed by oxidation. The bulb is normally filled with an inert gas (nitrogen, argon, or krypton), to inhibit evaporation of tungsten from the filament and to reduce the required strength of the glass envelope. Incandescent bulbs can be produced cheaply, for a wide range of operating voltages, ranging from one to several hundred volts.

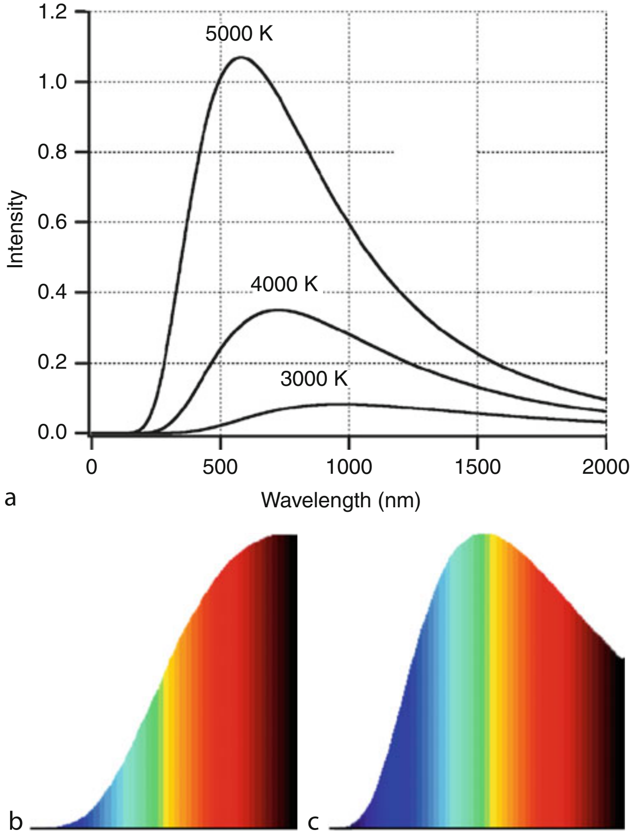

Fig. 7.4

Radiometric black body emission spectra. (a) Graphs for three different source temperatures. Abscissa: Wavelength (nm). Ordinate, intensity, arbitrary units. (b) Representing the same data in relation to perceived colour. Source temperature 3,000 K (about the same as that of a lamp filament). (c) Source temperature 5,000 K. The colour images were generated by a program in [5]

7.3.1 Quartz-Halogen Lamp

In a conventional lamp (not quartz halogen), the evaporated tungsten gradually condenses on the inner surface of the glass envelope, reducing light transmission. A vacuum-filled bulb darkens uniformly over the whole surface of the envelope, while a gas-filled bulb darkens on its uppermost part. A major development in the design of incandescent lamps resulted in improved life and greater efficiency. In a quartz halogen lamp, the tungsten filament is sealed into a small quartz envelope filled with a halogen gas: iodine or bromine. When tungsten evaporates from the filament, it combines with the gas to form a tungsten halide (Wo_2I_2 or Wo_2B_2), which does not react with the quartz envelope. However, tungsten halide does decompose on contact with the hot filament, depositing metallic tungsten preferentially on hot spots. The halide atoms are then free to capture further tungsten atoms as they boil off the filament. This is a self-correcting process, in which thin hot regions of the filament receive more tungsten atoms than thicker cool areas. Quartz must be used for the envelope, since ordinary glasses would melt at the higher operating temperature of this type of lamp. The high filament temperature increases the efficiency of energy conversion, apparent brightness and colour temperature. Raising the colour temperature increases the short-wave (blue) content of the emitted light.

The envelope can be modified by applying an optical coating, which might enhance, or inhibit, UV transmission. Thus, quartz halogen lamps can be made to generate visible light or UV-B radiation. A typical quartz halogen lamp will run for about 2,000 h, which is about twice as long as the life of a conventional filament lamp.

A further development that has improved quartz halogen lamp efficiency is an IR-reflective coating (IRC). The quartz envelope is coated with a multi-layered dichroic coating, which allows VIS light to be emitted and reflects some of the IR radiation back onto the filament. This type of lamp requires less power than standard halogen lamps to produce a given light output. The efficiency increase can be as much as 40%.

7.3.2 Analysing Perfomance

To a close approximation, a filament lamp behaves like a black body radiator. Hence, it is possible to represent its behaviour using the following equations [6–8].

Wien's Law (Explains the colour shift with varying filament temperature see ➲ Fig. 7.4).

$$\lambda_p = 2.898 \times 10^{-3}/T \tag{7.2}$$

Stefan's Law (Quantifies the total radiated power)

$$P = \sigma \,.\, A \,.\, T^4 \tag{7.3}$$

Planck Energy Distribution (Describes the spectrum for incandescent sources)

$$P_\lambda = \frac{2\pi hc^2}{\lambda^5\left(e^{(hc/\lambda kT)} - 1\right)} \tag{7.4}$$

where

A = Surface area of radiating body (i.e., the filament, m^2)
c = Speed of light in a vacuum, 3×10^8 ms^{-1}
h = Planck's constant (6.626×10^{-34} Js)

Table 7.5

Showing how the characteristics of an incandescent light bulb depend on the supply voltage, V

Operating characteristic	Varies in proportion to (approximate formulae)
Light output	$V^{3.4}$
Power consumption	$V^{1.6}$
Working life	V^{-16} (i.e., inversely related)
Colour temperature	$V^{0.42}$

These relationships are only valid for small variations of voltage (i.e., a few percent) around the nominal operating conditions. Notice that the working life is greatly reduced, even if the operating temperature is increased by only a few percent [2]

k = Boltzmann's Constant, 1.38×10^{-23} JK^{-1}
P = Power radiated (W, or Js^{-1})
P_λ= Power per unit area at wavelength λ (Wm^{-2})
T = Temperature of radiating body (K)
λ = Wavelength (m)
λ_p = Wavelength at which the black body radiation is a maximum (m)
σ = Stefan's Constant, 5.67×10^{-8} $Wm^{-2}K^{-4}$

The electrical performance of an incandescent lamp is summarised in ➲ *Table 7.5*. Notice the very rapid decline in working life as the filament temperature is raised.

7.3.3 Remarks

1. One of the problems that the standard incandescent light bulb presents is evaporation of metal (tungsten) from the filament. Inevitably, there are variations in resistivity along the filament, that cause non-uniform heating; hot spots form in regions of increased resistance. Filament thinning, by evaporation, occurs more in hot spots, thereby increasing their resistance, which in turn raises the filament temperature. This positive feedback shortens the life of the filament. Filament lamps are designed by reaching a compromise between operating efficiency (requiring high filament temperature) and longevity (low temperature).
2. Incandescent bulbs for general illumination applications can normally be expected to operate for several hundred hours. This is far shorter that the life expectancy of fluorescent and LED lamps. Special purpose theatrical, photographic, and motion-picture lamps may have a useful life of only a few hours. A distinction must be made between the rated and economic life of lamps used for machine vision. The rated life of an incandescent bulb is normally taken to be that time in which 50% of the lamps fail catastrophically. Replacement bulbs like this are relatively cheap, whereas the unscheduled downtime of production plant due to catastrophic lamp failure can be very high.
3. Incandescent lamps are physically fragile, having a thin glass envelope. When the envelope breaks, a cloud of particles (tungsten nitride and various tungsten oxides) is ejected

into the atmosphere and may be deposited on nearby optical surfaces. These will then require cleaning.

4. Apart from the obvious hazards of explosion, electric shock, burns to the skin and fire, some quartz halogen lamps can cause "sunburn" from the high levels of UV emitted. Eye damage (cataracts) can also be caused by UV. Surface contamination, especially from fingerprints, can damage the quartz envelope and lead to the creation of localised hot spots on the bulb surface. These may cause the bulb to fail prematurely, or even explode! Consequently, these lamps should be handled without ever touching the quartz envelope with bare hands. If the quartz is contaminated by fingerprints, it should be thoroughly cleaned using alcohol and then allowed to dry before use. To prevent injury due to explosion or fire, it may be necessary to operate quartz halogen bulbs within a protective enclosure.
5. The filaments of incandescent lamps are susceptible to vibration (microphony), which may cause the light output to fluctuate over a short time interval. The support wires cool the hot filament, causing local variations in light emission (➋ *Fig. 7.2*). Many lamps have C-, U-, or W-shaped filaments that do not radiate uniformly in all directions. Others have nominally linear filaments, which again radiate more in some directions than others. The diffusing inner surface of the envelope helps matters but does not provide a perfect solution. While these features are normally unimportant for illuminating a room, they are often critical for Machine Vision.
6. An important feature of incandescent lamps is that they change colour when the filament temperature varies. (The discussion at the beginning of ➋ Sect. 7.3 and ➋ *Fig. 7.4* show why this is so.) This is important, because it affects the way that we can control the lamp brightness. As the current through a light bulb increases, it normally becomes brighter and generates more short-wavelength radiation (UV and blue). To maintain good colour constancy throughout the working life of a lamp, it is often better to use a variable aperture, rather than changing the current.
7. Most of the power consumed by an incandescent lamp is converted into heat, rather than visible light. A standard incandescent light bulb produces more heat and requires more electrical power) than a quartz halogen lamp, a fluorescent lamp, or an LED device. For this and other reasons, incandescent light bulbs are falling out of favour, for domestic/commercial lighting. (At the time of writing, there are advocates in many countries pressing for a legally enforceable ban on incandescent lamps for environmental lighting.) Compact fluorescent lamps, and LEDs, use far less energy for a given light output. In Machine Vision, incandescent light bulbs are losing popularity to LEDs, for reasons that will become clear later.
8. The resistance of the filament is temperature dependent; the resistance when cold is much lower than when the lamp is lit. This means that there is a current surge when the lamp is first switched on (This is, of course, the moment when the filament is most likely to fuse.).
9. Since an incandescent lamp presents a resistive load, a simple dimmer, using pulse-width modulation and a standard power switch, can be used to control its brightness.
10. Thermal inertia of the filament of most incandescent filament lamps reduces the variation in light output during the mains power cycle. (50/60 Hz) However, some lamps (e.g., low power, high voltage) have thin filaments and do not provide a thermal inertia sufficient to prevent detectable flicker in a non-synchronous camera.
11. The life of an incandescent lamp is very sensitive to changes in the supply voltage; increasing the voltage by 5% halves the expected working life! (➋ *Table 7.5*).

12. The spectrum of an incandescent lamp is roughly similar to that of sunlight. In particular, there are no strong spectral peaks that might cause colours to be changed dramatically.
13. Despite all of their disadvantages, incandescent lamps are still widely used. However, the situation is likely to change in the near future; compact fluorescent tubes and LEDs are expected to take over many of the roles, outside Machine Vision, that have been previously been the domain of fragile glass bulbs containing hot wires.

7.4 Gas Discharge and Fluorescent Lamps

7.4.1 Physical Principles

A simple discharge lamp has two electrodes placed at the opposite ends of a glass tube, which contains an inert gas (e.g., argon, neon, krypton) at low pressure (typically 10^{-3} to 10^{-2} bar). A potential of several hundred volts is applied to the two electrodes, in order to start and then sustain a glow discharge. Initially, a few of the atoms within the gas are ionised. (Some mechanism may be built into the tube to initiate the discharge. This may consist of a hot filament, a weak source of beta radiation, or a rare-earth coating on the cathode.) Ions are propelled along the tube by the applied potential: electrons travel towards the anode and the heavier positive ions towards the cathode. High-speed ions colliding with neutral gas atoms will ionise them, thereby creating secondary ions, which are then accelerated by the applied field. The primary and secondary ions will then accelerate and collide with and ionise yet more atoms, thereby creating a cascade effect in which a large proportion of the atoms become ionised. The ionised gas is called a *plasma* and is able to conduct an electric current. This state is maintained as long as a sufficiently high potential difference exists between the electrodes. When positively charged ions strike the metal cathode, free atoms are released and join the inert gas atoms in the plasma. (This process is known as *sputtering*.) Once free, the metal atoms released from the cathode are able to join in the process of formation of a plasma. This therefore contains a mixture of free electrons, inert gas ions, metal ions, excited neutral inert-gas atoms and excited neutral metal atoms Neutral atoms become excited during low-energy collision between ions and neutral atoms. Excited atoms lose energy fairly quickly, by a variety of processes. Of prime concern for light generation is the fact that some of the excited atoms relax to a low-energy state by emitting photons in the ultra violet (high energy), or visible (lower energy) wavebands.

It is important to realise that the discharge does not glow uniformly throughout the space between the electrodes. ➋ *Figure 7.5* shows the main features. Notice the presence of dark regions. In a long tube, the positive column may be striated. In a short tube, fewer stripes are formed and the positive column becomes compressed. It may even disappear completely. However, the negative glow remains the same size.

7.4.2 Variations

Discharge lamps are available in many different forms and find a wide range of applications. Here is a list of the more important types:

- Fluorescent tubes (room lighting)
- Cold cathode fluorescent lamps (CCFL)

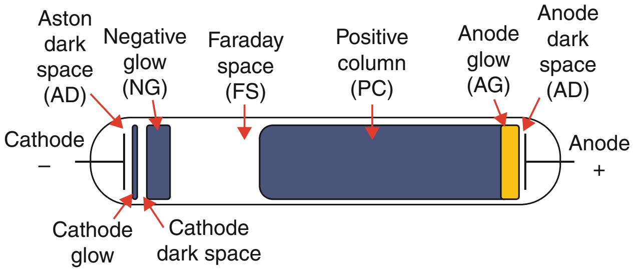

Fig. 7.5

Gas discharge lamp. The anode, cathode, Faraday and Aston spaces are all dark. Other regions emit visible and/or UV radiation

- Compact fluorescent (CFL)
- Mercury lamps (street lighting)
- Sodium lamps (street lighting)
- "Neon" display tubes (advertising signs)
- Plasma video displays
- Xenon flash tubes

The spectrum of the radiation generated by the plasma is determined by the composition of the gas and the cathode material. Adding a small amount of material to an inert gas can significantly alter the spectrum and the perceived colour of the emitted light. In a low pressure lamp, mercury or sodium is mixed with an inert gas, such as argon, neon, or a mixture of the two. The mixture is likely to contain 0.1–1.0% sodium/mercury vapor and 99.0–99.9% of the inert gas(es). Despite the low concentration of these additives, the emission spectrum is dominated by the energy transitions that occur as the metal atoms revert to their non-excited ("ground") state. These transitions involves well-defined energy jumps, and hence result in the emission of radiation within a series of narrow wavebands. At any given moment, most of the metal vapor atoms are non-excited and will readily re-absorb this radiation as they jump to the higher energy state that a neighbouring metal atom has just left. In order to reduce re-absorption, it is sensible to keep the concentration of the metal vapour low, compared to that of the inert gas. The concentration of the inert gas atoms controls the mean path length of free electrons travelled between collisions and hence is largely responsible for determining the electrical characteristics of the discharge.

7.4.3 Fluorescent Lamps

Fluorescent tubes are commonly used to illuminate rooms, corridors and industrial workstations (environmental lighting). Despite their familiarity, details of their operating characteristics are rarely appreciated.

A fluorescent lamp is a gas-discharge lamp that uses low-pressure mixture of ionised gaseous mercury and an inert gas (argon, xenon, krypton, neon, or a mixture of these). The UV radiation generated in this way is converted into visible light by a fluorescent coating on the inner surface of the tube. (It is usual to refer to this coating as a *phosphor*, although it is *fluorescence*, rather than phosphorescence, that generates most of the light.) A UV photon emitted by the plasma is absorbed by an atom within the coating, which then emits a long-wavelength (lower energy) VIS photon. If the UV photon has a higher energy than that needed to generate a VIS photon, the "excess" simply raises the temperature the phosphor coating.

Most of the UV energy generated by the mercury-inert gas plasma is at wavelengths of 0.254 µm (about 65%) and 0.185 µm (10–20%). The spectrum of the visible light generated by a fluorescent tube is determined by the fluorescent coating (➜ *Fig. 7.6*). By careful blending of various phosphor materials, it is possible to produce a fluorescent tube whose light produces approximately the same subjective sensation as day-light. This is not the same as saying that the two spectra are similar. In some cases, the output spectrum from a fluorescent tube has strong peaks, while in others, the spectrum is smooth. When viewed directly, or projected onto a white surface, the colour sensation produced by two tubes may appear to be very similar (e.g., approximating day-light) but quite different on a coloured surface (➜ *Fig. 7.6*). Many people find the light produced by some fluorescent lamps harsh and unpleasant and prefer the "warmer" (redder) glow from an incandescent filament lamp as being more relaxing. A healthy person may appear to have an unnatural and unhealthy skin tone when he/she sits beneath a fluorescent lamp. Modern "daylight" fluorescent tubes have, to a large extent overcome these objections to their use. When she is buying a dress, the author's wife still

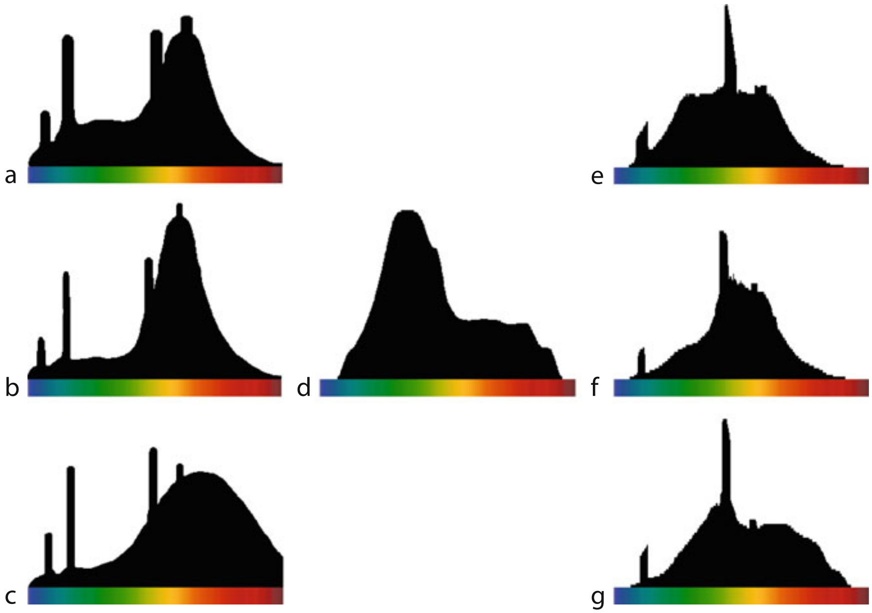

Fig. 7.6

Vividly coloured surfaces sometimes exaggerate the differences between light sources that subjectively appear similar. In the past, this made fluorescent lamps unpopular for domestic use. (a)–(c) Radiometric spectra of three fluorescent tubes. The manufacturer describes these lamps as "Cool white," "Warm white," and "Warm white deluxe," respectively. (d) Reflectance characteristic of a sample surface. This is the spectrum of the light reflected from a "green" surface illuminated with pure white light. (e)–(g) Spectra of the light reflected from the surface when it is illuminated by the fluorescent tubes (Adapted from data in [9])

takes it to a window to assess its "real colour." On the very rare occasions when he accompanies her on shopping expeditions, he observes that this behaviour is not unique! This is evidence that lamp technology requires further development.

7.4.4 Driver Circuits

Fluorescent lamps require an auxiliary device, called a ballast, to regulate the current flow through the tube. When operating from AC mains power, an inductor is normally connected in series with the plasma tube (➲ *Fig. 7.7*). This limits the current surge that would otherwise occur when the plasma starts to conduct current. (The plasma tube presents a negative resistance, which would lead to run-away operating conditions without the ballast.) This inductor also helps to maintain the glow for longer, when the supply voltage falls below the critical value needed to maintain the discharge. The ballast is also necessary to ensure that the voltage applied to the tube is high enough to initiate the discharge. It is common practice to use an auto-transformer to raise the voltage applied to the tube above the so-called *striking voltage*. An auto-transformer can also act as the ballast inductor. A capacitor may also be needed to adjust the current-voltage phase (i.e., ensure that the power factor is close to unity). When operated directly from a DC supply, the polarity of the applied voltage should be reversed regularly, to make sure that liquid mercury does not accumulates at one end of the tube. However, fluorescent lamps are only rarely operated directly from DC. For Machine Vision applications, it is common to employ an inverter running at a frequency considerably higher than the camera's field-scan frequency; the inverter frequency is typically 10–50 kHz. Fluorescent lamps running directly from mains power, flicker at twice the line frequency. (100/120 Hz) During each mains cycle, the supply voltage twice drops to a value that is unable to sustain current flow through the plasma. The resulting flicker is normally imperceptible to the human eye but, for a camera, it can be a serious nuisance; hum bars are visible when the video signal is viewed on a monitor (➲ *Fig. 7.8*). When the video signal is digitised, the hum bars produce

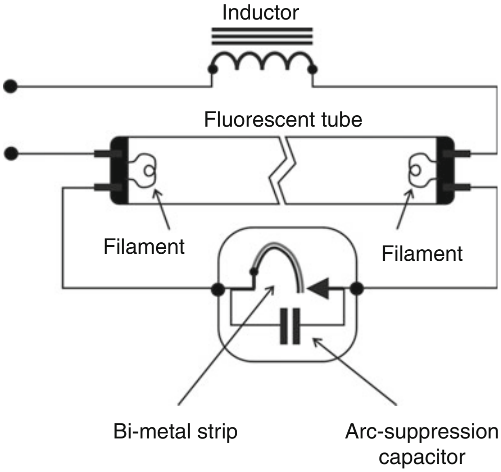

Fig. 7.7
Ballast and starter for a fluorescent tube

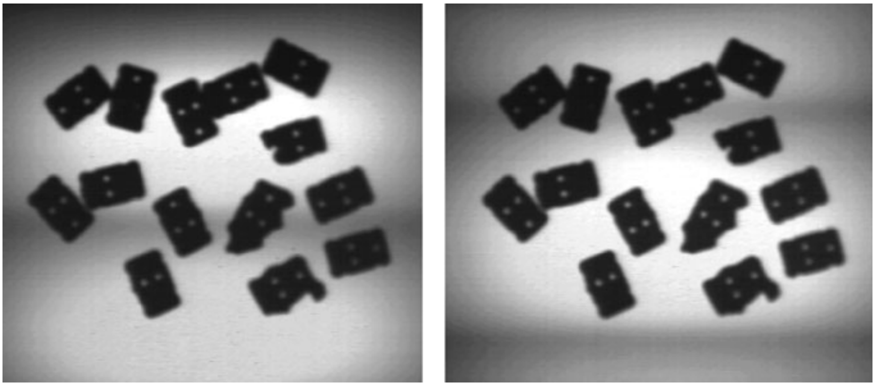

Fig. 7.8
Hum bars caused by fluorescent lighting that is not synchronised to the camera. The dark bars move slowly up/down the monitor screen (A similar effect occurs when LED lights are driven from an alternating current source)

a slow change in the intensity along the vertical axis of the image. Flicker is more pronounced if the tube is not operating symmetrically during the two half cycles of the supply voltage.

Most fluorescent light fixtures cannot be connected to a standard dimmer intended for incandescent lamps. Nevertheless, there are numerous commercial devices available to do this. These usually rely on electronic inverters to apply (square-wave) pulses of variable width to the tube. Most dimmers keep the filament(s) fully heated all through the AC power cycle. As the current through the plasma is reduced to zero, the ions quickly combine with free electrons to form neutral atoms. As the supply voltage rises again, the hot filament ensures that there is a plentiful supply of ionised atoms available to re-form the plasma and “re-ignite” the discharge.

7.4.5 Ageing

The efficiency of new fluorescent tubes may vary from about 16–95 lmW^{-1}. The phosphor degrades as the tube ages, resulting in a significant reduction in the average brightness over its working life. Most readers will be aware of this from their personal experience; when new fluorescent tubes are fitted in a room, there is a noticeable increase in brightness. After about 25,000 h, the lamp brightness will typically be half that of a new tube (Some manufacturers claim a longer working life.).

7.4.6 Compact Fluorescent Lamp (CFL)

A Compact Fluorescent Lamp (CFL) is a folded tube, fitted with a standard bayonet or screw connector, and an integral electronic starter/ballast unit. It is designed to be a direct replacement for a regular incandescent bulb, although it is often larger and heavier (*Fig. 7.3*). Since it uses a high-frequency driver, a CFL does not produce significant flicker. The author has often experienced difficulty in running two CFLs from the same domestic supply line; the electronic drivers appear to generate sufficient interference to cause one unit to stop the other from working properly. Sometimes, neither CFL will ignite.

7.4.7 UV Fluorescent Tubes

The phosphor and glass envelope in a standard fluorescent tube both attenuate UV emissions that are harmful to people. (The chief dangers are skin cancer and cataracts.) By simply omitting the phosphor altogether, it is possible to a lamp that is a strong source of short-wave UV radiation. To maximise the UV transmission through the glass tube, Quartz or Wood's glass is often used. The latter also attenuates visible light and hence increases the UV: VIS ratio. This ensures that UV-induced fluorescence can be seen more easily. Producing fluorescence is only one of the potential uses for UV light, which can also be used directly for imaging. Some of the possibilities are illustrated in Appendix I. However, optical components and cameras for use in the UV waveband are expensive. Despite the health hazards, UV fluorescent tubes are in wide-spread use: germicidal lamps, insect traps, viewing fluorescent ink/paint (e.g., for security marking), microphotolithography, erasing EPROMs, sun-beds and for curing materials, such as inks and adhesives (for dentistry and a range of industrial applications). "Blacklights" are fluorescent lamps that generate UV radiation just outside the visible waveband (UV-A, wavelength about 0.360 μm). They are built in a similar way to conventional fluorescent lamps but the glass tube is coated with a special phosphor that converts dangerous short-wave UV to safer UV-A.

7.4.8 Electrodeless Induction Lamp

An *Electrodeless Induction Lamp (EIL)* is a fluorescent tube in which the discharge is sustained by electro-magnetic induction, rather than an applied potential gradient between two electrodes. In an EIL, there are no electrodes within the glass tube containing the plasma. Instead, two coils, connected in series, form the primary of a transformer. The secondary is formed by a closed loop (i.e., a torus) of mercury-argon plasma. The primary coils and the mercury-argon (Hg-A) plasma torus are coupled magnetically. The device operates as a transformer with a negative resistance in the secondary circuit. Induction sustains the current flow in the plasma. The inside of the bulb has a fluorescent-conductive coating to suppress EM radiation. Since it has no filament, an electrodeless induction lamp has a very long life; one manufacturer (Osram Sylvania Inc., [10]) states that the light output for a 100 W lamp falls to 70% of its initial value after 60,000 h and is still above 65% after 1,00,000 h also see ❯ *Table 7.6*).

Table 7.6
Typical electrodeless induction lamp

Feature	After 100 h	After 60,000 h
Luminous Flux (lm)	8,000 lm	5,600 lm
Luminous Efficacy (lm/W)	80	56
Power consumption	23 W	
Warm up (90% of final output)	30 s	
Operating frequency	250 KHz	

The author once observed a standard 6′ (0.914 m) fluorescent tube fully illuminated by an intense 16 kHz field, which pervaded the whole of a large room in a low-frequency radio transmitter facility. However, the radiation level was so high that it would be unwise to spend long working there. The point is that there does not need to be a direct connection in order to sustain the discharge in a tube of this type. In certain situations, it is useful to be able to operate a light source remotely, without any direct connection to it.

7.4.9 Cold-Cathode Fluorescent Lamps

Unlike a normal fluorescent tube, a cold-cathode fluorescent lamp (CCFL) has no electrically heated filament. CCFLs sometimes have a rare earth coating on the cathode to enhance electron emission, while others contain a source of beta radiation, to initiate ionisation of the gas. Small CCFLs are often supplied with an electronic driver board, which is also conveniently small. This allows the device to be driven from a low-voltage supply. CCFLs are available in a range of colours and UV-A versions are available.

A typical laptop computer display uses one or more CCFLs for the backlight. A CCFL provides a bright white light source that can be diffused by a panel behind the LCD. Since it does not generate much heat, the CCFL does not raise the temperature of the surrounding components much above ambient level. The diameter of a CCFL for backlighting a computer screen may be a small as 2 mm and its length over 300 mm. It is easily broken! One of the most frequent uses for CCFLs is by car enthusiasts and computer hobbyists who adorn their beloved toys with lamps that cast an earie glow.

7.4.10 Remarks

The dangers of handling and safe disposal of fluorescent lamps are well understood, as they have been widely used over many years for environmental lighting. Fluorescent lamps contain mercury: typically 6 mg for a modern 25–40 W lamp. (Older devices contain considerably more than this.) When the tube has been in use for a long time, most of the mercury is in the phosphor, which is scattered as a fine powder when the tube breaks. Mercury presents a general health hazard, but particularly for pregnant women and children. Hence, when fluorescent lamps are to be used in the vicinity of food-stuffs and pharmaceuticals they should be protected within a suitable enclosure.

Despite the higher initial cost of a fluorescent tube, compared to an incandescent lamp, its lower energy consumption over its working life makes it cheaper.

Some people are pathologically sensitive to mains powered fluorescent light. People with epilepsy, autism, lupus and Asperger’s syndrome may feel ill when they are subjected to the flickering of fluorescent tubes. The author cannot tolerate flickering fluorescent lights for more than a few seconds, as he finds it extremely irritating!.

Fluorescent lamps require a ballast to stabilize the lamp and to provide the initial striking voltage required to initiate ionisation and creation of the plasma. Electromagnetic ballasts are often used for mains powered fluorescent light and may produce an annoying audible humming, or buzzing, noise.

Fluorescent lamps can be driven from a low-voltage DC (direct current) supply, by using an electronic inverter. (Remember that conventional lamp ballasts do not operate on direct current.) If this is not properly designed, the overall efficiency can be greatly reduced, due to ohmic energy loss in ballast resistors.

When a tube is driven from a high-voltage DC supply (i.e., high enough voltage to strike the arc), the mercury tends to migrate to one end of the tube. In this case, one end of the lamp produces most of the light. To avoid this, the lamp, or the polarity of the voltage applied to it, should be reversed frequently.

Fluorescent lamps present a non-linear load and generate troublesome harmonics, which can be troublesome on the mains power supply. Care should be taken to remove these by suitable filtering. Radio-frequency electrical noise is also generated by the arc.

Fluorescent lamps operate best at room temperature; at much lower or higher temperatures, efficiency decreases. At low temperatures (below freezing) special lamps may be needed. A "cold start" driver is available.

7.5 Light Emitting Diodes (LEDs)

For many Machine Vision applications, LEDs provide the ideal light source. Individual LEDs are physically small; a light-emitting chip is far smaller than the familiar packaged device. A large number of unpackaged LED chips can be mounted directly onto a rigid board, or flexible circuit, or assembled into a 3-dimensional structure.

Using LEDs, it is possible to build light sources with a very wide range of shapes and spectral characteristics. LEDs are highly efficient and are electrically safe, since they only require low operating voltages. As a result, they can be operated safely in an explosive atmosphere. Individual LEDs are often packaged so that they generate a narrow cone of light that can be directed as needed, rather than spreading unwanted light in all directions. This reduces the likelihood of triggering migraine and epileptic seizures, when they are strobed. LEDs are efficient and generate little unwanted heat. Strobing reduces heat generation to an absolute minimum. They can be overdriven in pulsed mode ("turbo-charged"), to provide a bright, short-duration pulse of light, just at the moment when it is needed. It should be noted, however, that some high-powered LEDs do not lend themselves to overdriving. LEDs are available in a wide range of colours. They are also available for working in the UV-A and NIR wavebands (➲ *Fig. 7.9*). Since they are so versatile, assemblies of LEDs present numerous possibilities that were not available previously. The principal characteristics of LEDs are summarised in ➲ *Table 7.7*.

7.5.1 LED Spectra

LEDs are available to cover the whole of the visible (VIS) spectrum, in increments of 0.01 μm. Moreover, LEDs are available for the near infra-red (NIR) and near ultra-violet (NUV, UV-A) wavebands. "White" LEDs can be built in one of two ways:

1. A single component package may contain three separate diodes, whose emissions combine to give the visual impression of white light. Devices of the kind are known as RGB LEDs. It is sometimes possible to drive each LED separately, thereby allowing the visual sensation of colour to be adjusted.
2. A UV LED is used to illuminate a fluorescent material (Sometimes, this is erroneously called a phosphor.).

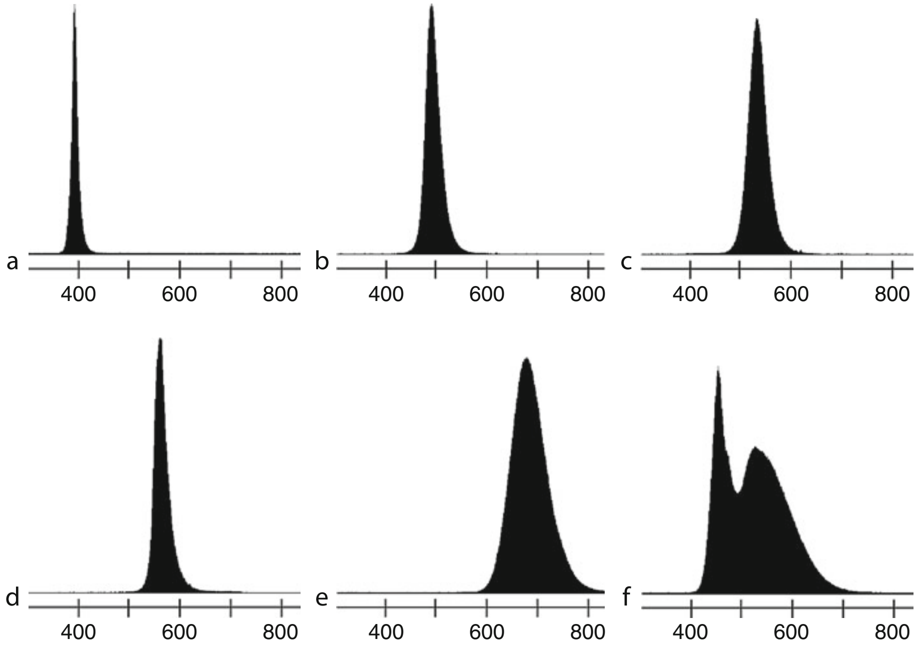

Fig. 7.9

Sample LED spectra. The horizontal scale is measured in nanometres. (a) Near UV (UV-A) (b) Blue. (c) Green. (d) Yellow. (e) Red/IR. (f) "White" LED, obtained by exploiting fluorescence. Although this gives the subjective impression of being nearly white, the spectrum in the VIS waveband is far from flat

The narrow waveband of a single-colour LED can be used to good effect in some applications requiring simple colour discrimination. (A similar effect can be obtained using a white light source and a narrow band-pass filter.) Using a narrow part of the spectrum can be beneficial in a less obvious way: the effects of lens aberrations are minimised, thereby allowing sharp focussing to be achieved. Narrow-band LEDs, used in conjunction with a matching narrow bandpass filter over the camera lens, provides an effective way to reduce the effects of ambient light, which almost always has a broad spectrum.

We have already pointed out that, by mixing the light from a suitably chosen set of LEDs, it is possible to approximate the visual effect produced by white light. More generally, we can adjust the mixing proportions of three "primary" light sources to generate a very wide range of colours, as perceived by a human observer (➲ *Fig 7.13b*). The reader may well take this as an indicator that we can build a programmable LED array whose colour can be changed at will. Such a device would be very useful for Machine Vision but there is a snag! In practice, a large number of quite different spectra may be perceived in the same way by a human being. (This is called *metamerism.*) A camera viewing two metameric surfaces that are both illuminated by the same three narrow-band LEDs, may well generate quite different RGB outputs. In other words, a given set of RGB camera outputs generated using this type of illumination source does not determine unequivocally what a person would see ➲ *Fig. 7.10* explains this. Illuminating a scene with multiple narrow-band LEDs has a somewhat limited value for fine colour discrimination.

Table 7.7
Summary of LED characteristics

Feature	Remarks
Size	The LED chip is physically small but it may be necessary to use a heat sink and provide environmental protection
Voltage	Low voltage; electrically safe to humans. Safe in an explosive atmosphere
Current	Low current; often $<$ 100 mA/LED. Easy to switch and strobe. A constant current source is usually prefered to a resistive current limiter
Power/heating	Low power. Little heat generated. Low thermal emission (for VIS & UV LEDs)
Power conversion	Efficient, comparable to discharge tubes
Operation (steady)	Simple circuitry
Operation (pulsed)	Peak output can be safely increased by strobing (called overdriving or *turbo-charging*)
Spectrum	LEDs naturally emit over a narrow spectral band. The spectrum can be adjusted (i.e., broadened/shifted) using fluorescence. Multi-spectral devices available. (two or three different LED chips are mounted in one package)
Beam angle	Most LED chips are not naturally narrow-beam emitters. However, they are often packaged with a lens, so that the output beam is concentrated into a narrow cone. This reduces light spillage, as well as improving efficiency and safety
Health/safety	Electrically safe
	Continuous operation: optically safe
	Pulsed operation: Risk of migraine & epilepsy low, due to narrow beam
Spectrum	Each LED emits over a narrow spectral band
	Emission spectrum can be broadened using fluorescence
	Wide choice of wavelengths: UV-VIS-IR in steps of 0.01 μm (➔ *Fig. 7.9*)
Packaging	Individual LEDs are very small. Heat sink may be needed for high power LEDs
	LEDs are available in encapsulated or "bare chip" form or in surface mount packages. Many LED chips, of different colours, can be mounted on a rigid board, semi-flexible sheeting, complex assemblies, endoscope, etc.
Working life	Measured in 10,000s of hours; typically 50,000 h
	For a discussion of the aging process see [11]
Multi-LED sources (Some possibilities – also see ➔ *Figs. 7.9* and ➔ *7.10*)	Single line of LEDs, uniform colour or white (most common)
	Three closely spaced lines of red, green and blue LEDs, switched separately
	Single line of LEDs; interleaved red, green and blue LEDs controlled separately
	Ring light; three circles of red, green and blue LEDs, controlled separately
	Ring light; interleaved red, green and blue LEDs, controlled separately
	Dark field; interleaved red, green and blue LEDs, controlled separately
	Back light; interleaved red, green and blue LEDs, controlled separately
	"Flying spot" moves along a linear, circular, spiral or random path
	"Rainbow" array; LEDs of different wavelengths (switched or steady operation)

7.5.2 LED Assemblies

LEDs are now finding application in domestic and commercial lighting fixtures, for example in retail displays. Multi-LED assemblies are now being offered as replacements for incandescent filament lamps, which are far less efficient and have a shorter working life. The data in *Table 7.8* relates to one such assembly: the TVR-7 spotlight, sold by Advanced Lumonics

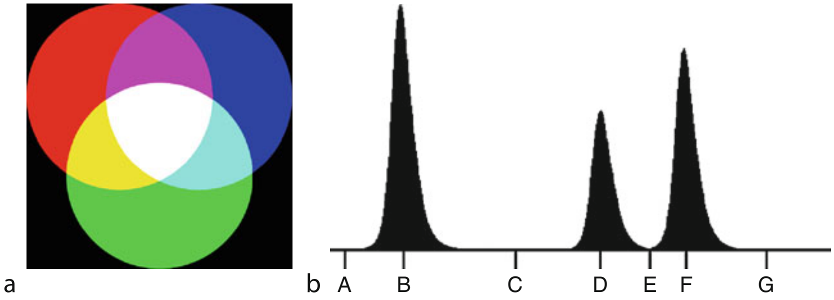

Fig. 7.10
Mixing light of different colours. (a) Classical representation of additive mixing of three primaries. A very wide range of colour sensations can be produced by varying the relative intensities of the three sources. (b) Spectrum of an additive mixture of light from 3 LEDs emitting light in narrow wavebands centred on B, D and F. By mixing light from these source, we can generate a wide variety of colours (including "white") However, no information can be gained about the spectral response of the subject at wavelengths, A, C, E and G

Table 7.8
LED assembly, sold as a replacement for a quartz halogen spotlight (see *Fig. 7.11*)

Feature	Comments
Physical construction	7 LEDs, 1 W each
	Aluminium radial fin heat sink
	Screw base
Input voltage	85–240 V (Same unit can be used in USA/Canada and in Europe)
Power consumption	7 W
Output	385 lm
Operating temperature	$\leq 53^\circ$
Beam Angle	30°
Performance	Equivalent to 80–100 W incandescent lamp
Life	>50,000 h (5.7 years continuous operation) (Life of an incandescent bulb: 1,000 h)
Cost (2007 prices)	Annual running cost: $3.00 (1 years @ 12 h/day)
	Over 11 years: US$100 (US$550 for a comparable incandescent bulb)
Environmental impact	Contains no hazardous substances. (Specifically no mercury)

Inc. [12] (see *Fig. 7.11*). This lamp is marketed as a replacement for a standard quartz halogen bulb and is intended to be used in architectural applications, such as creating mood lighting and illuminating wall hangings. The manufacturer recommends that this lamp be operated so that its beam is projected vertically downwards, in order to maximise convection cooling. Typically, cost and performance figures are based on the assumption that a LED lamp has a working life of 11 years. In this case, the manufacturer expects that it will last much longer,

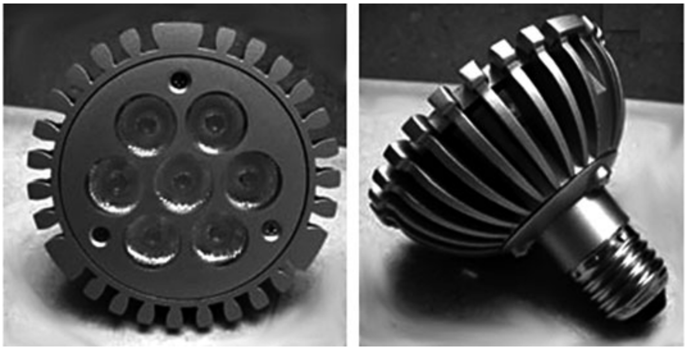

Fig. 7.11
A 7-LED spotlight, sold as a replacement for an 80 W incandescent lamp. Notice the finned heat-sink (From http://www.earthled.com/vr7.html accessed 7th April 2011)

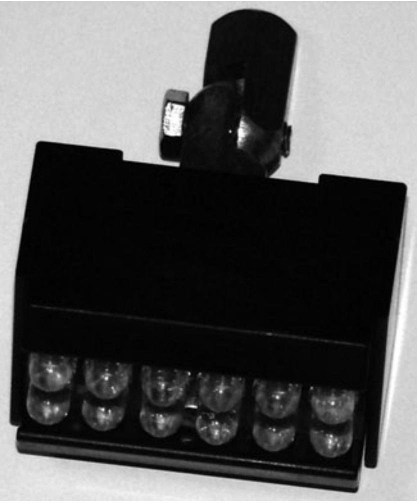

Fig. 7.12
Rugged 12-LED lighting module. These modules can be connected together in daisy-chain fashion and operated from a single DC power source, or strobe driver unit (Module supplied by LED lighting modules [14])

without giving a precise estimate of the life-time. Another series of LED lamps by the same manufacturer, is intended to provide replacements for fluorescent tubes [13]. One device of this type uses an array of 330 LEDs and provides an output of 1,350 lm. These two lamps are powered directly from the mains supply and therefore flash at 100/120 Hz. Although this is perfectly safe for human beings, LED lighting units powered directly from the mains supply are liable to generate hum bars when used in conjunction with some cameras.

Figure 7.12 shows another arrangement that is more suitable for industrial applications: 12 “white” LEDs are mounted in a ruggedised module. Several of these modules can be connected together in a “daisy chain” manner and can be driven by a pulsed, or direct current (DC) source. Clearly, there are numerous possible variations, with the LEDs arranged in lines, circles, rectangles, etc. LEDS can be mounted on rigid, semi-flexible or even flexible strips and sheets [15] (*Fig. 7.13*). LEDs can conveniently be mounted on a 3D structure, for example, along the lines of latitude, or longitude, on a hemisphere. “Naked” LED chips are also small enough to mount around the objective lens of a microscope, or endoscope. Some of the LED lighting unit that have been designed specifically for Machine Vision are shown in *Figs. 7.14* and *7.15*.

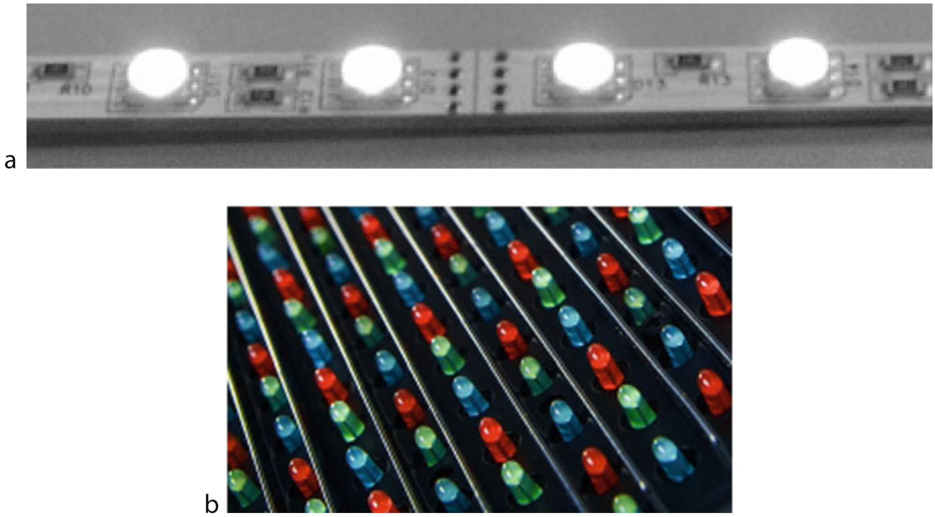

Fig. 7.13
The DIY approach to building LED arrays. (a) ‘‘Bare bones’’ LED light strip containing 30 RGB LEDs on a strip of length 575 mm. Strips can be butted together, or cut every 50 mm. The strip is physically and environmentally unprotected and is intended for use in retail displays. Although this particular device is not accurate enough for high precision Machine Vision applications, it suggests the possibility of creating illumination devices by literally cutting up and then re-assembling devices to suit the requirements of individual applications [16]. (b) An assembly of red, green and blue LEDs. By adjusting the drive currents for red, green and blue LEDs separately, the overall colour of the array appears to change and can even be made to approximate white. However, the spectrum always contains just three narrow peaks, with very little optical energy in the gaps between them

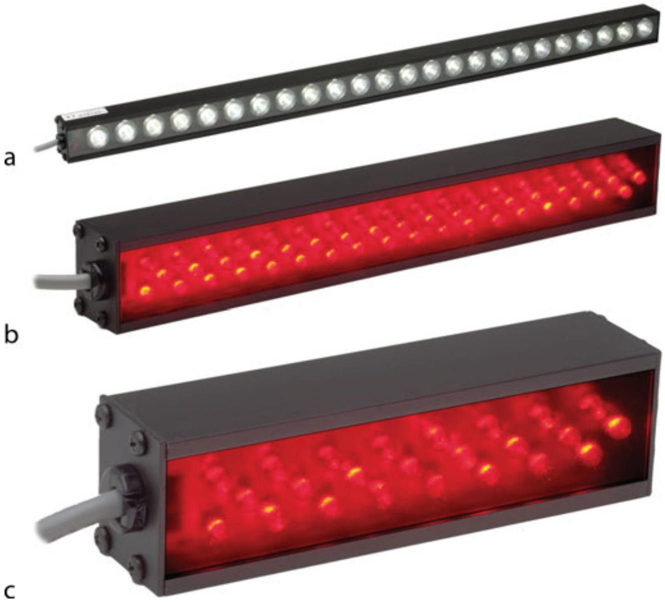

Fig. 7.14

Commercial LED assemblies. (a) Linear array. A diffuser might be fitted to provide more uniform back illumination. Available in lengths up to 2m. (b) and (c) Rectangular arrays, possibly incorporating LEDs of different colours. [Images kindly supplied by Advanced Illumination, Inc., Rochester VT 0576, USA.]

"Do it yourself" construction of a LED array requires great care. There are two principal difficulties:

1. Balancing the brightness of individual LEDs in the array.
2. Aligning the LEDs, so that their beams are all projected in the correct direction.

Specialist help is likely to be needed; several manufacturers will design a LED array for a given application. It is possible to specify the LED brightness, placement, wavelength(s) and operating conditions (DC or pulsed). One manufacturer has developed a lighting kit in which standard LED modules can be plugged into a PCB that has the wiring and drive circuits already installed. The LED module consists of a single LED placed at the focal point of a parabolic mirror. Each module emits a parallel beam (➲ *Fig. 7.16*). This concept could be developed further, to build a fully programmable array of RGB LEDs.

7.5.3 Driver Circuits

An LED has only two leads and is therefore a very simple device to operate: the drive circuit can be as simple as a DC power source and current-limiting resisitor (➲ *Fig. 7.17a*). Several LEDs can be operated together by connecting them is series (➲ *Fig. 7.17b*). If several LEDs are to be operated in parallel, separate current limiting resistors are needed for each one (➲ *Fig. 7.17c*). It is not good practice to connect LEDs directly in parallel. This will result in an uneven distribution of current through them, highly variable brightness and probably cascading failure of all LEDs.

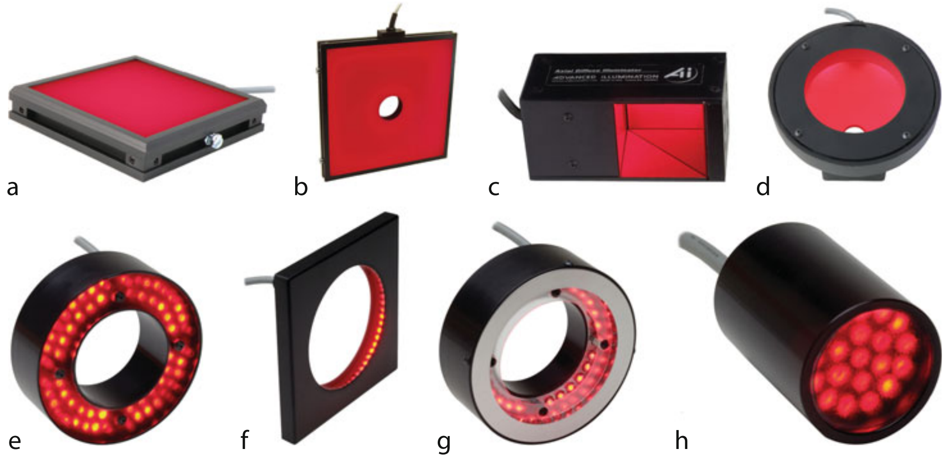

Fig. 7.15
More commercial LED modules for Machine Vision. These devices are available in an RGB "all colour" version. (a) Back-light. 100 × 100 mm. (b) Diffuse illuminator with central viewing aperture. Fig. 7.17

LED drivers. (a) Single LED. Its brightness is proportional to I_d. (b) LEDs in series; all receive the same current. (c) LEDs in parallel require separate resistors. (d) Strobing an LED using a series transistor switch is series with the LED. When T_1 is ON, the LED is also ON. (e) Strobing a LED using a shunt transistor switch. When T_2 is OFF, the LED is ON. This arrangement is wasteful of power but the transistor has no effect on the LED brightness

There are two ways to control the brightness of a LED:

1. Adjusting the drive current
2. Pulse width modulation (PWM)

A simple way to control the drive current is to vary either the supply voltage or the series resistor. An adaptive drive circuit can be built around an operational amplifier that receives a feedback signal from a photo-sensor measuring the light output level. Analogue control like this does readily not allow turbo-charging, or regular strobing.

In fact, digital control is easier to achieve. Bear in mind that a video camera effectively counts the number of photons falling on its photo-sensors over a finite period. (The light-integration period is a significant proportion of the video frame period.) Within this integration period, it does not matter how the light level varies with time; the only significant parameter is the integral over time of the light flux falling on each photo-sensor. There is no need for analogue control of the drive current. Synchronisation of a pulsed LED driver with the camera's light integration period may be necessary, to avoid creating hum bars. (➜ *Figure 7.8* shows hum bars generated by fluorescent lighting. The effect with LEDs is broadly similar.) Using simple feed-back control, it is possible to ensure that optimal image quality is maintained, even if the LED brightness varies significantly over time. Notice that strobing saves electrical power, making battery-powered lighting a possibility in certain situations. Even continuously operated LED lighting compares reasonably well with fluorescent and discharge lamps. In many applications, supplying short pulses of power to an LED lighting unit only when needed can reduce the power requirements by 1–2 orders of magnitude. Since LED lighting is highly directional, very little unwanted light is generated, thereby increasing the overall efficiency even further. Reducing stray light also invariably improves image quality too. When we consider all aspects of LED lighting, we see that it is almost ideal for Machine Vision although we must repeat the warning that strobed lighting presents significant health hazards. At least, the low light spillage from LEDs minimises the risk but careful screening and safety switches are still needed.

7.6 Supplement

7.6.1 Representative Spectra

➲ *Figure 7.18* shows a series of representative spectra from a variety of discharge lamps and compares them to daylight and an incandescent filament lamp. Notice the strong spectral spikes that typically occur with standard fluorescent tubes and other discharge lamps, which should only be used with great caution in applications involving colour-sensitive inspection. The spectral spikes occur at fixed wavelengths, determined by the materials forming the plasma. It is therefore impossible for a vision engineer to choose the wavelengths of the peaks a multi-spike spectrum. (This can be done with multi-element LED array.) Notice that incandescent lamps normally produce a smooth spectrum.

7.6.2 Describing the Colour of a Lamp

7.6.2.1 Black Body and Colour Temperature

The term *Black Body* refers to an object that absorbs all electromagnetic radiation incident upon it; no radiation is transmitted through it and none is reflected. All of the electromagnetic energy emitted by a black body is generated by the thermal agitation of atoms within it. This is an idealised, abstract concept, since no material acts a perfect black body radiator. An open window is a close approximation, as is a "white hot" incandescent tungsten wire.

The concept of *Colour temperature* was devised as way of characterising the colour of a black body light source. The precise form of the spectrum for an ideal black body has been calculated theoretically and can be characterised in closed mathematical form (➔ *Fig. 7.1*) (also see ➔ *Fig. 7.4*). Conversely, it is possible to estimate the temperature of a black body by examining its spectrum. The temperature of a black body radiator defines its spectrum exactly. Hence, we are able to represent the colour of a black body radiator by a single number, called the *Colour Temperature*. The colour temperature of a real light source is determined experimentally, by comparing its chromaticity visually with that of a black-body radiator. The temperature (in Kelvin, K) at which the ideal black-body radiator most closely matches the colour of the light source is taken to be its colour temperature. If a source is a perfect black body radiator, its physical temperature and colour temperature are the same. An incandescent filament lamp is a good approximation to a black body; its colour temperature is therefore close to that of its filament.

For a non-black body source, the *correlated colour temperature (CCT)* is a more appropriate way to characterise its colour. This is the physical temperature of a black body radiator, that is judged by the human eye to match the colour of the light from the lamp most closely. The CCT of a fluorescent lamp does not correspond to the physical temperature of any of its physical components, since the light is emitted from a (cold) phosphor bombarded by ultra-violet photons. Similarly, the CCT of an RGB LED source has no physical significance. The concept of colour temperature has no relevance whatsoever for nearly monochromatic sources, such as a green LED, a sodium vapour lamp, or a HeNe laser.

It is important to bear in mind that any wavelength-dependent absorption along the optical path will change the apparent colour temperature of the light. For example, when the Sun is low over the horizon, its effective colour temperature is about 2,500 K. At mid-day, when there is less atmospheric scattering/absorption, it is about 5,770 K. The illumination pathway in a vision system can modify the colour of the light beam and therefore alter its effective colour temperature. This includes the light gathering optics on the luminaire.

Colour temperature is important for historical reasons: it has long been used by photographers and environmental lighting engineers. However, it is a crude way of representing the colour of many types of lamp; more refined consideration of the spectrum is often required.

7.6.2.2 Colour Rendering Index (CRI)

The *colour Rendering Index* (or *Colour Rendition Index)*, measures the ability of a light source to reproduce the colours of various objects being illuminated by that source. Measuring the CRI for a given lamp requires subjective testing. The reader is referred elsewhere for a detailed description of the way in which the CRI is measured [17]. The CRI can only be used to compare two light

Table 7.9

Typical colour rendering indices for various light sources

Source	CRI
Fluorescent – "deluxe cool white"	86
Fluorescent – "daylight"	79
Fluorescent – "cool white"	65
Fluorescent – "deluxe warm white"	73
Fluorescent – "warm white"	55
Incandescent filament lamp	~ 100
Mercury – clear mercury	17
Mercury – white deluxe mercury	45
Metal halide (4,200 K)	85–95
Metal halide (5,400 K)	93
Sodium – high pressure sodium	25
Sodium – low pressure sodium	0–18
RGB LED array	Low values

sources that have very nearly the same colour temperature. The best possible rendition of colours is indicated by a CRI of 100. If a lamp has a CRI of zero, the lamp does not allow any colour discrimination whatsoever. Hence, a low-pressure sodium discharge lamp, which generates nearly monochromatic yellow light, has a CRI of nearly zero. On the other hand, an incandescent filament lamp has a CRI close to 100. A standard "cool white" fluorescent lamp has a CRI of 60–65. A "triphosphor" fluorescent lamp has a CRI of 80–90. LED sources that are nearly monochromatic have very low CRIs. Notice that a light source with a CRI = 80 and CT = 5,000 K is not necessarily better than one with CRI = 70 and CT = 4,000 K (➜ *Table 7.9*).

7.6.3 Analysing Beam Profiles

Almost all illumination systems are required to project light uniformly over the object/scene to be inspected. Since it is only necessary on rare occasions to create a non-uniform lighting pattern, we shall concentrate here on the simple task of characterising a uniform illumination field, using an image processor. In what follows here, we shall assume that the reader is familiar with the command repertoire of the QT image processor (➜ Chaps. 21 and ➜ 41).

7.6.3.1 Experimental Set-up

Place a plain matt white planar surface *in lieu* of the object to be inspected. The camera should view that surface normally.

Pre-processing (two suggestions, may be used singly or in tandem)

- *mdf(5)* *% Median filter – adjust parameter to taste*
- *caf(5)* *% Low pass (blurring) filter – adjust parameter to taste*

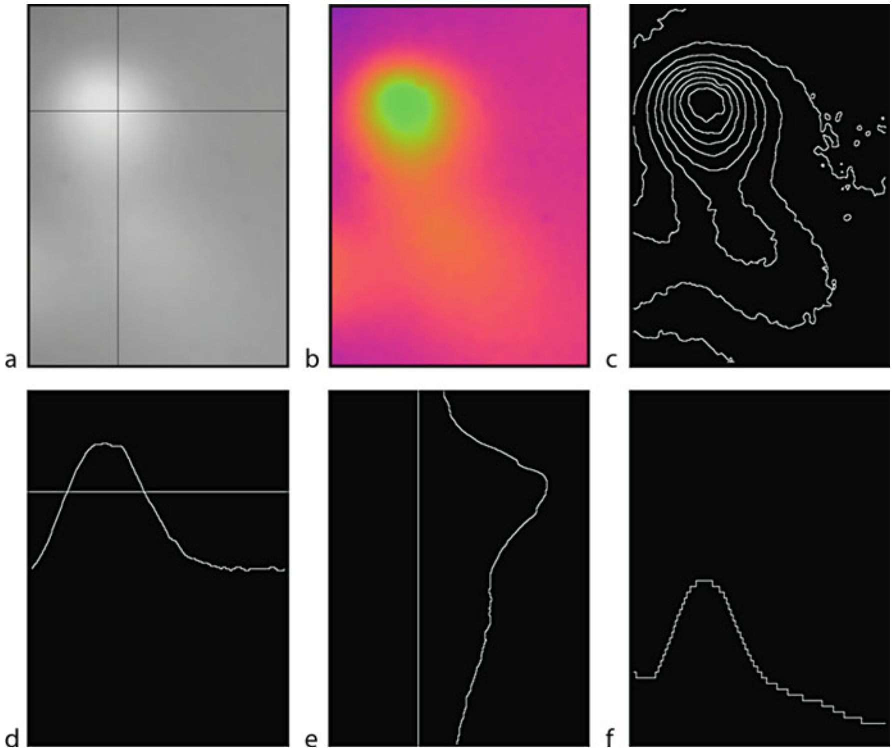

Fig. 7.19

Analysing lighting patterns using simple image processing operations. (a) Lighting pattern, contrived to have local bright spots. The black cross-lines indicate the sections for the profiles plotted in parts (d) and (f). (b) Pseudo-colour plot, provides a convenient way to identify bright/dark spots. (c) Intensity contours (isophotes). (d) Intensity profile, taken along a horizontal section. (e) Intensity profile, taken along a vertical section. (f) Plot of standard deviation along each column

Visual inspection (three options)

- *psc* % Pseudo colour (➲ *Fig. 7.19b*)
- *heq, psc* % Histogram equalisation & pseudo colour
- *enc, psc* % Enhance contrast & pseudo colour

Global Measurements (These suggestions may be used singly or together)

- *a = avg* *% Average intensity (a)*
- *b = dev* *% Standard deviation of intensity (b)*
- *[c,d] = gli;* *% Minimum & maximum intensities (c & d respectively)*
- *e = ihm; thr(x,x)* *% Most frequently occupied intensity level (e)*
- *wri, heq, thr, rei, mni, [x,f] = gli* *% Median intensity (variable f)*

Column Values (Curves plotted)

- *plt* % Intensity profile (➲ *Fig. 7.19d, e*)
- *csd,plt* *% Standard deviation along each column* (➲ *Fig. 7.19f*)

- *cox,[a,b] = dgw,plt(b)* *% Column maximum*
- *neg,cox,neg,[a,b] = dgw,plt(b)* *% Column minimum*

Isophotes (Intensity contours. See ➜ *Fig. 7.19c*)

mdf(5)	*% Median filter* – adjust parameter to taste
caf(5)	*% Low pass filtering* – adjust parameter to taste
sca(4)	*% Posterise – reduced intensity resolution (to four bits)*
sed	*% Edge detector*
thr(32)	*% Threshold* – adjust parameter to taste

8 Lighting-Viewing Methods

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_8,

Abstract: The image acquisition sub-system consists of one, or more, light sources, lenses and possibly mirrors, filters, prisms, polarisers, etc. It also contains one, or more, opto-electronic transducers (i.e., cameras and/or scanners). Simply knowing what "building bricks" are available is not enough; we must be able to construct an integrated system. Object presentation and transport are important and require that we address mechanical handling issues: grasping the object, as well as moving it before, during and after image capture. The type of viewing background is important, as are numerous seemingly mundane tasks, such as eliminating ambient light, building vibration-proof optical mountings and keeping optical components clean, dry and cool. In most applications, the placement of the camera relative to the object under inspection and the lights is critical; the image quality derived from the same object may vary from very poor to excellent, depending on the lighting-viewing conditions. This chapter introduces the catalogue of Lighting Viewing Methods (LVMs) in ➋ Chap. 40. The latter presents qualitative descriptions of a variety of "front end" configurations for a vision system. There can be no rigid formula-based approach to designing a lighting-viewing system. This does not, in any way, diminish the need for sound mathematical analysis, where it can be applied appropriately (e.g., lens design). There can be no equation to tell us when it is most appropriate to use, say, diffuse, or dark-field illumination, monochromatic or polarised light, or a combination of these. The system designer must use his/her judgment and experience. Most importantly, he/she must look at the widget and its surroundings! Two diagrammatic representations of the spatial relationship between the lights and camera are presented here. These are useful for recording and summarising the results of experimentation, which the author asserts is the only practical approach to designing the image acquisition sub-system.

This short chapter provides an introduction to the Catalogue of Lighting-Viewing Methods in ➋ Chap. 40.

8.1 Lighting-Viewing Sub-system (LVS)

The LVS is taken to include the following:

- The primary light source(s) and its associated power supply/driver circuit.
- Illumination optics.
- Imaging optics. (This includes devices such as filters, mirrors, lenses, polarisers, flexible or rigid coherent fibre-optic bundles, etc.)
- Integral camera optics (i.e., lens fitted directly to the body of the camera).
- Protective optical windows. (Both cameras and lights may need to be protected in harsh/dirty environments.)
- Camera. (This may employ any one of a range of scan patterns: line, area, radial ("wheel-spoke"), spiral, random, variable zoom. It may sense visible (VIS), ultra-violet (UV), or infra-red (IR) radiation.) It may use a solid-state photo-detector array, or less likely nowadays, a cathode ray tube.

The LVS is of crucial importance for the success of any industrial vision system; good lighting can often transform what would otherwise be an extremely difficult application into one that requires only the most straightforward image processing operations.

There is no well-defined optimum lighting pattern for even moderately complex objects (i.e., those having multiple facets, consisting of several different materials and those having several different types of surface finish). As a result, there can be no prescription for designing a good LVS; the design process relies heavily on human observation and intelligence. Experience counts, too! Knowledge about an object's material composition, surface finish and geometry can often help guide the design process but, in practice, cannot eliminate experimental investigation altogether. There are two reasons. Firstly, for most applications, it would not be cost-effective to design an LVS by modelling "good" widgets. (Here and in ➋ Chap. 40, the term *widget* is used to denote the object being examined.) Secondly, product defects are so highly variable and unpredictable that effective modelling is out of the question.

8.2 Parameters

Machine Vision owes its versatility in large part to the variety of different *lighting-viewing methods* (*LVMs*) that are available. (About 130 LVMs are listed in ➋ Chap. 40 and they can be used in combination.) One of the distinctive features of industrial Machine Vision is that we are very usually free to employ whatever LVM best suits the application. Within the synthetic, controlled environment of a well-run factory, there are often several options for the lighting-viewing conditions, thereby allowing us to optimise image quality. We can, for example, adjust all of the following:

- The number and spatial distribution of the light sources placed around the widget.
- The spatial pattern of light projected onto the widget.
- The intensity of each light source.
- The spectral emission of each light source. (While we can control the colour of the incident light, we are not limited to using only the VIS wave-band.)
- The polarisation of the light impinging on the widget.
- The spectral response of the camera, by placing suitable optical filters in its optical path.
- The polarisation of the light entering the camera.
- The temporal pattern of light projected onto the widget.
- The motion of the widget relative to the lighting-optical system and the lighting-optical system relative to the camera.
- The spatial coherence of the light projected onto the widget.

8.3 Light Sources

There are many different types of primary light sources available (➋ Chap. 7).

- Incandescent filament
- Fluorescent tubes
- Compact fluorescent tubes ("energy saving" types)
- Cold fluorescent tubes
- Gas discharge tube (mercury, sodium, "neon")
- Xenon flash tubes
- Laser, particularly diode lasers

- Electric arc
- Light Emitting Diodes (LEDs)
- Day-light
- Natural light
- Flames and objects heated by flames
- Self-luminous (The widget glows because it is hot.)

8.4 Optical Devices

We can also employ a wide range of optical devices to convey light to the widget and then to form, adjust and transmit an image to the camera. (➋ Chaps. 4 and ➋ 5) The list includes:

- Mirrors. These may be plane, convex, concave, or anamorphic.
- Lenses. These may be convex-convex, convex-concave, plano-convex, plano-concave, Fresnel, or cylindrical. They may be used singly, or in tandem, Micro-lens arrays are also available.
- Polarisers. These may be linear, circular or elliptical.
- Prisms. These come in a variety of shapes providing a range of functions.
- Filters. These may be short-pass, long-pass, band-pass, band-stop.
- Beam-splitters and devices made of birefringent materials.
- Gratings and diffraction filters.
- Quarter-wave plates.
- Diffusers. These may rely on transmission or reflection.
- Fibre-optics. These may be flexible, or rigid, often in the form of a rod or plate.

8.5 Types of Cameras

Several different types of image sensor can be used:

- Array-scan
- Line-scan
- Circular scan (At the time of writing, these are no longer available commercially. Such a sensor can be simulated by sampling a high-resolution image array.)
- Random (program controlled) scan
- Laser scanner
- Range sensor (Several types of range sensor are available. See ➋ Chaps. 9 and ➋ 15)

An image sensor may detect radiation in any of the following spectral bands:

- Visible wave-band (VIS, monochrome or colour)
- Infra-red (IR) radiation
- Thermal radiation (part of the IR wave-band)
- Ultra-violet (UV) radiation
- Multi-spectral, possibly covering VIS, UV and IR
- X-rays
- Gamma rays

Specialised image sensors are also used in Machine Vision and may be based on detecting:

- Eddy currents
- Electron beams
- Magnetic fields
- Microwaves
- Neutron beams
- Nuclear magnetic resonance
- Pressure
- Surface height using a tactile sensor
- Ultra-sound

8.6 Mechanical Handling

So far, we have merely indicated what individual items of equipment are available to the vision engineer; there has been no attempt to list how an LVS can be designed. There are other choices to be made:

- Where are the lights to be placed relative to the widget, optical components and camera?
- How are the widgets to be presented for inspection? They may be presented to the camera individually or in groups, depending on the mechanical handling.
- If the widgets are grouped together, are they touching or overlapping?
- If the widgets arrive singly, are the position and/or orientation known precisely?
- Is the widget static or moving at the moment when the image is acquired?
- If the widgets are moving, is the speed and direction of travel known precisely?
- Is the widget motion linear or rotary?

In many cases, we can use the "natural" motion of artefacts as they are being transported around the factory, or arrange for the widgets to be moved in some controlled way past the camera.

8.7 Experimenting with Lighting

The wide range of options available for each part of the LVS provides great versatility but imposes a considerable burden on the vision engineer when choosing a suitable lighting-viewing method. The task of finding a good LVM is often perplexing, particularly for newcomers to Machine Vision. They frequently make the mistake of restricting their attention to familiar domestic/office illumination equipment (e.g., a desk lamp) and standard illumination-viewing configurations. They do so because they under-estimate the wide temporal and spatial variations in brightness and colour that occur in natural and artificial environmental lighting. These parameters do not normally affect human vision significantly but can seriously disturb automated image processing. It is unrealistic to believe that software can always compensate for poor lighting. Adopting a casual approach to lighting will almost always make the overall system much more complex and far less reliable than it should be. It is only by understanding the general physical principles involved in image formation and appreciating the relative merits of a wide range of LVMs that an optimal system can be selected/designed.

8.7.1 Taking an Initial Look at the Widget

The most powerful weapon in the vision engineer's armoury is his/her own sight. *First of all, look at the widget*! By moving a "point" source of light around the widget and observing its changing appearance, it is often possible to gain a great deal of valuable insight about which LVMs might be appropriate. To be most effective, this should be done in an otherwise darkened room. A white LED torch provides a narrow directional beam and is ideal for this stage of the experimentation. (Make sure that the LED generates a broad spectrum of light and does not rely on mixing three beams with narrow-spectral peaks from separate red green and blue LED chips.) This preliminary visual examination will often identify the characteristics (e.g., reflectance, colour, height, shape and surface orientation) that determine or limit the contrast of important features. In many cases, it is also worthwhile examining the widgets using a simple camera-monitor video link. This will probably give a more accurate impression of what a vision system "sees" than a person can with the unaided eye. In a large majority of cases, explorative visual examination like this can help the engineer a great deal.

8.7.2 Prototyping the LVS

The next stage of the design process is to construct a *crude* prototype LVS, by manually adjusting the relative positions of the widget, lamp(s) and camera, until a high-contrast image has been obtained. This may simply involve nothing more complicated than holding a lamp in place by hand and judging image quality by eye. However, it is usually better to use an interactive image processing system, as this can provide objective measurements of image quality. (Algorithms for analysing the images are often invented/discovered here as well!) To be most effective, the experimental work should be conducted in a darkened laboratory equipped with a wide range of light sources and optical components: lenses, mirrors, prisms, gratings, filters, beam-splitters, polarisers, diffusers, component mountings, clamps, etc. Together with an interactive image processor (e.g., QT, ➲ Chap. 21), these constitute a very useful prototyping tool kit.

Using the same optical and lighting equipment, but held firmly in place using appropriate clamps and mountings, a second-stage prototype is built, then modified in a more rigorous

◘ Fig. 8.1
Archibald and Illumination Diagrams. Archibald is a tiny "ant" which crawls over the surface of the widget but is unaware of its orientation. The Archibald Diagram is a map, drawn on the plane tangential to the widget surface and indicates where Archibald sees the lights and camera. (a) Front illumination. Archibald is on a horizontal surface. The light source is above the horizon. (b) Archibald and illumination diagrams. These are the same for the lighting-viewing configuration shown in (a). (c) Front illumination. Archibald is on an inclined surface. However, the Illumination Diagram for this situation is identical to that shown in (b). (d) Archibald diagram for the configuration in (c). Notice that the projections of the light(s) and camera have both moved. (e) Back illumination. The light source is below the horizon. (f) Archibald and Illumination Diagrams are identical, since Archibald is on an horizontal surface. The Archibald Diagram for back illumination is drawn by projecting the light source onto the hemisphere above Archibald

experimental investigation. The aim is to produce a conceptual design for the target (i.e., factory-floor) system.

Over a period of more than 30 years, the author collected together a range of illumination and optical devices specifically for experimentation in this manner and has seen several other university and company laboratories do the same. In the author's own personal experience, the experimental approach has been successful in *several hundred* very varied applications studies. These did not all result in factory installations but, in the vast majority of them, it was possible to demonstrate technical feasibility, or lack of it, in a very short time. Over the same period, the author has been closely involved with the development of a series interactive image processors, the latest of which is QT (➜ Chaps. 21 and ➜ 41). Both parts of the prototyping tool kit (i.e., optics-lighting and image processing) are essential for this approach to be really effective.

As a general principle, the initial design work for an LVS should never be undertaken sitting at a desk; a few hours in the laboratory is far more profitably spent!

8.8 Characterising the LVS

Once the prototype LVS has been built and proven, it is necessary to design a well-engineered version or installation on the factory floor. In order to do this, it is necessary to measure the prototype LVS carefully. This can, of course, be done painstakingly and tediously using a ruler but there are other faster ways to achieve the same result using a camera and the interactive image processor again. One of these methods uses an hemispherical mirror and the other a fish-eye lens. These are used in conjunction with a camera used solely for this purpose. (This calibration camera is not part of the prototype LVS.) The angular positions of the lights can be

(LVM 46) (c) "Cloudy day" light source, projects light in all directions. (LVM 85) (d) Eight "point sources" providing multi-directional grazing illumination. (e) Dark-field illumination, with line-scan camera (LVM 27) (f) Coaxial illumination and viewing. Light effectively comes from the camera (LVM 15)

measured automatically, very quickly and easily. The result is a diagram akin to the maps of stars in the night sky and called an *Illumination Diagram*. This and the related *Archibald Diagram* are explained in ➋ *Fig. 8.1*. Although they are more complicated, Archibald Diagrams are able to detect the possibility of specular reflection (glinting) better than Illumination Diagrams. However, to do this, an Archibald Diagram has to be drawn for each surface angle. For this reason, Illumination Diagrams are normally preferred. Six sample Illumination Diagrams are shown in ➋ *Fig. 8.2*. Others are shown in ➋ Chap. 40.

8.9 About the LVM Catalogue (➋ Chap. 40)

The entries in the catalogue should be regarded as being merely prompts guiding the practitioner towards a few possible solutions for a given application. Having thus identified a set of plausible suggestions, he/she can then concentrate on evaluating them experimentally, to find the best one.

The principal LVMs are presented in ➋ Chap. 40 in general non-quantitative form, without reference to physical scale, or cost. In some cases, proprietary lighting units are available to implement these ideas.

The LVMs can be used singly, or in various combinations. For example, it is possible to perform a useful inspection function using simultaneous back illumination at one wavelength and front illumination at another (LVM 20). Another example is to combine range maps and colour images, or x-rays and UV-VIS fluorescence. Clearly, we cannot list all possible combinations and, in practice, a great deal of experimentation and cunning is required, to obtain the best results.

The LVMs are presented in alphabetical order, since it is not possible to define any useful and more "natural" ordering.

Light sources are represented graphically, using icons suggesting the use of filament lamps. It should be understood, however, that in many cases, other light sources, such as discharge tubes, compact fluorescent lamps and LEDs might be more appropriate.

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_9,

Abstract: This chapter gives an overview of why scanning systems are used rather than more straightforward imaging systems. Different classes of scanner and optical systems are described along with the tradeoffs in performance that have to be made when balancing different performance requirements. Detailed performance of a particular parabolic mirror, large area scanner is presented.

9.1 Introduction

Two dimensional detectors are ubiquitous and relatively cheap. CCD or CMOS cameras are used for a large proportion of machine vision applications. Frame and field rates of these cameras are usually in the range 50–120 Hz and resolution is usually less than 1 Mega-pixel. For applications for which these specifications are not a limitation there are a wide range of cameras with standard lens fittings e.g. C-mount, and video interfaces to PCI cards to interface with a desktop computer. Software to control these cameras is equally easy to find. To obtain cameras outside these specifications gets much more difficult and costly. High speed cameras are available but require special interfaces. If the data rate is very high, separate memory may have to be used to obtain the speed required. Higher spatial resolution is equally difficult to obtain. Higher resolution implies a larger semiconductor chip size with consequent lower yields. Worse the detector will probably not be in production anyway because the volume of potential sales does not justify the high one off cost of a new chip design. This limitation has been circumvented by using multiple chips, especially in astronomy, but there are severe technical difficulties in mounting the chips close together and with enough accuracy to use the resulting data on a single rectangular grid.

It is in these slightly unusual circumstances that the use of a scanner may give the best combination of cost and performance, although they will always be a bit more difficult to use than a simple imaging system.

A scanner works by having fewer detectors than is required in the image, but moving either the image, the object or the detectors so that the scanner obtains the data sequentially. In the most extreme case only one detector is needed. In some circumstances, such as the far infrared, it is impossible at the current state of technology to build arrays of detectors. The scanner therefore is the only way to obtain high resolution images at these wavelengths.

There are very many permutations of scanner possible. Resolution, detector speed, detector efficiency, and the availability or otherwise of multiple detectors all affect the optimum design for a particular imaging system. This chapter attempts to group the possible solutions into some kind of order although there are probably exceptions to every generalisation one can make about scanner design.

9.1.1 Advantages

Scanners reduce the number of detectors needed from the usual one or more per pixel. A typical colour CCD camera uses three detectors per pixel. Reduction of the number of detectors has hidden benefits as well as the obvious ones. If for example one detector is used there are few calibration problems. The detector is the same for every pixel so detector noise, efficiency etc. is also the same for every pixel. Fewer detectors also means less electronics.

Two dimensional and even one-dimensional i.e. line detectors lose efficiency due to the areas between detectors which are insensitive to light. With modern Detective Quantum Efficiencies (DQE) of better than 50% this factor can become quite significant. A scanner can be made to use closely fitting pixels or even overlapping pixels if detection is more important than imaging resolution.

The characteristics of a scanner e.g. resolution, imaging speed, etc. can be varied by large factors without changes to hardware. A typical CCD camera will have a fixed or very nearly fixed frame rate and spatial resolution.

The detector(s) can be sensitive all of the time. Two dimensional arrays typically have an imaging and data read out phase of operation. Typical scanner detectors run continuously.

If only part of the final image is being measured at any one time then only that part of the object needs to be illuminated. This allows very bright laser illumination to produce fluorescence for example. This idea can be extended, and usually is, so that the spatial resolution of the device is determined by the illuminated spot rather than the size and optics of the detector. It is relatively easy to produce a small illuminated spot compared to producing the same resolution over a large two dimensional field. A scanner is therefore the best way to produce very high resolution images. To take an extreme example, atomic force microscopes are essentially single detector scanners using various physical effects on a single detector to obtain resolutions down to atomic diameters.

Resolution is usually the reason that scanners are used. This may not be just resolution of very small features but be resolution of relatively large features but on very large objects. This is often the case in material production, where glass or aluminium sheet of several metres width is monitored for flaws during production.

If, as in the above example, the surface to be imaged is moving in a known manner, then only sequential one dimensional images need to be acquired to get a full two-dimensional image. There are then no problems with images overlapping or leaving gaps, or relating one image to the next.

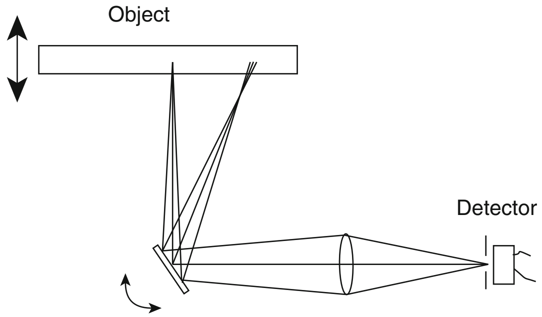
9.1.2 Disadvantages

The main disadvantage of scanning is that some moving parts are required. This must be true if the number of detectors is smaller than the number of pixels in the image. How this is achieved is a major part of scanner design. There is currently no good way to steer optical beams without moving parts. The closest is using opto-acoustic crystals which can be electrically excited to diffract light, but the angular deflection available is small. The only scanners that don't need moving parts use line detectors which are moved bodily (see next section).

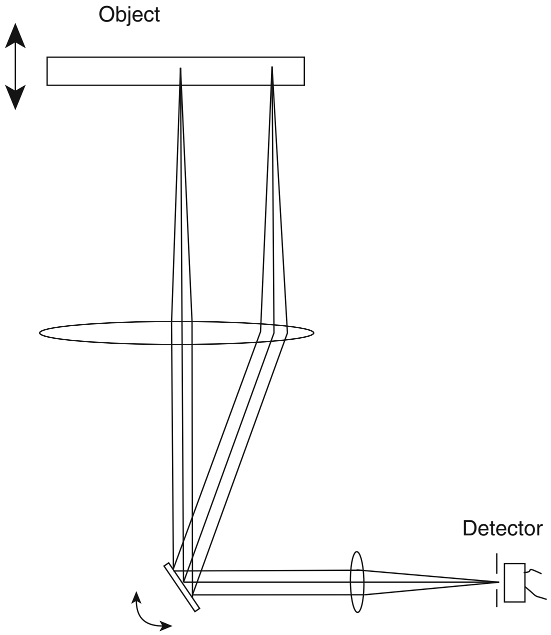
9.2 Types of Scanner

9.2.1 Resolution by Imaging

The very simplest form of imaging would be to move a detector over the surface of interest in a two dimensional raster. This has very little to recommend it. The next simplest is the arrangement shown in ➋ *Fig. 9.1*. The surface is illuminated over the entire range of



■ **Fig. 9.1**
The simplest kind of scanner sometimes called a post-objective scanner



■ **Fig. 9.2**
A pre-objective scanner which requires an optical component at least the size of the scan

the scan. Points on the scan are sequentially imaged onto a detector. The size of the stop at the detector sets the spatial resolution. The imaged area is scanned across the object by rotating a mirror.

The arrangement has a serious drawback; the distance from lens to surface is not constant through the scan so the system cannot be in perfect focus for the entire scan. A lesser problem is that the angle at which the surface is imaged changes with scan position which will again give differing results across the scan. Both of these drawbacks can be removed by using the configuration in *Fig. 9.2*. This is sometimes called pre-objective scanning as opposed to the system in *Fig. 9.1*, which is post-objective scanning. The drawback of this system is that a lens of the same diameter as the object being imaged is needed. If the large lens is at its focal length from the surface then perfect imaging can be obtained and the angle at which the surface is scanned stays constant for the entire scan. The above assumes, of course that the lenses are perfect and less obviously that the diameter of the beam illuminating the large lens approaches zero. This is because for a perfect lens rays emanating from the centre of the scanner mirror will all end up parallel as they approach the surface. This is not true of the rays not emanating from the centre of the mirror. The other optical limitation is connected to the first. The angular resolution of an optical system can only be approximated by

$$R = 1.2\ \text{Lambda}/d$$

where d is the diameter of the beam and Lambda is its wavelength. This is a direct consequence of the wave nature of light so can only be alleviated by using shorter, that is bluer, wavelengths. This requirement is in direct opposition to the previous requirement for perfect imaging that the beam be vanishingly narrow.

The interplay between these two constraints and the necessity for at least one large curved optical component have largely been responsible for the many permutations of scanner that have been developed.

9.2.2 Resolution by Spot Projection

An alternative to illuminating the entire scan and imaging a part of it, is to illuminate one spot on the scan at a time and have a detector that collects light equally from the entire length of the scan. In this case the detectors in *Figs. 9.1* and *9.2* would be replaced by a light source and the illumination system by a detector.

Where resolution is by spot projection, in most cases, the light source will be a laser of some sort. This optical arrangement allows the entire output of the laser to illuminate one spot on the object at a time. This is very efficient in use of laser power, and it is relatively easy to get a very bright spot which can be useful in specialised cases such as stimulating fluorescence. The drawback is that a large detector is necessary. In any optical system the luminosity is conserved or made worse

$$wA = \text{constant}$$

or in words, the product of solid angle and area (of light beam) is constant. This therefore implies that to detect a large proportion of the light coming from a large area of an object the detector must also be correspondingly large. The most efficient way to use detector area is to illuminate it with as large a range of angles as possible, but of course a hemisphere is the largest solid angle with which one can illuminate a flat detector. However clever the optics, there is a limit to how efficient the detector system can be made. *Figure 9.3* shows a combined system where the same optics are used for illumination and light detection. The semi-silvered mirror should be 50% reflecting and transmitting for best signal, which results in a loss of three quarters of the available light. The focal ratio or F number of the beams in this system are also high, so although the arrangement looks attractive it is not very efficient.

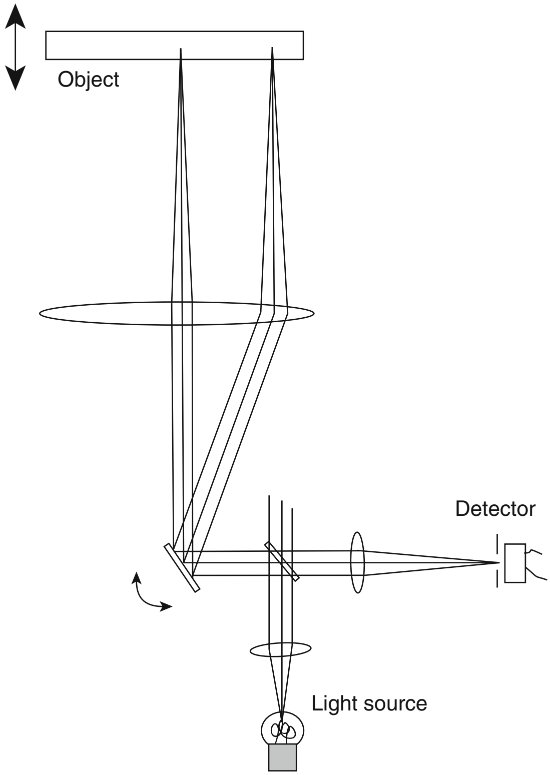


Fig. 9.3
A pre-objective scanner. Note the system for using the same optics for spot projection and imaging

9.3 Uses

9.3.1 Input

9.3.1.1 Document Reading

This is one of the most common use of scanners. They are normally of "flat bed" form, that is the document is placed on a flat sheet of glass to be scanned. These scanners leave the document stationary and move the whole scanning apparatus across the document. The entire scan length is illuminated at all times, and resolution is obtained by a stop affecting the detector.

Scanners of this type often have very impressive optical performance, especially considering their low cost. Resolution of 5,000 lines per inch can be obtained. The use of inches in this context is almost universal. The example above equates to about 200 lines/mm. This performance is achieved by the use of plastic aspheric lenses. The aberrations mentioned in the introduction can be carefully balanced. Unit costs of plastic lenses are very low, but the one off costs of producing the high-pressure forming tools are high. These kind of lenses are therefore only available to volume manufacturers. It should also be noted that the quoted resolution is not at a contrast of 100%. It is often not stated what contrast has been used for the measurement, so actual resolution may not be quite as good as expected. The other performance criteria usually used is the dynamic range of the intensity response. This is usually quoted as a power of ten, i.e. 3.3 means an intensity range of 2,000 or $10^{3.3}$. A large dynamic range is needed to get all the information in pictures, and especially when film is being scanned. High dynamic range requires the removal of as much stray light as possible by clever design, baffles etc. and by anti-reflection coating the optical components. This can raise production costs significantly so the difference between budget and premium scanners can often be seen best in their dynamic ranges.

It is difficult to design a scanner that gives equally bright images across the length of the scan. Typically the image will darken at the ends of the scan. This is usually combated by having the scanner scan a patch of reflective or clear glass before the scan proper starts. This allows the scanner to adjust the output intensity values in the rest of the scan to give an even response.

Even with the techniques above, it is difficult to get very high resolutions over a large document. In a single scan, possibly 10,000 elements can be obtained but 100,000 cannot. This problem is removed in some large flatbed scanners by scanning the document in 'swathes'. A bit like mowing a lawn in strips. The strips are then joined together using software so that the user is not conscious of the operation. Another approach is to have a lens system that can be changed to give very high resolution over a small scan for scanning film for example or a lower resolution over a bigger scan for paper.

9.3.1.2 Bar Codes

Bar code scanners are probably the most numerous scanners in existence. They range from relatively simple devices to extremely clever and difficult systems. An example of a simple system is that used by check out counters in shops. The scanner is placed against a bar code of the correct size and measures the width of each bar resulting in a binary number denoting the object. The cheapest of these are not actually scanners but linear array imaging devices. At the other end of the range are systems used to measure bar coded tags on luggage as the luggage passes on a conveyor. This needs to be accomplished unattended. This is usually done by using a large number of scanning beams at different angles and positions such that at least one beam will cross a bar code at an angle at which reading it is possible. The signature of a beam crossing a barcode must be separated from ambient light, flickering fluorescent lamps, etc. Details of the modulation and detection circuitry used are proprietary secrets. The best way to find out about these system is the drawings made public in patent applications (see ➲ *Fig. 9.20*).

9.3.1.3 Film to Video

This is a commercially important area as data storage takes over from analogue media. It is not particularly difficult in optical terms because of the relatively small number of pixels in video image. Scans should however be done at higher than the output resolution. The film image can be processed to improve tonal characteristics, colour and even remove blemishes such as dust and scratches. Scratches and dust can be preferentially imaged using near infrared and this information used to adjust the RGB channels.

9.3.1.4 Film to Still

Digital cameras are beginning to take over from film-based cameras, but where very high resolution is needed, film is still superior. A CCD imager with ten million pixels is now common, but a 4 × 5 in. sheet of film digitised in colour at 5,000 lines per inch gives 500 million pixels of each primary colour. Very high-resolution CCDs are now available but are very expensive and still cannot match these numbers. Because ultimate performance is the reason for using film in these situations, the film is normally scanned with a drum scanner, see ➋ Sect. 9.6. These scanners have the best optical performance of any scanner, and the fact that the scanned film must be bent for operation of the scanner is not a drawback.

9.3.1.5 Quality Control

Some products lend themselves particularly well to imaging using a scanner, especially products produced as a web, i.e. a continuous sheet. By imaging a line across the web as it is produced, the entire area is covered without any problems of overlap etc. Particular cases are float glass, aluminium sheet and various plastic sheeting materials. These all have the advantage that they have very flat and reasonably shiny surfaces. A blemish will depart from the flatness and reflectivity of the correct material. A scanner of the type in ➋ *Fig. 9.3* can be effective even without the large lens. The scanner can be arranged at an angle to the surface so that reflected light for a good surface does not reflect back to the detector. A blemish however will reflect light. This arrangement has the advantage that for a good surface the 'image' is black. Blemishes appear as lighter areas. This makes image processing extremely easy and also allows the scanner to detect blemishes smaller than its optical resolution. Even a blemish smaller than the resolution limit will reflect light which can be detected.

A property of scanners that is often overlooked is that the optics can be at an angle to the scanned surface. This will produce images which are similar to the ones one would see looking at the surface from that angle but without the geometrical distortion caused by perspective. Many blemishes, such as scratches, are much easier to see both when obliquely illuminated and obliquely viewed. In general, surfaces get more reflective at oblique angles. A scanner can accomplish this while maintaining the shape of the object in the resultant image.

9.3.2 Remote Sensing, Military

Multi-element detectors for visible wavelengths are now easy to obtain, but infrared and ultraviolet are still problematic. Scanners have the characteristic of reducing the number of detectors required, sometimes to just one, so that extreme wavelengths can be used for imaging. Another aspect of this is that the beam coming from the scanner can be separated into separate wavelengths and separate detectors. In effect, an entire spectrum can be obtained from each point in the image. This characteristic can be used to detect very subtle effects such as diseased plants from satellite orbit. The military possibilities are obvious. A major problem with such systems is the combination of high spatial and high spectral resolution creates very large quantities of data.

➋ *Figure 9.4* show a reconnaissance imaging system using a line detector and optics placed using the Schiempflug condition [6] to map a swathe of land. This is a rare example of a scanner with no moving parts, unless you count the aircraft.

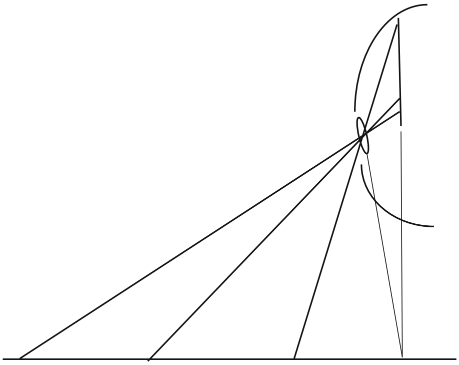

Fig. 9.4
Surveillance or mapping scans taken by flying a plane across an area. The only moving part is the plane. Imaging conforms to Schiempflug condition [6]

9.3.3 Three Dimensional

Three dimensional scanning depends on parallax between views or in other words stereo. As long as a unique point in space can be viewed from two separate positions the coordinates of the point can be calculated by geometry using the angles to the point from the two viewing positions. Although the idea is conceptually simple there are great practical difficulties. The worst problem is correspondence i.e. viewing the same point in the second view corresponding to the point chosen in the first view. Obtaining this correspondence in the general case from two randomly chosen viewpoints is very unreliable. The design of three dimensional scanners and indeed stereo systems is largely composed of techniques to make this matching of points reliable.

The correspondence problem is difficult because there is no reliable way to tell if a match has been made correctly between two views. More constraints are needed to allow self consistency checks, or to put it another way add some redundancy to the system. In stereo systems this can be accomplished by using a third viewpoint. If all three views agree on a three dimensional position for a point then there is little chance that the match is incorrect.

In the case of scanners a typical solution to this problem is to constrain the geometry of the setup so that matching is unequivocal. An example is shown in *Fig. 9.5*. A line of light is imaged on the object surface. The surface is then viewed by a camera in the same plane as the projection system. The horizontal displacement in the image is a measure of the position of the projected light on the surface. If a one dimensional detector placed along the plane of the optics is used the position of detector with largest response measures the position of the object surface. By rotating the object, a complete perimeter of the object can be measured. By moving the whole optical arrangement up and down a complete surface can be generated. This can also be achieved by just moving the linear detector up and down.

The weakness of this kind of system is that it requires that the directions of the optics, images and rotations all be accurately aligned. The ultimate resolution of this kind of system is that corresponding to one pixel of the detector. This is typically 10 μ across. Setting the rest of the system up to this accuracy is almost impossibly difficult. An alternative using two-dimensional detectors is shown in *Fig. 9.6*. This system uses three optical systems, two for

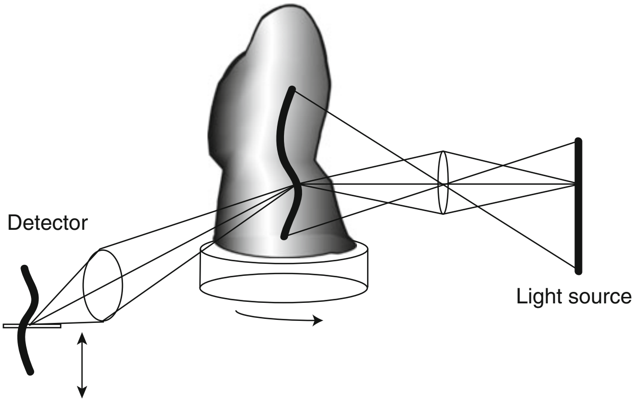

Fig. 9.5
Three-dimensional scanner using scanner geometry as reference

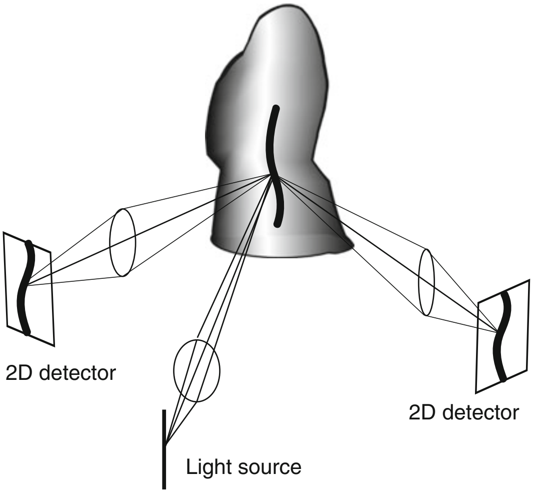

Fig. 9.6
Three-dimensional scanner using self-calibration as reference

imaging and one for light projection. The light projection system illuminates just one point on the projected line at a time. The benefit of this arrangement is that it is completely general in the sense that whatever the relative angles of the cameras and projection system, if the cameras can see the projected spot, then an accurate calculation of spot position can be made. This presupposes that the system has been accurately calibrated by viewing known, accurate three-dimensional positions.

The two systems, although superficially similar, are based on two different premises. The system in *Fig. 9.5* depends on the accurate physical construction of the mechanical and optical components. The system in *Fig. 9.6* depends on accurately measuring the characteristics of the optical system using known positions. It could be argued that the *Fig. 9.5* system could also be calibrated in this way, but for calibration to be successful all the variables affecting the system must be taken into account by the calibration. This is almost certainly impossible with *Fig. 9.5*. In *Fig. 9.6*, the calibration depends entirely on getting the characteristics of the two cameras. This is relatively easy if the cameras geometry is completely linear, i.e. acts like a pinhole camera. Even if this is not the case, there is considerable literature on obtaining non-linearities by observing known objects.

The area of three dimensional scanners is broad one. It has been used for the accurate measurement of turbine blades, reverse engineering mechanical components for which plans are not available to measuring the shape of people to obtain optimum dress sizes and measure drifts in population characteristics. The permutation of optical arrangements is almost limitless, however systems that can be rigorously calibrated are in my experience more likely to be effective than those that depend on accurate construction.

9.4 Output

9.4.1 Laser Printers

Laser printers typically work by writing the image on a drum and then printing the resulting image onto paper. The drum is electrostatically charged but covered in a photoconductor. Exposing any part of the drum to light allows the charge for that area to leak away. If the drum is exposed to very finely divided carbon, the toner, the toner will stick to the charged parts of the drum only. By exposing the drum to the inverse image we want printed i.e. light exposed gives white, we can produce a convenient form of printing.

A scanner is used to expose the drum. For an A4 printer of 1,200 dpi, there are approximately 10,000 dots across the width of the page. This is about the limit for reasonably priced scanners. This is a scanner using resolution by spot projection as already discussed but without the need for a detector.

9.4.2 Image Setters

Image setting is the process of turning digital data describing images or text into a mask or printing plate that can be used for high volume printing. Quality of image is usually a prime concern. Glossy magazines and books are produced in this way. Time to produce a plate is not critical. Most image setters therefore use a drum scanner. The mask or plate is wrapped around a drum which is rotated at high speed. A writing head moves linearly down the drum writing the image. See the section on drum scanners. The resolution is very high because of the easy constraints on the optics, but mechanical accuracy has to match the optical performance.

9.4.3 Semiconductors

This is a very specialised use of scanning. Some of the images produced probably have the best resolution of any images ever produced. Techniques are being developed all the time to produce finer resolution circuit elements which allow more gates and therefore a better or faster computer chip. Traditionally a mask for a particular evaporation or doping process would be written using a high resolution image setter to produce a mask approximately 10 times the size required. This mask is then imaged at the correct size onto a photosensitive surface using extremely high-quality optics and ultraviolet light. Ultraviolet light is convenient for the exposure of the photo sensitive surface but, more importantly, the short wavelength allows finer detail. The resolution of any optical system is limited by the wavelength being used.

Even ultraviolet is now too long wavelength for some uses, so electron beam scanners which have a much smaller wavelength are used instead. This is the same kind of technology used in scanning electron microscopes. Because they are charged, electron beams can be steered and focussed by electric fields, but this is taking us outside the range of this chapter.

9.4.4 Printed Circuit Boards

The masks are produced in much the same way as for film image setting. The required resolution even for small surface mount components is quite easy to obtain.

9.5 Performance

9.5.1 Modulation Transfer Function

Probably the best way to express performance is the Modulation Transfer Function (MTF). This plots the contrast for a sine wave intensity image viewed by the instrument. An example is shown in ➋ *Fig. 9.18*. Note that even a perfect optical system does not give 100% contrast for anything other than very low spatial frequencies. Quoting a dots per inch or lines per millimetre figure is really not useful without saying at what contrast this spatial frequency is imaged. A typical assumption is that contrast is 30%, but this is by no means guaranteed. Given the MTF, it is quite easy to simulate the acquired image for a given perfect image and hence decide on performance issues.

9.5.2 Scan Length/Speed

These terms are mainly self-explanatory, although scan speed can be misleading. Most systems require a gap between traverses due to the scanning technique see ➋ Sect. 9.8, so the spot speed is likely to be higher than the scans per second would suggest. See ➋ *Fig. 9.12* for a way of reducing dead time by using two input beams to a rotating prism scanner. Depending on the scanning system, the scan can by mono or bidirectional.

9.5.3 Number of Channels Out

By the nature of scanners the number of channels out can be large. Total data rates can be extremely large.

9.5.4 Linearity, Aberrations

We have been assuming that the scanner will produce at a constant rate of movement of spot or image position. The angular movement of the scanner mirror will not produce a linear scan unless great care is taken. The optics are unlikely to produce a constant spot movement for a given change in mirror angle. Lenses can be designed to approach this and are sometimes called f-theta lens. Scanners with galvonometric scan mirrors (Sect. 9.9) will not move at a perfectly constant rate to give a triangular angle versus time response, especially as the maximum speed of the scanner is approached.

Many scanners use mirrors for the main optical components. This implies in many cases that they must be used slightly off-axis. This results in the nominal scan line actually being slightly curved. This translates to a scanned perfectly straight line appearing to be slightly curved. The spot size of the imaging or projection system will vary over the length of the scan giving a non-constant resolution or MTF. Optical efficiency may also vary for different positions on the scan giving apparent brightness changes across a scan. Chromatic aberrations are also possible for systems that use transmitting optical components as well as mirrors.

Some scanners have very high performance in some aspects such as resolution, but it is important to note that much of the published work on scanners is on ways of balancing imperfections in different aspects of performance to obtain optimum total performance.

9.5.5 Dead Time

Most scanners cannot produce a spot on the scan line 100% of the time. If a mirror needs to have its rotation direction reversed, this will take time. Similarly, rotating prism scanners do not produce a spot on the scan line all the time see Sect. 9.9.

9.5.6 Contrast, Artefacts

The dynamic range of a scan is a very important attribute, especially if amplitude information is being used. Decreasing stray light involves baffles, anti-reflective coatings on optical surfaces and careful design. Getting very good performance is hard, for example light can bounce or scatter from the ground periphery of circular optical components, see *Fig. 9.7*. This is very difficult to reduce. The best cure is to prevent it happening by judicious use of field and aperture stops.

A particular problem with scanners is that there may be scattered light at a few discrete angles of scan that find their way to the detector. This will result in streaks in the image produced which are very visible and hard to remove.

Scanning prism systems can produce a variety of unwanted effects. If the angle of each facet is not identical or the rotational axis does not go through the centre of symmetry of the polygon scan paths can cross. This results in obvious artefacts in the image, especially in features parallel to the scan direction. Other types of scanners using lead screws are also prone to this kind of error. The easiest way to avoid these problems is to have identical optical and electrical characteristics for each scan line, e.g. galvanometric scanning in one direction only and discard the return scan.

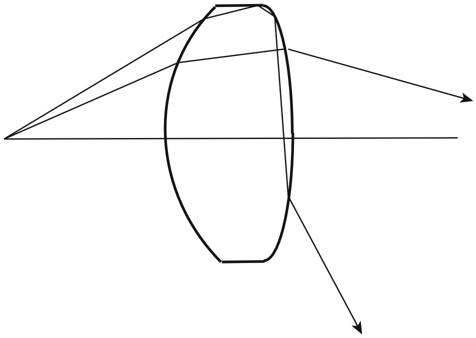

Fig. 9.7
Shows how light may be internally reflected in optical components, reducing dynamic range and contrast

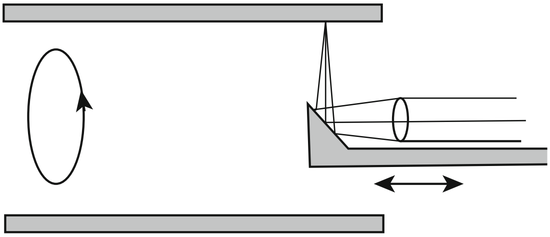

Fig. 9.8
Configuration of basic drum scanner using internal scanning

9.6 Scanner Configurations

9.6.1 Internal Drum

The basic internal drum scanner is shown in *Fig. 9.8*. Note that the lens is attached to the moving carriage. The beam will traverse the inside of the drum in a continuous spiral as the drum rotates and the carriage moves through the drum. There are many permutations of this arrangement. If the light reflecting back from the internal surface of the drum is collected as in *Fig. 9.3*, then this diagram is complete. For transparent sheets the drum needs to be transparent and a detector can be placed on the outside of the drum picking up the light from the spot focussed on the interior of the drum.

In this example, the film or document is placed on the inside of the drum, and just centrifugal forces may be enough to keep the document flat against the internal surface of the drum. Conversely, the document or transparency can be placed on the outside of the drum. This makes loading a document slightly easier, but the document must be held in place possibly by electrostatic forces produced by charging the drum.

The above systems use a rotating drum. It is possible to rotate the beam around the inside of the drum possibly using a rotating pentaprism as in *Fig. 9.9*. This will obviously only work

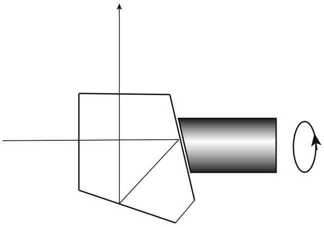

Fig. 9.9
Alternative scanning head for internal drum scanner

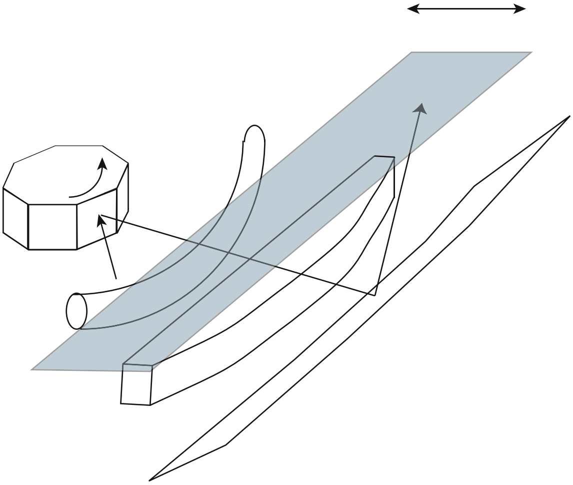

Fig. 9.10
Schematic of typical flat bed scanner showing use of aspheric plastic optics

for a detector which uses the projection optical path as in *Fig. 9.3*. The advantage of this arrangement is that the only moving component is small and light which allows high-speed scans. The fast moving part is also safely contained within the drum. The advantage of the drum scanner is that the optics work at a fixed angle and position with a very small field of view allowing very good resolution.

9.6.2 Flatbed

A typical flatbed scanner configuration is shown in *Fig. 9.10*. The beam is steered by a rotating prism. The optics are all aspheric starting with a bent cylinder going on to aspheric transmissive components and an aspheric mirror. The figure shows resolution by projecting a spot of light on the surface but typically the entire width of the surface would be illuminated, and the field of view of the detector would be scanned across the surface.

9.7 Light Sources

For systems that use imaging for resolution rather than spot projection, the most common illumination is either high frequency fluorescent or multiple LED. Fluorescents have a convenient shape, are efficient and can have a tailored output with wavelength. It is of course very important that the brightness variations do not interact with the imaging. Domestic fluorescents for example can flicker at 100 Hz. The fluorescents in this use are driven at a frequency that is higher than the relaxation time of the phosphor. This ensures constant output.

Light emitting diodes are also very efficient and easy to drive. For a domestic colour scanner the colours of the illuminating diodes can be matched to the response of the red, green and blue detectors giving accurate perceived colour rendition. Multiple LEDs are used rather than trying to use optics to spread the light over the line of the scan.

Scanners whose resolution depends on the projected spot typically use lasers. These produce a high luminosity beam which is relatively easy and efficient to concentrate as a spot on the object. Laser diodes are now relatively cheap and are an obvious choice for this application. There are two problems for this use however. Laser diodes produce an asymmetric beam profile which is usually unhelpful. Usually cylindrical lenses or a pair of prisms, as in ➲ *Fig. 9.11*, are used to make the beam more symmetric, although by conservation of luminosity, all characteristics of the beam cannot be made symmetric at once. The other problem is that the drive electronics for a diode of medium or high power are not simple. Laser diodes tend to exhibit negative resistance characteristics and should be driven with an approximately constant current source. In some cases, a resonant drive circuit is used which results in the diode switching on and off at several Kilohertz. These are obviously not suitable for use in a scanner. Laser diodes are normally used at near their maximum ratings, requiring good accuracy and reliability from the drive electronics.

9.8 Detectors

Scanners are often selected so that an unusual detector can be used to create images. There is essentially no limit to the detectors that can be used on scanners because even a single detector can be made to produce images. Having said that, there are some common threads in the choice of scanner detectors. The ability to image from a small number of detectors is bought at the expense of time division multiplexing the detector. This implies that the detector must operate rapidly. Most scanners are not very optically efficient; that is they operate at high *F* numbers. Comparing a CCD two-dimensional 1,000 × 1,000 imaging system with a *F*1.4 lens

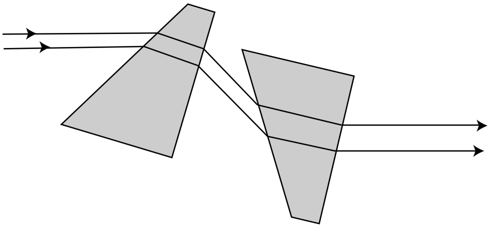

Fig. 9.11
Two prisms used to make diode output approach axial symmetry

to a scanner using one detector and a typical *F* number of 40, the difference in light collected per unit time is obvious. This implies that the scanner detector as well as being fast must also be very sensitive.

Photodiodes can be used as scanner detectors, but it is difficult to arrange good efficiency above about 2 MHz bandwidth. This is because the self-capacitance of the diode limits the bandwidth see [4]. A modern alternative is the avalanche photodiode or APD. The inherent gain of these devices, around 10–1,000 in most cases, allows higher speed operation. Photomultipliers, although not being solid state, have perfect characteristics for scanner use. They have high photon-multiplying gain, up to 10^6, and also very good frequency response into the 100 MHz range. They also have good quantum efficiency. Modern devices can also be quite small and robust, although they do require a high voltage, but even APDs require a high bias voltage, although not as high as a photomultiplier.

Flat bed scanners often use line detectors to speed operation. Line detectors of 10,000 pixels are now available. This can result in a system without a scanning mirror where the surface is just sequentially imaged onto the line detector by moving the detector and its optics across the surface. The movement is normally made using a stepper motor. This results in a system which is half way between a normal two-dimensional imaging system and a scanner. Line detectors with large numbers of elements are usually based on CCD or CMOS technology. Small line detectors, i.e. 16 elements, are often photodiodes or APDs.

9.9 Beam Deflection

9.9.1 Galvonometric

Galvonometric scanners work in the same way as an analogue panel meter. They are essentially a small permanent magnet direct current motor, but constrained to move less than half a revolution and therefore not requiring commutation. They are extremely easy to use; deflection being proportional to applied current. The axis of the rotation can be made coincident with the surface of the scanning mirror making the optical design simpler. Two systems can be put in series to produce XY scanning.

The main drawback of this type of scanner is speed. This limitation gets worse as the mirrors size and weight increases. A small gain in speed can be accomplished by making the scanner resonant. This has the attendant limitation of working only over a very narrow range of frequencies and producing a sinusoidal scan.

9.9.2 Rotating Prism

A rotating prism is a convenient way of obtaining rapid scanning. During operation no accelerations are needed removing problems of vibration, speed of response etc. The rotating prism also has some disadvantages. When housed in a protective shield the construction is similar to a siren. The rate of facet arrival at is likely to be in the kilohertz range. They can therefore be very noisy. Because there is more than one facet, usually 8 or 10, each scan line does not use the same optics. Any variations or inaccuracies in the facets will produce visible results in the scan. The alignment of rotation axis with facets is also critical. Because the rotation speed is constant it is not possible to linearise scans by changing the scan rate in parts of the scan.

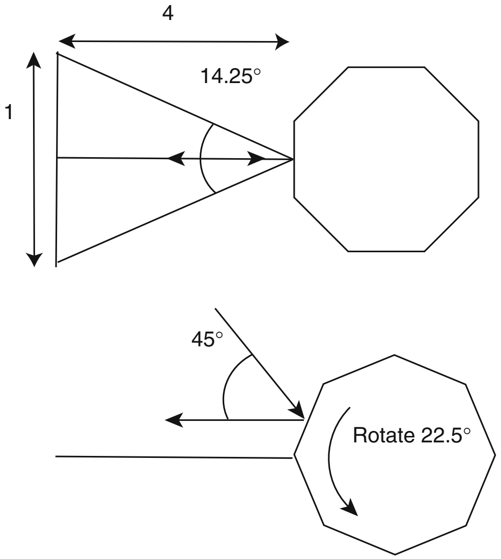

Fig. 9.12
Using two input beams to a polygonal scanner to obtain better time efficiency

The optics of this type of scanner are difficult to handle. The faces of the prism do not rotate about the point that the principle ray hits the surface. This will result in a beam displacement as well as change in angle. This needs to be included in the modelling of the system. The final problem is that they are inefficient in the sense that for most optical set ups the beam will be traversing the wanted range of angles for a relatively small proportion of the time.

The system in ➋ *Fig. 9.12* is *F*4, so the total scan angle will be 14.25° (tan $\theta/2 = 1/8$). To obtain this angle, the mirror will only need to move 7.125°. If the prism has 8 sides, then the angle between prisms is 360/8 or 45°. Every facet will therefore be useful for 7.125/45 or 15.8% of the time. In this case, the scanner is operational for less than one sixth of the time.

The above figures can be made better by increasing the number of facets which reduces the size of each facet. The entire prism thus needs to be larger with consequential increase in cost. An alternative is to illuminate more than one facet from different angles. This technique is also shown in ➋ *Fig. 9.12*. In the top diagram, the light is projected on the prism horizontally from the left and is reflected back horizontally. When the prism has rotated half a facet we want the output beam to again be horizontal. This is shown in the bottom half of the diagram. Note that there is a vertical displacement in the beam from the first example. A similar technique can be used with three input beams. The optics of this can get complicated but is useful for low-performance scanners such bar code readers, where speed of operation is more important than ultimate resolution.

9.9.3 Rotating Wedge

A rotating wedge in the projected beam will scan the beam in a circle. It would be possible to use two contra-rotating wedges to produce an approximately linear scan (➋ *Fig. 9.14*); however, I have never seen this implemented. By superimposing the scan from two wedges, one

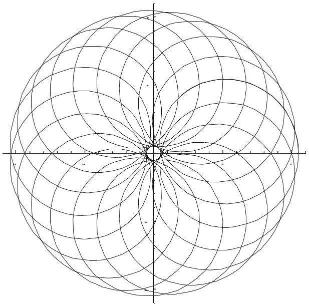

Fig. 9.13
Scan pattern from two rotating wedges in series

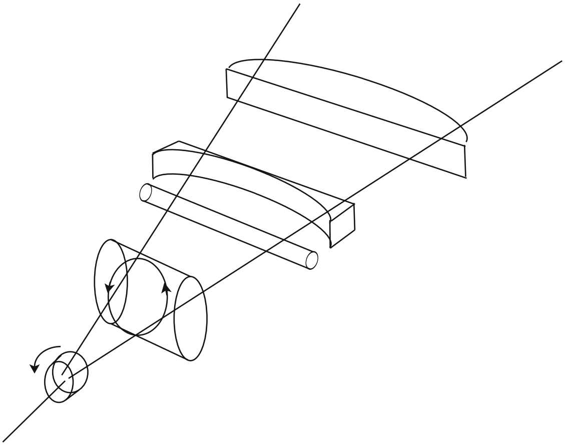

Fig. 9.14
Rotating wedge used in combination with cylindrical lenses to produce a linear scan

going 20 times as fast as the other, the scan pattern in *Fig. 9.13* can be obtained. This is a good approximation of using all angles within a solid angle and is useful for barcode reading.

9.9.4 Prismatic

Another form of scanning prism is shown in *Fig. 9.15*. This scans and changes direction and is often used in barcode scanners. This kind of prism is not generally available in small quantities.

9.9.5 Optoacoustic etc.

It would be very convenient to have a scanning system that used no moving parts; this is after all the main drawback of scanners. Two techniques have been developed to do this, but neither has been generally adopted.

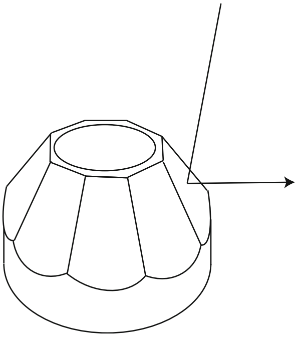

Fig. 9.15
Prismatic scanner used to scan and change beam direction

By setting up an acoustic standing wave in a crystal, one can obtain a regular variation in density and refractive index through the crystal. This can be used as a grating to deflect light of a particular wavelength. Changing the grating spacing will change the angle of deflection and this can be accomplished by changing the driving frequency causing the acoustic waves. This technique can only produce small changes in refractive index and small changes in beam deflection.

Another technique is to use an electro-optic crystal such as KDP (KH_2PO_4) to rotate the plane of polarisation of a scanning beam. The polarisation of the resulting beam can then be used to scan the angle of the resulting beam using another crystal with asymmetric structure such as calcite. Again the angles available are small, but this method can work at 1 MHz so is one of the fastest canning techniques available.

The invention of a practical and reasonably cheap scanning system without moving parts would revolutionise this area of technology.

9.10 Optics

For anything but the simplest of scanners, an optical component the size of the scan is required. The nature of this component is therefore critical to the design. Mirrors have a major advantage in this use. They do not suffer from chromatic aberration, and it is easier and cheaper to make large curved mirrors than it is to make lenses. Large lenses are also very heavy and because of the large path length through glass can be inefficient. Having decided on use of a mirror what is the best shape? In general, spherical mirrors are a poor choice because of spherical aberration. In this case, there is little chance to correct this in other optical components.

Parabolic mirrors are very nearly as easy to make as spherical ones. The differences between the two shapes are actually very small for a mirror of reasonably high *F* number. A parabolic mirror produces perfect images at infinity at the parabolic focus. To turn this around, if a beam is scanned in angle from the focus, this will result in perfectly parallel rays emerging from the mirror. This, unfortunately, is only true for an infinitely narrow beam, but it is a much better starting point than a spherical mirror. See ➲ *Fig. 9.16*. This scans a parallel pencil of beams from the parabolic focus to produce a focussed spot at the focal length. This produces a very good spot on axis but a much poorer one-off axis. In reference [5], a optimum arrangement of

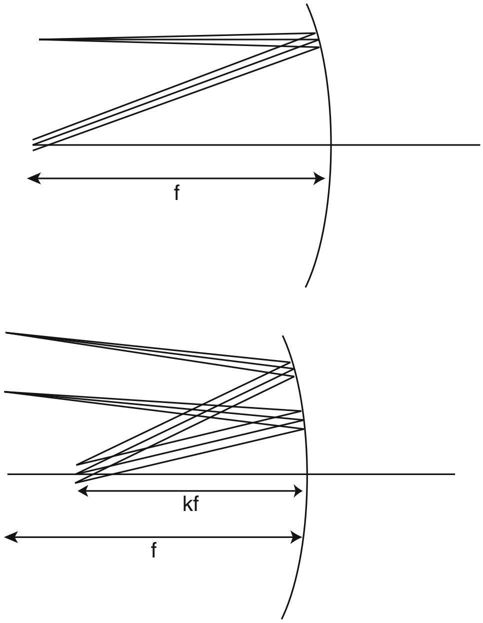

Fig. 9.16
The top is the optical arrangement for a parabolic mirror with scan mirror at its focus. The bottom arrangement discovered by [5] is usually a better compromise with *k* approx. 0.7

parabolic scanner is developed. This balances spot size and linearity of scan. The value of *k* is around 0.7. Not that in this arrangement even the principle rays are not parallel to the axis. For an actual optical diagram and performance model for a real system, see Sect. 9.11.

Note that the effective F number of most scanners is very high. If an *F*4 parabolic mirror is used in the above case, this does not mean that the light collection ability of the system is equivalent to an *F*4 camera. Only a small part of the mirror is used at any one time, resulting in an effective *F* number of 40 or 50.

The optics of drum scanners are much easier because the scanning is all done mechanically so the scanner optics only need to accurately image one on-axis point. Drum scanners therefore have a big advantage in the production of high-resolution and high dynamic range scans. They can also be made optically efficient, i.e. a low *F* number because the imaging optics are very close to the imaged surface, see *Figs. 9.8* and *9.9*.

9.11 Real Examples

9.11.1 Large Throw Scanner

Figure 9.17 shows the configuration of a parabolic scanner with a scan length of 75 cm designed for the quality control of ceramic tiles. This uses the optimisations suggested by [5] and is also operated slightly off-axis to prevent the beam scanning mirror getting in the way of the light pencil.

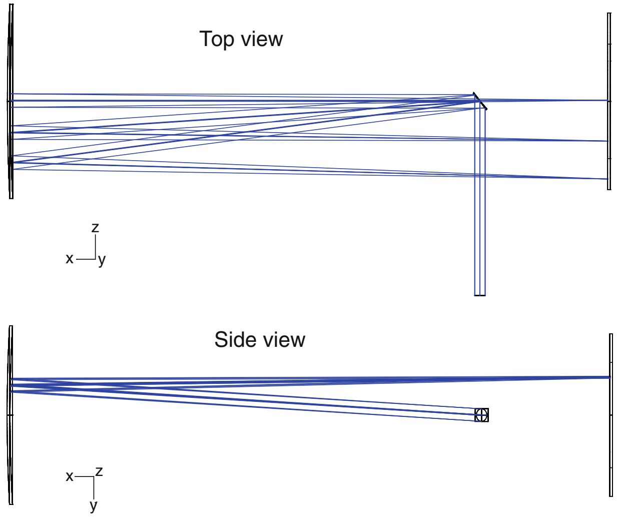

Fig. 9.17
Practical design of a scanner [3] using principles as *Fig. 9.16*. The diagram is to scale and was obtained from the output of an optical CAD programme called "Zemax"

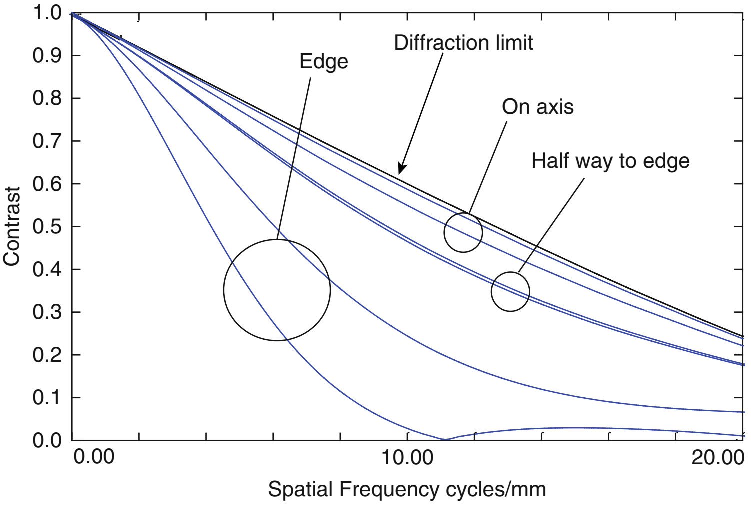

Fig. 9.18
Modulation transfer characteristics of the design in *Fig. 9.17*

The MTF is shown in *Fig. 9.18*. There are seven lines altogether. The top line is the performance of a diffraction-limited system with the same beam size. The next two lines down are the MTF horizontal and vertical of the beam half way to the edge of the scan. Note that MTF is direction dependant, and that the performance at this point is nearly as good as the theoretical limit. Next two lines down are the performance on axis, and the last two are the

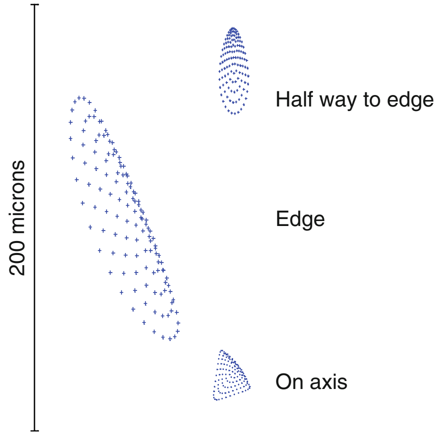

Fig. 9.19
The revolution performance from *Fig. 9.17* shown in a different way as spot size and shape at different parts of the scan

performance at the edge of the scan. The same performance is shown in a different way in *Fig. 9.19*, where the spot size and shape is shown at the same three points on the scan.

Making the beam size bigger would have improved the performance at the centre of the scan which is almost as good as theoretical but decreased the performance at the edge of the scan. If a different scan length or different *F* number mirror were used, the trade-offs of the design would all be subtly different.

9.11.2 Barcode Reader

Getting details of barcode systems is difficult because designs are financially sensitive to the companies that produce them; however, the patent system has as one of its principles that designs must be disclosed so patents are a good source of information.

Figure 9.20 shows a simple barcode system. Light is projected from a diode source through a collimating lens and bounced from a flat mirror onto the scanning mirror. The scanning is essentially a galvanometric scanner using a spring strip to give both suspension of the mirror and restoring force to centre the scan. The mirror is driven by a permanent magnet suspended in the centre of a magnet coil. This produces a much simpler system then a typical moving coil metre movement with hair springs for restoring force.

The received light traverses a similar optical path but uses a curved mirror to collect as much light as possible to be focussed on the detector. The arrangement of curved and flat mirror used in both the inward and outward path is much more efficient than the maximum 25% available from a semi-silvered mirror. The flat portion of the mirror probably only occupies 10% of the curved mirror giving approximately 100% efficiency for the outward beam and possibly 90% for the returning beam.

The combination of design ideas gives a simple compact and efficient design, however, this scanner only produces a linear scan across any object. *Figure 9.21* shows how a rotating prism scanner with faces which are not all at the same angle combined with two or more fixed steering

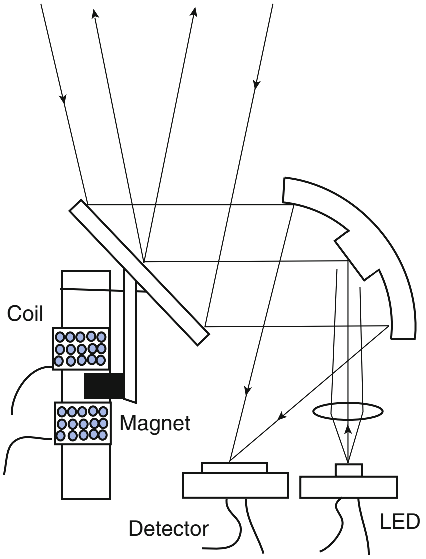

Fig. 9.20

Barcode scanning system from [2] showing clever combination of techniques to give a linear scan

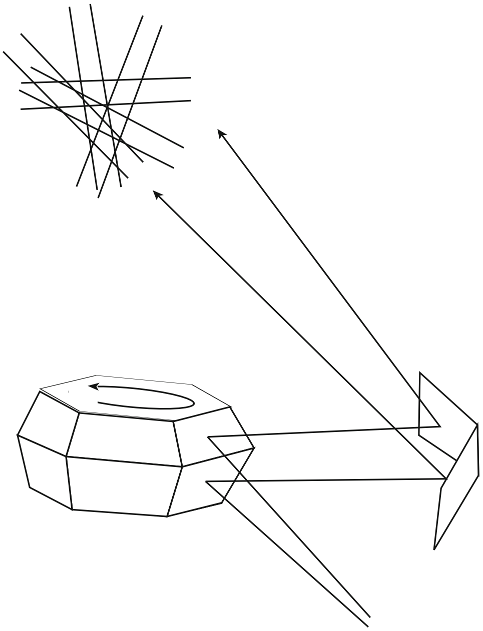

Fig. 9.21

Basic principle of producing multiple scan lines at different placements and angles

mirrors can produce a scan with multiple output beams separated in *x* and *y* directions ad at different angles. ➔ *Figure 9.13* shows the pattern produced by two rotating wedges rotated at different speeds, an alternative way of covering an area.

9.12 Conclusions

There are a very large range of scanner configurations covering an extreme range of uses. Scanners are usually used for specialised tasks which either cannot be accomplished with straightforward imaging or are more convenient for a specific use. Anything which requires extreme resolution in terms of total number of pixels produced, or large numbers of output channels or extreme wavelengths is a candidate for a scanner solution.

This chapter has concentrated on the configuration and optics of scanners; however, for any particular use, the data collection and image processing should be considered as an integral part of the design.

10.1 Image Acquisition Devices

10.1.1 Introduction

In machine vision systems, the job of the image acquisition device is to receive a pattern of illumination from an optical system and convert this varying photon signal into a varying electrical signal that is a true representation of its spatial and temporal variations. To build such a device requires combining an image sensor with electronics to operate it in a form that meets the optical, electrical, mechanical and environmental requirements of the system in which it must operate. This combination is called a camera. Because the operation and performance of a camera is often largely constrained by the image sensor in it, an understanding of sensor characteristics can speed identification of cameras suitable for particular tasks.

Like all transducers, image sensors have limitations – in signal handling capacity, in noise, in linearity, in stability and in time response. Uniquely, image sensors are subject to limitations in spatial resolution, in optical crosstalk, and in spatial, spectral and temporal uniformity.

Selecting a sensor is thus an exercise in understanding the characteristics of the optical signal available, defining the data to be extracted from the optical signal and selecting an image sensor that can bridge the gap between the two. Unfortunately, this exercise often results in zero candidate image sensors, prompting additional effort to make the required data more apparent in the optical signal, to raise the sophistication level of the post-acquisition data processing or to identify compromises that produce the best overall result. Just as often, candidate image sensors prove not to provide the expected data quality due to behaviour not initially recognized as relevant or due to discrepancies between the performance promised in the data sheet and the performance measured on the bench.

To further complicate selection, all the protracted and sincere efforts to normalize the presentation of image sensor performance specifications have still left wide discrepancies in test methods and presentation, forcing the imaging practitioner to understand what image sensors do and how they do it at a fundamental level.

10.2 Image Sensors

While an enormous number of physical mechanisms have been identified that can convert an incoming photon flux into an electrical signal, there are three groups of these that have been most often used in image sensors. The earliest sensors were based on the photoelectric effect, in which a material will emit electron into a vacuum when struck by photons with sufficient energy. In most practical sensors, these materials are transparent so that the photons can enter one side (generally the outside of a glass vacuum envelope) and the electrons exit the other. These materials are called photocathodes. Though still common in low-light-level instrumentation and x-ray imaging, they are rare in machine vision systems because the sensors using them tend to suffer from noise, distortion and signal non-linearities.

A second, mostly abandoned, group is photoconductors, in which the resistance of the material varies with exposure to light. Simple CdS cells used to control lighting are an example of this device type. Photoconductors were widely used in camera tubes, especially antimony trisulfide (Sb_2S_3) and various selenium compounds because they were relatively easy to produce in uniform films and operate at relatively low voltages. However, these materials suffer from signal non-linearities and from various forms of signal fatigue, which leads relatively quickly to burned-in images in static scene environments like those found in most machine vision tasks. In addition, all camera tubes are subject to geometric image distortions and to influences from external magnetic and electrical fields. Still, some photoconductors have survived in solid-state devices, especially in infrared applications.

Most current images sensor are made from photovoltaics, materials in which incoming light generates a voltage across a diode fabricated in the material. However, these materials are generally not run in the voltage-generating (or forward-biased) mode like solar cells, rather, they are reverse biased by an external voltage and generate a signal through the recombination of charge initiated by incoming photons. These materials are particularly well-suited to machine vision applications because they generate charge signals that are exactly proportional to the number of incoming photons and because they can be readily fabricated into geometrically stable monolithic planes. Even so, there are numerous sources of error in detectors made from these materials that the potential user needs to consider.

10.2.1 Basic Image Sensor Requirements

By far, the most commonly used image sensor material is silicon because silicon:

- responds strongly to visible light
- can be manufactured in sizes useful for image sensing,
- uses manufacturing processes and tools well-developed for other silicon devices,
- has performance characteristics compatible with the needs of high image data quality and
- can support fabrication of a wide selection of image sensor configurations at reasonable cost.

The process of building image sensors starts with the same base silicon material used in transistors, microprocessors and other silicon devices. These are wafers, typically 0.3 mm thick, with diameters from 100 to 300 mm cut from large cylindrical single crystals. The wafer is termed the *substrate* and is generally intrinsic silicon. That is, it is essentially pure silicon. With rare exceptions, discussed later, intrinsic silicon is not useful for making image sensors so impurities are introduced into the silicon crystal – a process called *doping* – to provide free electrons or holes that provide electrical conductivity. These impurities could be introduced into the wafer by thermal diffusion or by ion implantation but most commonly, they are incorporated into a new silicon layer grown on the wafer by a process called vapour phase epitaxy. This very uniform, doped *epitaxial* (literally "fixed on the surface") layer, perhaps 50 μm thick, will form the foundation for the fabrication of the image sensor.

To form an image sensor requires providing the silicon layer with a set of physical features that define the desired functions and performance. Fundamentally, any image sensor must take in incoming light, convert it to charge, keep the charge localized to the place where it was converted, hold the charge until the time for readout has arrived and then read out the signal generated by the charge. Each of these requirements adds complexity to the structure of the imager.

Any photodiode can perform the first two steps, converting incoming light to charge, but photodiodes do not preserve any information about the place of arrival of the light and do not hold the charge for readout, instead producing a continuous photocurrent. An array of photodiodes can provide spatial location information and a little additional circuitry can hold the signal and read it out on command. Thus an imager could be simply an array of photodiodes with some extra circuitry fabricated directly on the silicon wafer in a size appropriate to the imaging application. Some imagers are precisely this combination but many take advantage of the additional capabilities afforded by the ability of silicon to perform other useful functions.

10.2.2 Pixel Terminology

The terminology in use to describe pixels is very inconsistent in the technical literature, in product documentation and even in standards. In this chapter, terms have the meanings given here:

Pixel – Since its inception, this term has assumed so many different meanings that it often produces argument rather than communication. Entire articles have been written on this problem. In this book, the term *pixel* refers to any individually addressable detection or display element. This could be a photodiode in an image sensor or an LCD transmission location on a display. By extension, an *RGB pixel* refers to a triad of pixels associated with each other to detect or produce colour and a *multichannel pixel* refers to any set of pixels associated with each other to detect any sort of multispectral energy. The convention will be always to attach a modifier to the word "pixel" when referring to any collection of independently-addressable detection or display elements. A *superpixel* is a group of pixels combined spatially for some purpose. *Subpixel* refers to characteristics of pixels useful for consideration at dimensions smaller than the pixel itself.

Pixel Pitch – The vector distance between adjacent pixels. In the case where some pixels perform different functions from their nearest neighbours the pixel pitch and the pixel size of pixels of identical function are not equal. In image sensors or displays with non-rectangular pixel arrangements, both x and y (horizontal and vertical) dimensions may need to be specified.

Pixel Size – The entire spatial extent taken up by a pixel including its named functional purpose and all local auxiliary apparatus. Not necessarily equal to pixel pitch. Pixel size generally requires specification of two dimensions even in single-row image sensors.

10.2.3 Building Blocks

Image sensors are made up of arrays of small structures designed to perform the basic functions of converting light to charge, holding the charge and reading out the signal from the charge and to provide a variety of auxiliary functions to improve flexibility of operation or performance. Some of these structures operate at the pixel level while others may operate on rows or columns of pixels or on the image sensor more generally. The span of operation of particular structures helps define the functions a particular image sensor can perform.

10.2.3.1 Charge Generation and Storage

The most important element in an image sensor is a small volume of silicon in which the normal charge carriers present have been removed to allow storage of new charge carriers generated by incoming photons. Two methods are used to generate these storage volumes – charge storage wells, primarily in CCD image sensors and reverse-biased photodiodes, primarily in CMOS imagers. However, there are many examples of CCDs in which the photon detection is performed by reverse biased photodiodes.

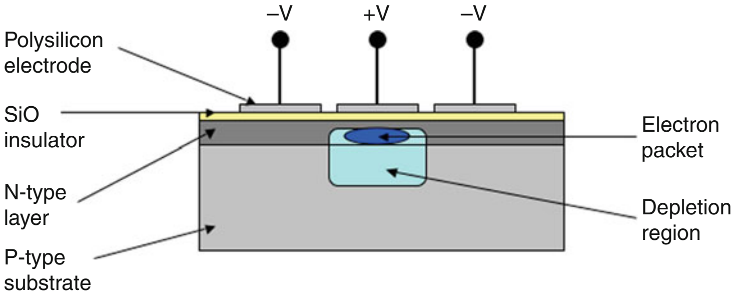
CCD Potential Well

In a CCD, the charge storage well is generated by the application of external electric fields to a silicon P-N junction formed by a P-doped substrate and an N-doped channel (➋ *Fig. 10.1*) using insulated electrodes on the silicon surface. These are structurally metal-oxide-semiconductor (MOS) devices. A positive voltage is applied to the top of the silicon through an insulating layer while the negative voltage is connected to the bottom of the silicon. The resulting field sweeps the charge away from the junction forming a depletion region called the *potential well.* Incoming photons generate hole-electron pairs. The holes travel to the negative connection and the electrons accumulate under the insulating plate but away from the silicon surface. This can continue to occur until enough electrons have been created to neutralize the effect of the positive voltage. Any further hole-electron pairs generated will simply recombine after a while. The number of electrons that can be stored is called the *full-well capacity.* Most CCDs have a full-well capacity of 20,000–100,000 electrons, depending primarily on the area of the well. The upper limit is around 700,000 electrons because charge packets larger than that are very difficult to transport without significant loss.

Note that the CCD structure can work without the top N-doped layer: in this case, the electrons simply accumulate under the insulator. However, allowing the signal charge to collect at the surface of the silicon reduces the charge transfer efficiency and increases dark current. As a result, essentially all modern CCDs use the P-doped *buried channel.*

Photodiode

The most common photodiodes are simply reverse-biased P-N junction diodes arranged so that light can strike them (➋ *Fig. 10.2*). The N-doped side of the diode is connected to a positive voltage and the P-doped side is connected to a negative voltage. Reverse-biasing produces a depletion region by extracting charge on both sides of the junction between the N and P type silicon. Arriving photons generate charge anywhere in the silicon. The charges separate and move to opposite sides of the junction causing current to flow. While the continuous production of current from arriving photons is useful in single-diode measurement applications, the diodes in image sensors must be equipped to share readout circuitry. In imaging sensors, the positive voltage is only connected for a short time to deplete the device and is then disconnected using a switch. This allows the photon-generated charge to slowly accumulate,



■ **Fig. 10.1**

CCD device, consisting of a P-doped substrate and an N-doped channel. The potential well is generated by applying an external electric field

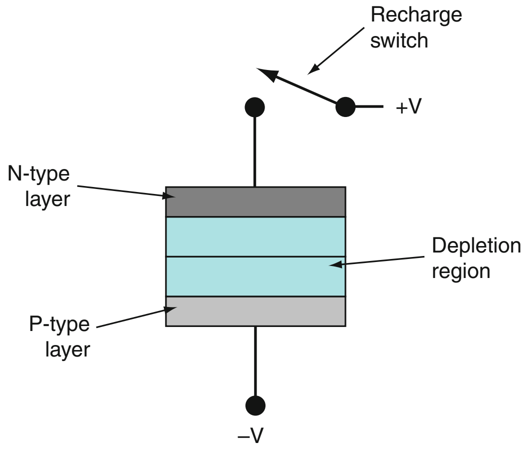


Fig. 10.2
Photodiode using a reverse-biased P-N junction

neutralizing the depletion region. The amount of charge required to completely neutralize the depletion layer is the photodiode's full well capacity. The signal from the photodiode can be read either by measuring the amount of charge that flows when the switch is closed or by measuring the voltage across the diode just before the switch is closed.

10.2.3.2 Signal Transport and Output

Signals generated by the photodetectors must be available for reading off the sensor chip to be of any use. There are two ways to do this – transport the charge packet itself to the output or measure the voltage generated by the packet and transmit this to the output. In CCDs, the charge packet is almost always carried to the output using *transport registers*, whether it was generated by the storage well or a separate photodiode. Since there is no good way to transport charge packets off an image sensor chip, it is still necessary to convert the packets to a voltage right at the last step. The conversion is made by a *sampling node*, which is a small capacitor that receives the charge at the end of the transport.

In most CMOS sensors, the charge to voltage conversion is done using a sampling node at each photodiode. The voltages measured there are simply copied thorough various gating structures to the output. This is the source of a major difference in the operation of CCD and CMOS image sensors. Because the CCD has only one sampling node (at the output) this same sampling node is used for every charge packet. This arrangement allows easy access to the sampling node for performing functions other than charge packet readout, including *correlated double sampling* (CDS), which will be discussed later. In contrast, CMOS image sensors have sampling nodes for every photodiode so these are not easily accessible for external use. Separate sampling nodes also raise the possibility that the sampling process can introduce non-uniformity in the image due to slight differences in the sampling node properties. This leads to one component of *fixed pattern noise* (FPN) in CMOS imagers.

Once the charge is converted to voltage, it can be amplified and buffered before leaving the chip. However, CCDs can support only one polarity of MOS transistor, either NMOS or PMOS, depending on the device structure. With only one polarity available, the only amplifier available is a source follower with a gain less than one. The typical CCD has a two-stage follower with a gain in the range of 0.8–0.9. CMOS image sensors can include complementary transistor pairs, which can provide gain of any desired value and essentially any other analogue or digital function possible with CMOS circuitry. This additional flexibility is another major difference between CCD and CMOS imagers.

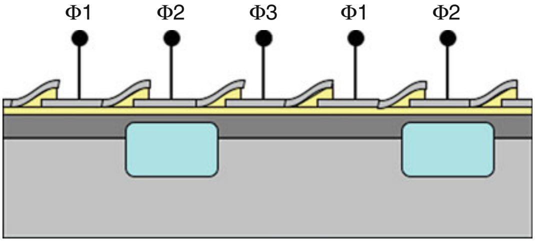
10.2.4 CCD Structures

Although the CCD image sensor is conceptually quite simple, consisting minimally of a set of vertical transfer registers, a horizontal transport register and a readout node, many varieties of these have been developed to meet different requirements. Knowing which variety was chosen for a particular image sensor can provide substantial information about performance characteristics and operating requirements of the sensor if the effects of choosing particular varieties are understood.

10.2.4.1 Transport Registers

The simplest CCD transport register (➔ *Fig. 10.3*) consists sets of three electrodes. A positive voltage, typically in the range of 5–15 V, is applied to electrode set Φ2 to create a series of potential wells. Over time, light arrives and generates electrons that are held in the wells. When the exposure is over, a positive voltage is applied to electrodes Φ3 to create potential wells there and then the voltage over the original Φ2 wells is slowly lowered to force the electrons to move into the Φ3 wells under the influence of the potential difference. The process is then repeated sequentially with so the charge can continue to be moved to the right. The slight electrode overlap assures that the potential wells will connect when the voltage is moved from one electrode to the next.

A register with three sets of electrodes is called a *three-phase* register. This is the simplest register because it has the fewest number of electrodes that can keep adjacent charge packets separated without additional structures in the silicon. In a three-phase register, there must be



■ Fig. 10.3
Simple CCD transport register. Charge packages are moved along the register by a three-phase clock applied to electrodes Φ1–Φ3

two electrodes at zero between charge packets. If there was only one, then when the voltages changed to move the packets, all of the electrodes would be positive at once and the charge packets could merge. It is possible to make a *two-phase* register with alternating on and off electrodes but this requires adding a diffusion at one edge of all of the electrodes at the silicon surface to provide a permanent voltage offset that can steer the charge packets in the right direction. The main problem with three-phase registers is that only one third of the silicon can be used to store charge. The other two thirds only provides space to apply the transport voltages between packets.

The proportion of the silicon used for charge storage can be increased to one half with a *four-phase* register. In this type, two electrodes are energized and the other two are at zero during charge accumulation and then the four electrodes are cycled to move the charge. The electrodes must be closer-spaced than in a three-phase register to maintain the same spacing between charge packets and four controllable voltages are needed rather than three, but the capacity to store charge is increased by 50%.

About half of the silicon space can also be used for charge storage in *virtual-phase* registers. These have only one voltage that is changed, relying on a complex set of diffusions in the silicon to provide fields to keep the charge moving in the right direction. This additional device complexity can add noise and increase dark current. Unlike the other register types, virtual-phase registers do not accommodate transporting charge in the reverse direction.

For all transport registers, *charge transport efficiency* (CTE) is a critical parameter. Each time the charge packet is moved from one cell to the next, some of the charge can be left behind. This smears out the signal as the packets of different sizes start to mix together. While a single shift losing, say, 0.1% of its charge might be acceptable, 1,000 shifts, typical of even small sensors, would deliver only $(0.999)^{1000}$ or 36.7% of the original signal to the output. An 0.01% loss per shift would deliver 90.5%, still generally unacceptable, and an 0.001% loss would deliver 99.0%. 0.001% loss corresponds to 0.99999 of the charge delivered per shift, the so-called "five nines" CTE. This is generally considered the minimum practical efficiency. Typical CCD registers now have between five nines and six nines CTE when operated properly.

10.2.4.2 Light-Sensitive Registers

When potential wells were originally linked to form transport registers for use in bucket-brigade analogue memory devices, the electrodes were made of aluminium just like any other silicon device conductors. After the discovery at Bell Laboratories that potential wells could act as sensitive, noiseless photon detectors, replacing the aluminium with something transparent to visible light became important. Currently, two materials are used. In the vast majority of CCD image sensors, the electrodes are polysilicon, selected for its easy fabrication and high conductivity. Unfortunately, polysilicon *is* silicon and absorbs light itself. This absorption has the biggest impact on the blue end of the spectrum because blue is more strongly absorbed than longer-wavelength light. As a result, early CCD image sensors had deficient blue response.

To improve blue response, sensor designers moved from straight-line electrodes to patterns that included areas free from polysilicon to allow blue light to reach the underlying detector. Some detectors now have electrodes made of indium tin oxide (ITO), which is a transparent conductor. ITO is more resistive than polysilicon so the speed and length of the electrodes is more limited but ITO does allow more blue light through. For very high blue response, *backside thinning* is used, which is discussed in detail below.

10.2.4.3 CCD Pixel Boundaries

In order to have a pixel, it is necessary to create a structure that converts photons to charge and then hold the charge at the place it was detected until the signal can be read out. Pixel boundaries are generally created in two ways. To produce isolated photodiodes all of the photodiode boundaries can be created during the semiconductor fabrication process by diffusing or implanting or depositing materials in the silicon that create electronic barriers to keep adjacent charge packets separated. These barriers are usually wrapped closely around the photodiodes so that charge that is generated in any photodiode remains there. To get signals in and out of the photodiodes requires only provision of aluminium conductors near the surface of the silicon because in a simple array of photodiodes the charge never moves.

In CCDs, however, the charge must move. The pixel boundaries in CCDs where the registers are photosensitive are, therefore, defined in one direction by the voltages applied to the electrodes. In the other direction, the pixel boundaries are formed in the silicon using silicon fabrication processes. Thus, in these CCD types, the boundaries between columns of pixels are permanent but the divisions along the column exist only when power is applied. Even in CCDs that use photodiodes for light detection one of the sides of the photodiode is usually defined by an applied voltage from an electrode not from a semiconductor process step.

10.2.4.4 Sampling Node

When a charge packet arrives at the point where it is to be sent off-chip, it must first be converted to a voltage. The simplest way to do this is to place the charge packet on a capacitor where the simple formula

$$V = \frac{Q}{C}$$

shows that the voltage generated (V) is proportional to the size of the charge packet (Q) for a fixed capacitance (C). If Q is set to be the charge of one electron (1.6×10^{-19} Coulombs) then the equation becomes

$$V = \frac{n_e Q_e}{C} \text{ or, rearranging, } \frac{V}{n_e} = \frac{Q_e}{C}$$

where n_e is the number of electrons in the charge packet. The value of the capacitor determines the *conversion factor* in volts per electron, which sets the output voltage range of the image sensor.

Typical CCDs have a conversion factor in the range of 5–10 microvolts per electron. Higher values than this are very difficult to achieve because the sampling node capacitor must be very small. The limit is often just stray capacitance from other nearby structures. The conversion factor may have to be intentionally set lower in image sensors with high full well capacity to avoid generating voltages larger than the output amplifier can handle.

10.2.5 Common CCD Architectures

Four types currently make up almost all CCD area sensors sold – *full frame* (FF), *frame transfer* (FT), *interline transfer* (IT) and *frame interline transfer* (FIT). Almost all of these are *frontside illuminated*, that is built so that the light enters on the same surface of the device that holds the circuitry, and they are almost all *single-tap*, having only one output point. There are some exceptions and a few additional variations on the structures that will be discussed in detail below. In all of the figures in this section, the light grey areas are sensitive to light and the dark grey areas are covered with aluminium. The arrows show the direction of charge motion when the electrodes are operating.

10.2.5.1 Full Frame Architecture

The Full Frame CCD image sensor (➔ *Fig. 10.4*) is the simplest type. It consists of a set of photosensitive registers arranged next to each other in columns with a transport register at the bottom configured so that each well can receive charge from a different column. In a typical operating cycle, light is prevented from reaching the sensor by a shutter and then the charge is cleared from the photosensitive registers while the image sensor is in the dark. The shutter is opened for the desired exposure interval and then closed. In the dark, the charge in all of the columns is shifted down by one row so that the last row moves into the horizontal transport register. A faster clock then moves the charge packets in the horizontal transport register to the sampling node to generate the output voltage. When the row is complete, the next row is moved down for readout. This process is repeated until all rows have been read. The sensor is the ready for another exposure.

FF Advantages

Of all front-illuminated CCD sensor types, the FF type has the largest percentage of the silicon area sensitive to light. The only truly insensitive parts are the diffusions in the silicon that define the boundaries between the columns. The vertical registers generally have three or four phase electrode sets and the horizontal register is often a special form of two phase electrode set that is designed to always move the charge packets in the correct direction. The waveforms used to drive FF sensors are simple – a set of phase drivers for vertical transport and a second set of drivers for horizontal transport, usually connected together and run from a single master clock. Since the vertical transport is always allowed more time that the interval required to read out

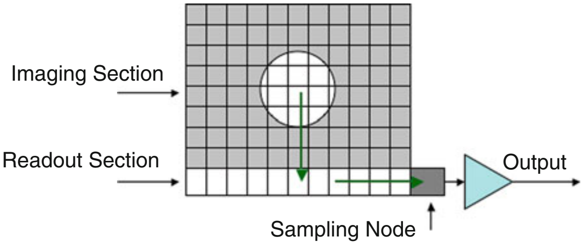


Fig. 10.4
Full-frame CCD image sensor

a row, the vertical electrodes can be designed to allow the maximum amount of light to pass and for maximum charge transfer efficiency even with large charge packets without regard for speed. This simple, slow structure has resulted in adoption of the FF architecture for design of most high-performance scientific devices.

Higher speed can be obtained in FF devices by providing more than one output from the horizontal transport register. The register is simply split into segments – 2, 4, 8 or more – so that these can be read out simultaneously. This reduces the line output time and, therefore, the time to read out a complete frame. In two-output devices, the horizontal registers may be arranged so that half of the image comes out on opposite corners or half comes out on one corner and half in the centre. The opposite-corner scheme is easier to fabricate but causes half to the image to be reversed.

Alternatively, the device can be split horizontally in the centre and read out through both top and bottom horizontal registers. This has the advantage of reducing the number of vertical shifts required but results in half of the image emerging upside down. In devices require very high speed, both vertical and horizontal segmentation may be applied. All segmentation imposes the requirement to provide separate readout electronics for each output.

FF Limitations

The defining requirement for implementing FF sensors is that they must be read out in the dark. Because the pixels remain light-sensitive while entire image is shifted vertically during readout, any illumination falling on the sensor will generate vertical stripes. More rapid vertical shifting can reduce the amount of this striping but cannot eliminate it entirely. Since each line must be completely read out before another vertical shift can occur, faster vertical transfer requires similar increases in horizontal readout rates.

The striping can be different above and below any bright points in the image because the stripe will be generated above the points for exposure during the current readout interval and below the points for exposure during the previous readout interval. This leads slanted stripes with breaks at the bright points when horizontal motion is present. If the pixels can all be reset at the end of each scan, then stripes will appear only above the bright points.

FF sensors can also suffer from vertical stripes that result from light overloads. The boundaries between pixels are defined only by barriers produced by applied voltages. Large exposures can generate enough charge to raise the pixel voltage above the barrier, allowing charge to spill into pixels above and below the overloaded area. In extreme cases, entire columns of pixels can be affected. To avoid this, some sensors are provided with *antiblooming* structures adjacent to each of the columns to drain off excess charge, thereby preventing the pixel voltage from rising above the barrier level. Because any light that falls on the antiblooming structures generates charge that is lost, the *fill factor* of sensors with these structures is reduced.

FF Applications

Full-frame sensors can be used wherever readout in the dark is practical. In most scientific imaging applications, the light can be easily controlled so FF sensors work well. Because FF imagers can be easily made with large pixels and low-noise readout amplifiers and because they are very compatible with cooling and backside illumination, they are very widely used in high-performance scientific cameras. Since scientific devices tend to need large numbers of large pixels and to support both high dynamic range and high resolution, the simple structure of FF sensors maximizes silicon utilization and minimizes fabrication complexity. FF sensors with active areas almost as large as an entire silicon wafer have been fabricated for scientific use.

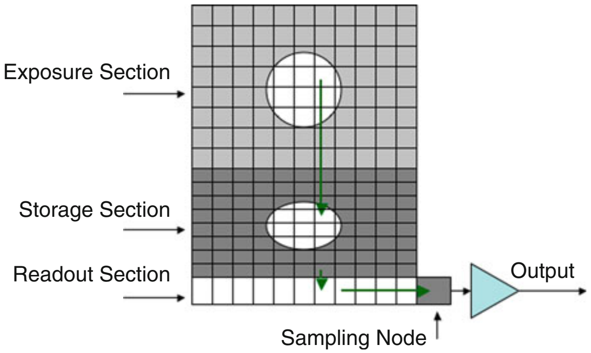
Almost all CCDs used in digital cameras for photography are the FF type because of the high utilization of silicon area and because this type of camera has a shutter to permit readout in the dark. However, FF sensors are not suitable for use in video cameras because the striping would be severe. Striping also prevents use of FF sensors in industrial applications except perhaps where the illumination is pulsed and the stray illumination is very low.

10.2.5.2 Frame Transfer Architecture

The Frame Transfer (FT) architecture (➋ *Fig. 10.5*) was developed as the first CCD type suitable for continuous (video) imaging. In an FT sensor, the exposure and readout functions of the sensor are physically separated with the exposure section built essentially identical the an FF sensor and a storage section almost a copy of the exposure section but covered with an opaque layer (usually aluminium) as shown in ➋ *Fig. 10.5*. In an FT sensor, the exposure and readout can occur almost simultaneously because while the exposure section collects light for a new image, the previous image, held in the storage section, is shifted out.

The FT sensor is slightly more complicated to operate that an FF sensor because the exposure and storage section need separate shift drivers. In a typical cycle for a simple 30 frame-per-second *progressive scan* video camera, the exposure section is collecting light and the charge is not moving while the previous information in the storage section is shifting down to the readout section line by line. After the shifting is complete, the two sections are connected to the same clocks and the entire image is quickly moved down from the exposure section to the storage section. The line shift rate during the transfer is typically several hundred times faster than the readout line shifting rate. Since the charge pattern moves down very rapidly, the vertical striping is reduced relative to the FF striping. After the shift, the scanning is disconnected from the exposure section and the readout resumes at a slower shift rate.

Generally, the CCD cells in the storage section are smaller than the pixels in the exposure section because there is no need to efficiently collect light, no need to provide a square matrix and no need to provide anti-blooming protection. A few extra rows are usually added at the top



■ Fig. 10.5
Frame Transfer (FT) architecture. Data relating to the previous image is shifted out while the imaging section collects light for the next one

of the storage section and covered with the opaque layer to provide a buffer between the edge of the light-collecting pixels and the storage cells. This prevents stray light from getting into the first few rows of the storage area that contain image data where it can generate spurious charge that can produce white background patches in the image.

FT Advantages

FT sensors can accommodate an additional type of antiblooming structure. Anti-blooming structures similar to those in FF sensor can be implemented for good results, however, the separation between exposure and storage sections also allows incorporation of antiblooming structures placed beneath the sensor array, so-called vertical antiblooming (VAB). Because the VAB structure is placed beneath the CCD structure rather than next to it the fill factor is not affected. However, VAB must be implemented carefully or it can introduce non-uniformity in the image and non-linearity in the sensor light response curve.

With a reverse charge dump, FT sensors can approximate simultaneous *electronic shuttering*, the electronic equivalent of a mechanical shutter. The reverse charge dump is a single long channel placed at the top of the exposure area into which charge can be transferred when the lines in the exposure section are shifted up instead of down. Charge moving into the dump is simply carried away and disposed of. If the Exposure array is shifted up rapidly, then any charge generated by illumination is quickly removed. Then, when an exposure is ready to be started, the shifting is stopped. During the reverse shifting, the time for accumulation of charge is longest in the row just about to be dumped so there is some non-uniformity in the background when the exposure starts. This prevents the shuttering from being perfect. Unfortunately, the line at the top of the exposure section that had the longest exposure during the dump process is also the last line to be moved under the opaque layer in the storage section. This effect can be minimized by designing sensors that can scan extremely rapidly in the reverse direction when, fortunately, preservation of image data quality of no importance. The reverse scan frequency in a sensor designed for this operation is typically around 5 MHz. For a sensor with 1,024 lines, this produces a total delay from the top to the bottom of the picture of about 200 μs.

FT Limitations

While the vertical striping is generally manageable, it can still be seen when very bright objects are in the image. With a 30 Hz frame rate and a 1 MHz vertical transfer frequency, a 1k × 1k sensor will have a ratio of frame exposure time to vertical transport time of about 30:1. With a bright spot 10% of the raster height that produces a signal just at saturation for the normal exposure, the vertical striping signal will be about 1/300 of full scale or slightly less than one LSB in an 8-bit system. Smaller or dimmer spots can be regarded as insignificant in most cases but larger or brighter spots will almost always produce visible and measurable artefacts. Vertical striping is worse in high frame rate FT sensors because the ratio of the frame readout time to the vertical transfer time is lower. Vertical striping can be eliminated by the use of a shutter that blocks the light during vertical transport. Synchronized rotating shutters were common when FT devices were used for many years in broadcast television cameras.

With the addition of the storage area, the FT sensors are less space-efficient than FF sensors. Backside illumination is more problematic because light must be prevented from striking the back of the storage section.

FT Applications

Frame transfer sensors are used where high fill factor is needed in situations where the light is on all the time. (Fill factor is the ratio of the area of regions capable of collecting light to the total area of the camera's "retina".) FT sensors offer some additional flexibility in camera design because the exposure and readout functions are disconnected in time. This is especially useful in long-exposure applications where reverse scanning can provide an approximately simultaneous start to an exposure and vertical transport can provide a similar termination. In such situations, the readout timing of the signal from the storage area can be optimized for data quality since it is independent of the exposure timing.

FT sensors are also useful in partial scanning situations. If only a subset of the lines contain useful data, then after vertical transport, the vertical shifting can continue at the high rate until the first useful line is reached, then slowed to the normal readout speed to capture the useful lines. After the last useful line is read, the remaining lines can be left in place to be transported out at the beginning of the next image. To support rapid vertical transport of lines without readout shifting, the readout section be designed to quickly dump the charge from the arriving lines. Failure to provide this capability will result in filling the wells and halting further transport of charge.

Because FT sensors generally have fill factors approaching 100%, they generate a minimum of aliasing. This makes them useful in viewing objects with highly structured surfaces where providing optical filtering is not practical. The aliasing is also comparable in the horizontal and vertical directions so object orientation is not critical.

FT sensors are relatively easy to bin. (Binning is a procedure in which several pixels are grouped into a function unit) Some sensors support vertical binning by providing access to the vertical transport phases in a way that allows double-height pixels to be defined and transported. Some sensors have even supported 1.5-height pixels. Alternatively, two rows can be transported into the readout register before they are shifted out. Many sensors include registers with storage capacity sufficient to allow this. Similarly, horizontal binning can be implemented by shifting two (or more) pixels into the readout node before sampling.

Finally, producing interlaced images with FT sensor only requires selecting phase lines that define the top and bottom of the pixels in alternate fields. Some sensors will actually only produce full vertical resolution in an interlaced mode. In these, the pixel areas overlap between fields so vertical resolution (and aliasing) are reduced.

10.2.5.3 Interline Transfer Architecture

In Interline Transfer sensors, the exposure and storage sections are alternated column by column in the same area of the silicon as shown in ➲ *Fig. 10.6*. Each column of photosensitive elements has next to it a vertical transfer register covered with aluminium. The group of transfer registers makes up the storage area. Light is collected in the photoelements, which may be CCD wells or photodiodes, and then the accumulated charge is moved from all photoelements simultaneously into the neighbouring transfer registers. After this move, the charge is shifted vertically, one line at a time, into the output register for readout. For faster operation, IT devices can incorporate multiple taps and can support split vertical scanning

Many variations on this basic arrangement exist, each with its own characteristics. Although the photoelements appear to be in columns as in FT sensors, the photoelements in IT sensors are not connected together vertically because there is no need to shift vertically in the

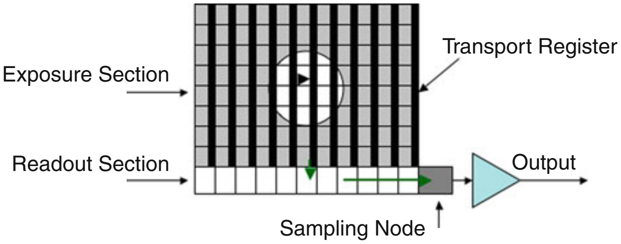


Fig. 10.6
Interline transfer sensor

photosensitive areas. Fundamentally, the photoelement can be either a CCD well or a photodiode. Typically, the CCD well has lower noise because it does not have to be reset but the photodiode has higher quantum efficiency because it does not require phase lines on its input surface. The large variety of configurations for photoelements now available has blurred the lines significantly so when the details of operation are important, thorough investigation of the actual configuration in candidate sensors may be required.

Transferring the charge from the elements to the transport registers may occur at a specified time or continuously until the time to scan has arrived. There may be some advantage to continuous transfer because the possibility of leaving some charge behind is reduced and because continuous transfer may allow the use of *pinned* photodiodes, which can have lower noise because they do not need to be reset [1].

IT Advantages

IT sensors also offer the possibility of electronic exposure control. If the photoelements are equipped so that all of them in the sensor can be simultaneously reset upon application of an external signal, then this signal can be used to define the beginning of an exposure. Since the end of the exposure is defined by end of the time that the charge is transferred to the transport register, the duration of the exposure is set by the difference between these two times. If the scanning is periodic, then the end of the transfer time will be periodic and fixed at a particular point in the exposure-readout cycle. This means that although the duration of the exposure can be varied, the position of the exposure in the cycle cannot. As a result, if the exposure must be synchronized with an external event, it is necessary to time the entire cycle to this event by operating in an *external trigger* mode in which entire images can be produced on demand.

Because the photoelements are all isolated vertically from one another, the possibility of blooming along the photoelement columns is essentially eliminated. Antiblooming drains can be added between each column of photoelements and the transfer register for the column to the left as part of the isolation structure required between them. When the photoelements are isolated on all sides like this, blooming can be kept under very tight control.

Closely-spaced exposure pairs may be taken with IT imagers. Assuming that the vertical registers are cleared, one exposure is taken in the normal way so that the charge ends up stored in the registers. As soon as the transfer to the registers is complete, another image may be taken. This is held in the photodiodes until the readout of the first image is complete. The second image can then be shifted to the registers and read out. With typical transfer times, the two images can be acquired only a few hundred microseconds apart. This process only works correctly with strobed illumination, otherwise the accumulation of light in the photodiodes will cause the second image to be exposed for a time equal to the difference between the length of the first exposure and the total readout time. The first exposure must occur just before the transfer for the images to be spaced closely in time. Of course, the minimum interval between acquisitions of pairs of these images is two complete readout periods.

In the CCD universe, IT sensors offer the most compact arrangement of functions; only CMOS imagers can offer more complexity in a similarly small space.

IT Limitations

Like FT sensors, IT sensors suffer from vertical striping but the cause is slightly different. Because there is no direct illumination of the vertical transport register where the charge is shifted, it would seem that there should be no striping. Unfortunately, the close proximity of the photoelements to the transport registers allows some light to sneak under the opaque aluminium layer. The amount is generally small, but the shifting proceeds slowly so there is ample time for the stray light to produce a signal. In a typical IT sensor, the vertical shifting takes exactly one frame to be completed. This means that the integration time for the stray light is essentially equal to the integration time for the photodiodes acquiring the desired image. Thus, even if the leakage is only 1%, the signal produced in the transport registers by an area just at saturation will be larger than one LSB in an eight-bit system. Oversaturated points can produce much larger stray signals. Confusing matters is the problem that the stray light is acquired from the frame that will be produced after the frame currently in the transport registers. Thus, fast-moving bright objects can cause vertical striping away from the positions where they appear in the real image. This problem is exacerbated by lenses with their last element very close to the sensor because the proportion of light rays arriving at the sensor at low angles – exactly the rays that get under the aluminium – is increased.

A substantial portion of the surface area of IT sensors is taken up with the vertical transport registers resulting in low fill factor and proportionally reduced net quantum efficiency [2]. In sensors with very small pixel geometry, the fill factor can be below 50%. The need to squeeze both the photoelements and the transport registers into a compact area also restricts the well capacity to 50% or less of the capacity of FT sensors with similar pixel spacing imposing a limit on dynamic range.

Because IT imagers typically incorporate junction photodiodes rather than charge wells for detection of incoming light, it is possible for some small amount of this charge to be left behind during the shift to the vertical transport register. This will show up as image retention or lag if observed frame-to-frame. Lag can be eliminated if the photodiodes are reset after each exposure or if pinned photodiodes are used.

IT Applications

IT sensors are very widely used in applications from machine vision and security to camcorders and medical systems due primarily to their small size and electronic shuttering capability. Their widespread use has led to the development of single-chip timing and scan generators to simplify camera design and minimize camera size and cost.

Many special-purpose IT sensors have been designed. IT sensors with photoelements of the UV-sensitive photodiode type are used to image masks and wafers with the same ultraviolet sources used in wafer production. With the non-photosensitive parts of the sensor protected by aluminium, these sensors are relatively immune to damage from UV photons.

Interesting hybrid sensors have been made in which the normal location of the photoelement is replaced by an isolated contact and a separate photosensitive layer is deposited over the entire sensor surface. This provides 100% fill factor and, with appropriate top layers, even infrared or ultraviolet sensitivity. Such devices are not common but the adaptability of the IT architecture continues to support many research efforts.

10.2.5.4 Frame Interline Transfer Architecture

The Frame Interline Transfer (FIT) architecture (➔ *Fig. 10.7*) was developed to provide both very low vertical striping and electronic exposure control. Striping in FT sensors, which have no exposure control, can be reduced only so far as the image can be moved rapidly from the imaging section to the storage section while IT sensors, which do have exposure control, have more striping as the exposure time is reduced. The FIT sensor is a combination of IT and FT in which the exposure section of an FT sensor is replaced by an IT sensor array. After the exposure, the charge can be shifted to the vertical transfer registers under the aluminium shields as in an IT device, but is then immediately shifted at high speed into an FT storage array below. As a result, the time available for accumulation of unwanted charge from light leaking under the shields is reduced to typically less than 1 ms with any exposure setting. The striping is thus reduced by both the effect of the shields and the rapid transfer out of the exposure section.

FIT Advantages

The FIT has an IT imaging section so the advantages of the IT sensor carry over such as low blooming, parallel reset and flexibility in designing the photodiodes.

The exposure in an FIT can end at any time, not just before the transfer to the storage section starts, because the image can be held under the shields until the FT storage section is ready for another image. However, as the image is held longer in the IT section, the time available for light to cause vertical striping increases. In the extreme case, with a short exposure at the beginning of the imaging cycle, the striping will be essentially identical to the striping of an IT device with the same exposure.

Closely-spaced exposure pairs with low striping may be taken with FIT imagers. Assuming that the storage section is cleared, one exposure is taken in the normal way so that the charge ends up stored in the storage section. As soon as the shift to storage is complete, another image

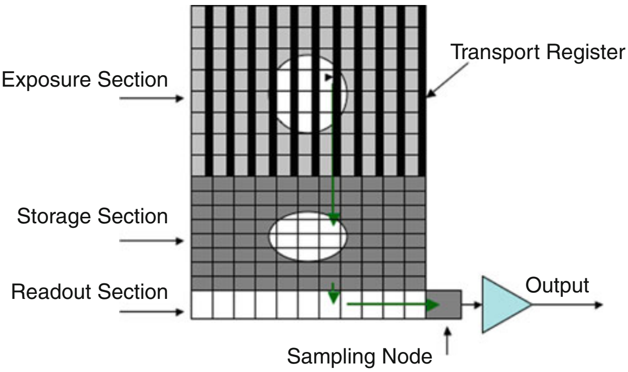

Fig. 10.7
Frame Interline Transfer (FIT) sensor

may be taken. This is the stored under the shields and held until the readout of the storage section is complete. The second image can then be shifted to storage and read out. With typical vertical transfer times, the two images can be acquired only a few hundred microseconds apart. If the illumination is strobed, the image can be closer. Of course, the minimum interval between acquisitions of pairs of these images is two complete readout periods.

FIT imagers can also take exposure triplets using pulsed illumination. When the exposure pair is complete a third exposure can be taken and held in the photodiodes until the first two images are read out. Images two and three can be more closely spaced than images one and two because the wait for the vertical shift does not apply. Readout of complete triplets takes three readout periods.

FIT Limitations

Because the FIT sensor has both FT and IT sections, it is at least as large as the equivalent FT sensor and 1.5–2 times as large as the equivalent IT sensor. In addition, it has the same fill factor restrictions as an IT sensor. FIT sensors cannot be charge binned in the imaging section like FT sensors because the imaging section is of the IT type. However, binning by holding the charge for more than one vertical shift into the output register remains possible.

FIT Applications

FIT imagers are used almost exclusively in professional television, where a rotating shutter is added to block the light during the brief transfer time so the striping is truly reduced to zero. The last bit of improved resistance to vertical striping provided by FIT sensors is generally not worth the extra cost in applications where the lighting can be controlled. The major exception is in microscope imaging using EMCCD sensors (see ➋ section "CCDs with Gain" below), where very bright objects must sometimes be tolerated in images which are otherwise very faint. Any application requiring strong stray light rejection might benefit from the use of FIT imagers.

10.2.6 Special CCD Architectures

The four main CCD architectures share many common features arranged in different ways for different advantages. Typically, these result in rectangular arrays of pixels with image data coming out in one corner. However, by modifying these simple arrangements and applying a few additional electronic features, the performance of CCD sensor can be expanded in several ways.

10.2.6.1 Multiple Outputs

Often, the speed of the sensor is limited by the maximum allowable clock rate of the horizontal transport register, typically around 30 MHz but often lower and occasionally higher. To get around this limitation, multiple transport registers may be used in conjunction with multiple output amplifiers. Several configurations have been implemented:

- Left-Right (2× speed increase) – The sensor is divided vertically so that the left half of the area is read out to the left and the right half is read out to the right through a transport register that lies along the bottom of the sensor. This is relatively simple to design but results in half of the pixel data coming out backwards with respect to the other half. The order of the lines is unaffected. This configuration can easily be applied to any of the architectures.

- Top-Bottom (2×) – The sensor is split into top and bottom halves, each with its own full-length transport register. The top and bottom line order is reversed but the pixel order can be the same for both halves. This configuration is easy to apply to FF imagers more difficult with IT imagers and much more difficult with FT and FIT imagers because the storage area must be split, half on the top and half on the bottom.
- Quadrant (4×) – The sensor is split both horizontally and vertically with readouts at all four corners. The data order comes out in all four possible combinations. Design is similar in complexity to the Top-Bottom configuration.
- Multi-Tap (nx) – The sensor is split vertically into several (n) stripes and each stripe has its own output. This scheme is only rarely used because designing transport registers that nearly touch on the ends, provide paths for the signals in the centre stripes to get out and provide high CTE is quite difficult. Generally, this configuration can only be applied if the pixel spacing is relatively large. The line order is undisturbed and all pixel data comes out in the same order.
- Sub-Sampled (4×) – In sensors with 2 × 2 colour filter arrays, the charge may be routed to separate outputs for each of the four array quadrants. This requires some complexity in the transport area because the four signals must somehow be separated using only charge transfer. This configuration is more likely to be found in CMOS sensors where implementation is easier.
- Column Readout (c×) – Each column (c) is fitted with its own readout amplifier. No transport register at all is used at the output. Due to practical limitation on the number of pins available on CCD packages and the power dissipated by large numbers of amplifiers, this configuration can be applied only to relatively small sensors.

Top-bottom splitting could also be applied to any of the last three configurations.

All tapped sensors share the problem of multiple output amplifiers that are not quite alike. Typically, the camera must include compensation for mismatch of both gain and offset between output channels to avoid striping in the final image.

10.2.6.2 CCDs with Gain

Ionization is an atomic process in which an incoming particle provides enough energy to an orbiting electron to free it. In semiconductor devices, freeing an electron means promoting it from the valence band to the conduction band. The energy to do this can be provided by an electron that has been accelerated through a large enough voltage so that it can strike a valence electron and promote it to the conduction band. The minimum energy for ionization in silicon is 1.18 eV. This sets the minimum electric field required to add that much energy to a conduction electron before it collides with another electron. The required field can be provided in a typical CCD transport register by raising the phase voltages used to move the charge to about 40 V.

Because there are other ways for electrons to lose the imparted energy, only about 1% of the electrons that move through a transport register stage ionize additional electrons but those that are ionized join the charge packet being shifted. This means that if 1,000 electrons enter the stage, about 1,010 electrons leave it. By using multiple stages as in a typical transport register, the number of electrons can be substantially multiplied. One electron will produce 1.01 electrons on average because ionization is a statistical process.

With 1% gain per stage, a gain of 2 requires 70 stages so a gain of 100 requires 463 stages and a gain of 1,000 requires about 700 stages. These are well within the constraints of designing and constructing transport registers. Fortunately, the multiplication process in silicon is nearly noise-free so adding a gain of 1,000 through impact ionization is feasible.

The result of adding the multiplication structure is that the sensitivity of a CCD can be increased by 1,000 with essentially no added noise with only the cost of adding a single 40-volt transport register. With this structure, a CCD can perform in low light levels as well as a sensor coupled to a traditional image intensifier while providing certain advantages.

- Since the intensifier can be eliminated, so can the fibre optic coupling, the high voltage, the image degradation and the attendant size, weight, distortion, noise and magnetic susceptibility.
- The sensor can be run with the multiplication function turned off. In this mode, it will produce the same image quality as it would if the register were not present at all.
- Because the quantum efficiency of silicon is higher than the quantum efficiency of photocathodes, the noise statistics of the incoming image photons are better.
- Silicon responds over a wider spectral region than photocathodes, including the near infrared.
- All of the normal surface treatments, such as colour filter arrays and microlenses can be applied to CCDs with multiplication registers.
- Since charge packets from all of the pixels go through the same register, there is no fixed pattern noise added in multiplication.

Of course, there is some added complexity to the design of the register. Consider, for instance, what happens if the charge packet entering the register is almost large enough to fill it. Some provision must be made to allow the size of this packet to be kept small enough to exceed the charge transport capacity. This is not a problem in normal CCDs. Special design is required to avoid high dark current at the high applied voltages. Many similar problems had to be addressed to make these sensors practical. These have been solved so the sensors are now readily available although they remain comparatively expensive.

The two most common applications for these sensors are night vision and fluorescence imaging in microscopes. They are useful wherever very low light levels are encountered.

10.2.6.3 Backside Illumination

CCDs of all architectures suffer in sensitivity because substantial parts of their areas are either taken up with non-photosensitive structures like transport registers or covered over with light-absorbing materials like polysilicon. To get around this problem, it is possible to illuminate the sensor from the back side, which has no structures. If a standard CCD is flipped over and backside illuminated only the near-infrared can be detected and the images will be fuzzy because most of the light is absorbed by the thick silicon and electron-hole pairs are generated far from the light-sensitive registers. The long distances allow most of the charge to recombine and much of the rest to spread laterally. Overcoming this requires thinning the silicon until it is thick enough to hold together but thin enough to permits capture of the charge in the right locations. This is a tedious process still only performed by a few facilities, mostly for high-performance astronomy applications. Carefully done, backside thinning can produce sensors with 90% peak quantum efficiency and spectral response from the near ultraviolet through the visible.

Aside from being very expensive, backside thinning has other limitations. The most important is that in backside illuminated sensors there is no way to block light from reaching all of the sensor structures. In IT sensors for instance, light must be prevented from reaching the vertical transport registers. Since this is not possible, IT sensors are not suitable for backside imaging. Even if the charge could be cleared from the registers, it would just be thrown away, essentially lowering the fill factor. Some other sensors do not work properly with backside illumination. Sensors with vertical antiblooming will have very low sensitivity because most of the charge will be generated and dumped in the anti-blooming layer. Essentially all backside illuminated devices are FF types without antiblooming. They are intended to be used in applications like astronomy where every photon counts. It is fortunate that the frame rates in astronomy are low because thinning devices increases the substrate resistance to the point where they cannot be scanned very fast.

10.2.6.4 Cooling

The dark current of CCD sensors may be reduced by cooling. The inverse of this is that the dark current of CCD sensors is raised by heating. Typically, the dark current will double for every 8°C rise in temperature. Sensor data sheets generally show the dark current at 25°C (although some show slightly lower temperatures – watch for this) but the temperatures inside cameras are generally warmer than this. The typical rise is about 20°C so the dark current even with a camera in room temperature ambient is already likely 45°C. That is the dark current is already nearly six times higher than the data sheet says. As an example, let us assume that the data sheet dark current is 50 pA/cm^2. In a 1k × 1k 10 μm pitch sensor, this is equivalent to accumulation of about 10 electrons/frame/pixel at 30 fps. In a real camera we multiply this by 6 for the rise from ambient and another 13 to account for the maximum 55°C maximum operating temperature. This results in a dark signal of 780 electrons. While this may not seem like much compared to well capacity, it carries with it a standard deviation of 28 electrons, which is likely larger than the sensor noise. As a result, the dynamic range of the camera may be limited by the noise in its dark current. In addition, non-uniformity in the dark current may mask subtle brightness variations in the image and “hot” pixels (those with unusually high dark current) could become a problem at these temperatures. Cooling, or just control of the temperature, can help these problems.

Note that cooling has little direct effect on the sensor noise. The sensor noise is roughly proportional to the square root of the absolute temperature. A 30°C change in temperature is also a change of 30 Kelvins, perhaps from 273 to 303 K. The increase in the sensor noise in this circumstance is only 5% while the dark current noise increases by 780% and becomes dominant.

10.2.7 CCDs for Line Scanning

Most imaging involves viewing of individual objects or of scenes. For these tasks, area imagers are suitable. However, when the object to be viewed is larger than an area camera can view in one shot at the necessary resolution or when the object to be viewed is in continuous linear motion, line scanning may be more appropriate. Line scanners sample the viewed object in only one dimension, relying on motion of the object to provide samples in the orthogonal direction. Traditionally, the direction along the sensor is "horizontal" and the orthogonal direction is "vertical", probably because of the usual direction of scan lines on displays. Oddly, in many actual inspection setups, it seems more natural to have the object move from left to right on the display because this mimics standing at the side of the object as it moves rather than on a catwalk above it. For this reason, "horizontal" and "vertical" are often replaced by "cross" and "down" respectively in referring to line scan directions.

While linescan sensors are simpler than area image sensors in some ways, certain features used only in linescan sensors merit special consideration.

10.2.7.1 One-Line Sensors

CCD linescan sensors are essentially one line of an FT image sensor consisting of a single row of wells isolated from each other by diffusion and connected by a charge transfer register from a readout register. The simplest current linescan sensors are built exactly this way. In operation, the wells are isolated from the readout register by a voltage (actually a negative voltage if the charge is electrons) to a transfer gate between them to trap the charge in the well during an exposure. When the exposure is over the barrier voltage is removed (and, perhaps, the well voltage is raised) to allow the stored charge to flow into the readout register. After the transfer, the barrier is raised again so the next exposure can start while the charge in the transport register is read out, just as in any CCD image sensor.

Variations abound. Because there is only one row there is no need for vertical charge transport, except to the readout register. As a result, the exposed area can actually be a true photodiode instead of a potential well without any fill factor penalty. This permits the photosensitive area to be tailored to the requirements for different applications. For instance,

- In spectroscopic sensors, the photodiodes can be long and thin to match a spectrometer slit.
- In ultraviolet applications like mask inspection, the diode can be optimized for UV response and protected from UV damage
- When high linearity or very low lag are required, the photodiode can be pinned
- Diodes that collect holes rather than electrons can be made so that the signal polarity can be reversed

The readout registers can be modified as well. As in the area imagers, the registers can be split left-right, top-bottom and into segments. In addition, the registers can be arranged so that one of the top of the sensor reads even pixels and one on the bottom reads odd pixels. This has the advantage of relaxing the design rules on the readout registers to make very high speed readout operation simpler while retaining high charge transfer efficiency. As with areas sensors the gain and offset of the various readout amplifiers on linescan sensors may need compensation. This is especially critical in the even-odd readout schemes because offset errors produce every-other-pixel patterns in images that can be hard to eliminate.

For very high line rates in short bursts, linescan sensors can be provided with a storage area essentially identical to those in area imagers. These permit the transfer of many lines of charge from the photodiodes at speeds much faster than the readout register can handle. The limit, of course, is the number of storage lines provided because at some point, the acquisition process has to be stopped to allow the storage area to be emptied. With some careful masking and adjustments in scan timing, the last line of many area imagers can be used in this way, too.

Access to both sides of the photodiodes allows other functions to be applied that are more difficult, if not impossible in area sensors. For instance, very robust, fully-adjustable anti-blooming can be provided because the anti-blooming voltage can be completely separated from the readout functions. Additionally, adding anti-blooming structures does not reduce fill factor because they can be positioned outside the photosensitive area. Structures to insert known charge packets can also be provided either at the end of the line or along the whole row to provide calibration data for CTE and non-uniformity.

One problem can arise in the design of linescan sensors that is rare in area sensors. Because the height of the photodiodes is essentially unconstrained, there can be a temptation to make them as large as possible and then compensate optically to improve the sensor dynamic range. Up to a point, this works, but two problems can occur if the photodiodes are too long. The first is excess lag. Since all of the diode charge has to move to the readout register while the transfer voltage is lowered, the charge farthest from the transfer gate may not have time to move all the way. This leftover charge will make of part of the next image. The second problem is the limited capacity of readout registers. Even with all of the design tricks applied, the maximum capacity of CCD transport registers is about 750,000 electrons. Beyond that, increasing amounts of charge will be left behind at each transfer, leading to poor CTE. Building diodes that can accumulate more charge than this is easy so any proposed sensor design including large diodes needs to be checked for potential excessive charge packet problems. This is why spectroscopic sensors that require very large charge storage capacity do not use transport registers for readout.

10.2.7.2 Time Delay and Integration

One limit to the usefulness of linescan sensors is their very short exposure times. Even though the exposure time can approach 100% of the total cycle time for acquiring and reading a line, the high line rates still lead to short exposures. With a 40 kHz line rate, common is sensors now, the maximum exposure time is only 25 µs. This leads to the need for very intense lighting – so bright that in some high-speed systems, the motion of the material cannot be stopped while the illumination is on due to the danger of starting a fire. As the need for speed increases, another technique can be applied, subject to certain very important restrictions, to increase the exposure time. This is time delay and integration – TDI.

If the image of a linearly moving object like a conveyor belt is viewed by an FT CCD image sensor, then the result is an image in which all of the points on the conveyer that pass a particular point on the sensor are added together. In other words, the image is smeared vertically. However, if the motion of the conveyer is aligned accurately with the vertical axis of the sensor, then the image will not be smeared horizontally. If the conveyor had a series of stripes aligned in its long direction, then an image of the moving conveyor would look just like an image of the conveyer if it were stopped. This is because the stripes are always aligned with the pixels on the sensor.

If the stripes are across the conveyor, then they will be smeared because they traverse the pixels. In theory, the camera could be moved with the conveyer to keep each point on the conveyer aligned with a particular row of pixels. That would be mechanically inconvenient and it would cut the conveyor image into a series of stills rather than generating one continuous image like a linescan camera.

Fortunately, in CCD imagers the normal scanning process requires that the charge be moved in a vertical direction during readout. Normally, this is done as fast as possible to avoid smearing the usual static scene. If the charge motion is slowed to match the speed of the image of the conveyor, then each point on the conveyer stays aligned with the charge it creates on the sensor as this charge is moved row by row down the sensor. To maintain the alignment, the charge can be moved instead of the camera. In this mode, the charge has the entire time the point traverses the sensor to accumulate. The exposure time is thus lengthened. The process of moving the charge is called time delay and integration because there is a delay between the time an object enters the field of view of the camera and the time it leaves that is exactly equal to the resulting integration time. With a sensor having 100 lines, the exposure time with a 40 kHz line rate would be 2.5 ms, providing substantial relief in the lighting brightness requirements.

It is worth noting that TDI was first applied in surveillance aircraft by pulling wide film across a slit parallel with the aircraft motion. Silicon TDI sensors were first developed as an electronic replacement for the film.

Requirements for TDI

TDI sounds simple enough but there are a number of important constraints that must be recognized if high-quality images are to be produced, mostly relating to keeping the object and the charge aligned.

- Use high-quality optics – Distortion in the optics will cause the image to wander as it traverses the field of view and wandering means blurring. Non-uniform MTF will cause non-uniformities in blurring from centre to edge.
- Assure accurate optical alignment – The image sensor must be parallel to the object and the lens optical axis must be perpendicular to both of these. Deviations result in variations in magnification across the field of view.
- Keep travel parallel – The rows on the sensor must be at right angles to the travel of the object. The rapid onset of smearing when the travel is misaligned can be used as a tool to align the camera accurately. Keep in mind that lenses invert the image when deciding which way to mount the camera.
- Hold a constant distance – The distance from the object to the camera must remain constant. Changes in distance imply changes in magnification so if the distance changes and the conveyor speed is constant, the charge motion will no longer match the conveyer image motion.
- Maintain synchronization – Assuming perfect alignment, correct synchronization between the object and the charge must be maintained. The details of various methods to achieve this are discussed below.
- Avoid vibration – Vibration of any sort will smear the image. There is no equivalent to strobing with TDI so the camera must remain very stable relative to the object at all times.

There are some variations that do not affect the image as they would with either area or single-line scanning. For instance, the illumination in a TDI system does not have to be uniform over the entire field of view. The signal from the camera is essentially an average of the illumination levels and so the output signal is always the same because each sum of lines sees the same total illumination. In addition, the extreme alignment requirements for light sources with line scan cameras are substantially eased. Whereas in line scan installations only a few percent of the light is typically in the right place for imaging, TDI illumination is area illumination and can be well over 50% utilized. However, uniformity across the field of view is still required because the averaging works only in the direction of travel.

Even stray objects between the camera and the object have a reduced effect as long as their motion is not synchronized with TDI scan. The switch from film to electronic imaging in the surveillance aircraft was driven by this fact. Non-uniform objects in the image path (clouds for instance) produce a non-removable imprint on static images, but in TDI images the effect of the clouds is smeared out and the contrast of the final image is improved. This works on film as well as in electronic imagers, but removing the bright offset from the clouds in the images is much easier in the electronic domain. The improvement in signal-to-noise ratio is proportional to the square root of the number of lines in the TDI sensor.

Synchronization Methods

Somehow, the motion of the image generated at the focal plane and the motion of the charge on the sensor must be kept moving together. Several methods have been used.

- Free running – In the surveillance example, the distances are long, the earth is stationary, the platform is stabilized and the aircraft speed can be well controlled. In this case, the speed of the image can be calculated and provided to the sensor clock circuits. Over practical time frames, the scanning will stay synchronized.
- Known speed – In some applications like glass sheet inspection, the object is stationary and the camera is moved. Since the camera speed is under the operator's control, the charge transfer speed can be made to match it.
- Drive the object – In processes where the conveyer or other moving object is controlled by an external clock, the clock can come from the camera to make the object move at a speed determined by the charge motion.

In all of these methods, the speed is constant because it is set by a controlled clock. This means that the integration time for every line is identical and, therefore, the signal generated by each line for a particular object brightness will always be the same. Unfortunately, many real-world applications do not permit external clock control as in the fourth synchronization example.

- Trigger the camera – Real moving objects like paper, plastics textiles, and almost everything else can't be clocked. Instead, they have rollers with rate encoders that can tell a scanning system how fast they are moving. This information can be converted to a train of pulses that are used to tell the charge when to shift.

Because the triggering rate can vary with time in this method, the integration time can vary from line-to-line also. This may require that the image processor keep track of the actual integration time for each line so the signal amplitudes of all lines can be normalized.

Limitations of TDI

While TDI can solve the sensitivity problem in many linescan applications, its tight geometric requirements limit the span of usefulness. Some specific considerations include:

- Parallax – The parallax phenomenon is familiar to anyone using line scan cameras. Parallax simply refers to the variation in viewing angle of the object from the centre of the image to the edge. Parallax will make objects at the edge of the image look different from those at the centre and causing, for instance, variations in the measured positions of edges. TDI imaging has parallax from the top to the bottom of the scanned field as well, but the reported result will be the average of the signals generated over the entire range of viewing angles. In objects that are not perfectly flat, this average will include data from all of the views in the scanned area.
- Speed variation – As noted above, variation in the speed of motion causes variation in the integration time line-by-line. In addition, each TDI imager will have upper and lower limits to scan speeds that can be tolerated. The upper limit is the same as for any line scan imager – it is simply the time required to read out a line. The lower limit may be set by accumulation of dark current or by saturation of the imager as the integration times lengthen.
- Flatness – TDI works best only on truly planar objects. Height variations cause both defocusing and loss of synchronization with charge motion. Telecentric optics can alleviate these problems if the coverage area is small enough.

Practical TDI Sensors

Although nearly any FF or FT CCD imager can be operated in a TDI mode, purpose-built TDI imagers have certain architectural features that optimize TDI performance. FT imagers have the disadvantage that they add a delay between the end of the exposure and the time that the line will be read out. This can be minimized by clocking each arriving line rapidly through the storage area but only if the process is fast enough to finish the traverse before the next line is ready. An advantage of retaining the storage area is that the TDI imager can be used to make images when the motion is stopped. This can facilitate system setup, alignment and troubleshooting.

Vertical transport in TDI imagers generally utilizes a four-phase structure so that each shift of a line is broken into four parts. While this reduces the charge storage capacity of the wells, it produces smoother motion than two or three phase structures and keeps the moving charge better aligned with the moving image.

While the integration time in TDI sensor could be increased without limit by adding lines, the practicalities of maintaining the geometric relationships and the diminishing returns of adding more line generally cross over in the neighbourhood of 100 lines. As a result, most TDI imagers have line counts in that range. Line counts of 96 or 128 are common. TDI imagers can be made faster by adding taps, but this can only be done on one side because the charge has to travel in a specific direction. Taps added to the other side can allow bidirectional operation. To provide limited exposure control, some TDI sensors have controls that can disconnect groups of lines from the scan signals. Thus, a 96-line sensor might also be capable of operation with 64, 48 or 32 active lines. The sensitivity adjustment is not smooth but may solve problems where the speed or lighting vary substantially. The active lines are those nearest the output so the centre of the image shifts as the number of active lines is changed.

10.2.8 CMOS Structures

CCDs are limited in the complexity of circuitry that can be included on-chip because they are essentially either NMOS or PMOS devices. That, is, they can support only one polarity of MOS transistor. While this structure is sufficient for gating and signal following functions, it cannot support fast logic gates or voltage amplification. For these, both transistor polarities are required. The circuit structure that has them both is called CMOS. Of course, CMOS processes have been around for a long time so it might be expected that high-performance imagers using them might also be that old. They reason that they have only recently emerged as competitors to CCDs in imaging lies in the restrictions of CMOS process.

One disadvantage of CCDs is that they must be made using special semiconductor fabrication processes tailored to producing the particular structures needed in CCDs for good performance. With CMOS, the early expectation was that CMOS processes already in use for digital logic could be directly applied to fabrication of imagers. Unfortunately, this was not the case. CMOS sensors require changes in the processes to support fabrication of high-quality photodiodes, a device not present in CMOS logic. In addition, geometric factors come into play.

10.2.8.1 Optical Structures

In CCD's the only large structures in the photosensitive area of the devices are the light conversion areas and, in interline devices, the transport registers. Some area might be taken up by antiblooming features but the majority of the area can be devoted to light sensing. In CMOS sensors, however, each pixel must be supplied with control and readout circuits consisting of multiple transistors. These take up significant space at the surface of the silicon, in the same plane as the photodiode. As a result, the fill factor in CMOS devices can be quite low, in the range of 30% in devices with small pixel pitch. Further, the metal interconnect lines must be built above the silicon surface with the result that each photodiode usually sits at the bottom of a hole. ➲ *Figure 10.8* shows the typical situation. As the pixel pitch is made smaller, a larger portion of the available area is taken up by the circuits and so the width of the hole relative to its depth gets smaller and smaller.

Microlenses

To provide enough light in small-pitch devices, a plastic layer is added to the surface with the upper side formed to make a small lens above each photodiode. Such structures are called microlens arrays. ➲ *Figure 10.9* illustrates these. (Also see ➲ Chap. 6) As the two sample rays show, much of the light that would have missed the photodiode will be directed to it by the microlens, increasing the effective collection efficiency by as much as a factor of 3. Microlenses

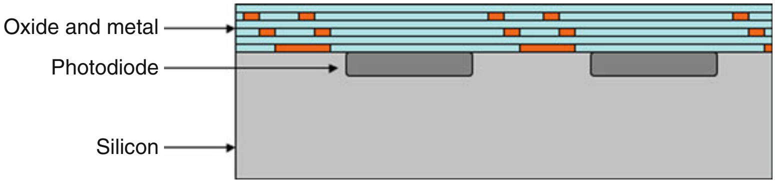

Fig. 10.8
CMOS sensor. Each pixel is supplied with control and readout circuits consisting of multiple transistors. These reduce the fill factor. Metal interconnect lines are placed above the silicon surface. Hence, the photodiodes are located below these

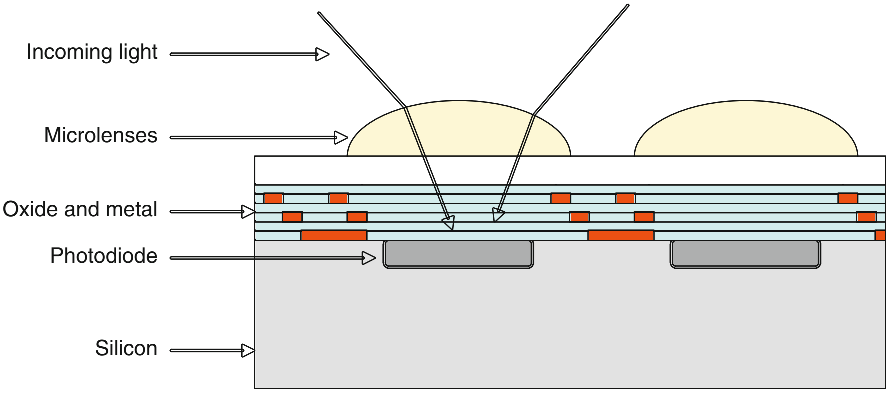

Fig. 10.9
Microlens dedicated to each individual protodiode. The microlens focusses light onto the photosensors, which improves the fill factor and increase the angle of acceptance for incoming photons

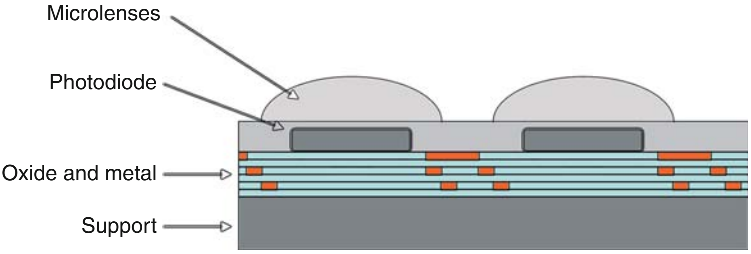

Fig. 10.10
Support wafer bonded to a thinned sensor array with microlenses

are most effective on pixels in the 2–5 μm pitch range. Larger pixels generally have sufficient collection efficiency and smaller ones have acceptance holes that become too deep and narrow to be helped much.

Backside Thinning

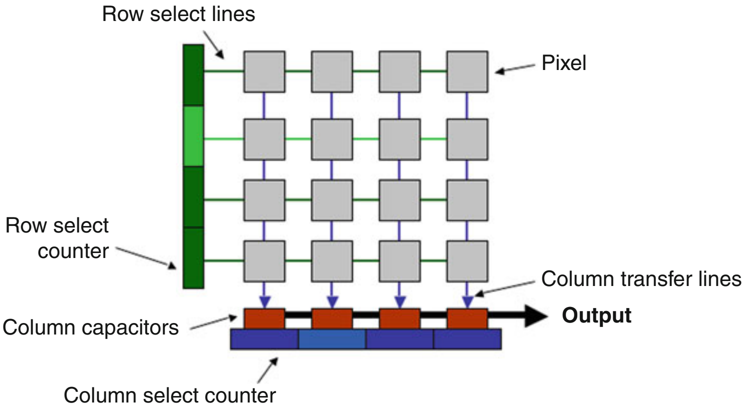
One solution to photon collection in very small pixels is backside thinning. Backside thinning of CMOS imagers is more difficult than for CCDs because of the large amount of structure in CMOS circuits. However, the improvements in quantum efficiency are similar. There are several methods to provide backside access for light to the photodiodes but all of them are similar in that they require the finished array to be thinned. A support wafer must be somehow bonded to the sensor array because after thinning the array silicon is typically less than 10 μm thick. Backside illumination eliminates the need for the light to enter a hole, but it does not improve the fill factor because the photodiodes and the circuitry remain in the same plane as shown in ➜ *Fig. 10.10*. Microlenses can still improve the collection efficiency.

10.2.8.2 Basic CMOS Operation

The baseline for all CMOS designs is the architecture shown in ➋ *Fig. 10.11*. The CMOS sensor is an array of photodiodes each supplied with sampling and switching circuits. In the simplest sensors, the entire array is reset by reverse biasing all of the photodiodes then disconnecting them from the reset voltage. The voltage across the photodiodes will drop as the exposure to light accumulates so that at some time, the voltages can be samples to produce image data. In the simplest CMOS sensors, this sampling is accomplished by transferring the voltages from a row of photodiodes selected by a row counter to a bank of capacitors at the bottom of the sensor so that these can be sequentially read out of the device by a column counter. Unlike the readout process in a CCD, CMOS readout does not move the actual charge generated by the incoming light. Only the voltage this charge generates is moved – actually, copied – from the pixel to the readout capacitor to the output. Significantly, this is a non-destructive process. After readout, the voltages are still in the pixel circuits so before the next image can be taken, the photodiodes have to be reset. The methods of reset and readout offer the option of a variety of pixel circuits. All of the configurations described here are of the active pixel sensor (APS) variety. Passive pixel sensor (PPS) configurations are slightly simpler but suffer from numerous performance deficiencies and so are rarely encountered.

10.2.8.3 Pixel Structures

CMOS allows a wide variety of sampling and amplification circuits to be incorporated into the pixel area so the actual variety of these circuits is quite broad. The complexity of these circuits is generally limited not by the lack of ideas for functions to be incorporated but by the lack of space to put them. As a result, the design emphasis usually centres on developing ways to maximize function while minimizing the circuitry needed for implementation. Much of the effort in these designs involves optimization of the structures and processes in the silicon itself.



◘ Fig. 10.11

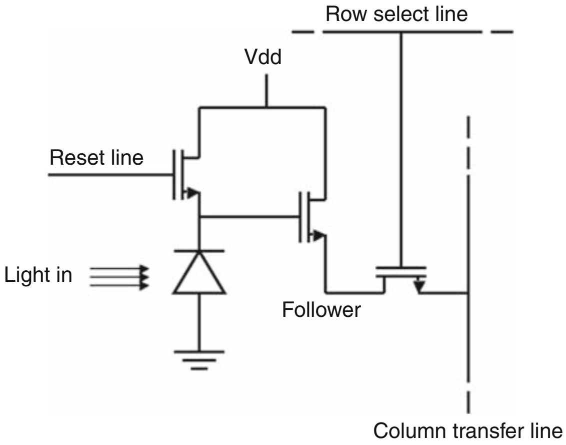
Basic CMOS sensor consisting of an array of photodiodes, each supplied with sampling and switching circuits

This level of examination is beyond the scope of this book but references are provided for those who are interested in the details of silicon device design and fabrication.

3T Pixel

The most common pixel structure is the three-transistor (3T) readout. A typical example is shown in ➋ *Fig. 10.12*. To initiate an exposure, the reset gate is turned on by a signal applied to the reset line. This connects the diode to the V_{DD} supply to fully reverse bias it. Reset may be applied to all photodiodes simultaneously or, in some sensors, to a row at a time. After reset, the voltage on the diode will slowly fall as the light arrives. The diode voltage is presented to the gate of the follower transistor. When it is time to read out a row, all of the column transfer transistors in that row are simultaneously turned on and the diode voltage is transferred through the column lines to the row of storage capacitors at the bottom of the array. Immediately after this transfer is complete (typically a few microseconds), the diode can be reset and the next exposure cycle can begin.

While this structure is simple, it suffers from two important problems. First, it has a high noise floor because the reset noise from the photodiode is included in the signal sent to the output. Since this noise is never independently measured, it cannot be subtracted as is done with CCDs. Second, since there is only a single row of output capacitors, only one line can be transferred from the array at a time. The next cannot be transferred until the readout is complete. This means that if all of the photodiodes are reset at the same time, the exposure of the photodiodes at the end of the readout will be longer than for the photodiodes at the beginning, producing top-to-bottom shading in the image. Three solutions to terminate the exposure of the whole sensor simultaneously are commonly applied. A mechanical shutter can be closed to allow readout in the dark. Similarly, the imaged area can be kept in the dark except during a short flash of light from an illuminator. If an all-electronic exposure control method that produces equivalent but not simultaneous exposure of the rows is acceptable, each line can be independently reset at a fixed time before readout. This is the "rolling shutter" to be discussed in more detail below. For simultaneous electronic exposure, more transistors are required.



■ **Fig. 10.12**
CMOS three-transistor pixel control and readout circuit

4T Pixels

Adding a fourth transistor permits separation of the exposure and readout functions thus enabling simultaneous or global electronic shuttering. The fourth transistor is usually added as shown in *Fig. 10.13* between the photodiode and the gate of the buffer transistor. In operation, the photodiodes are reset together while the transfer transistors are conductive and then at some later time the transfer transistors are closed, fixing the voltage on the gate of the follower. This voltage is then held until the row is transferred. In this way both the start and end of the exposure are electronically controlled.

While the transfer circuit is represented as a transistor switch and a capacitor to hold the voltage, in fact the capacitor is usually another charge storage well on the device and the photodiode is pinned, thus forcing the charge into the storage well as it is created. This arrangement has the advantage that is reduces the reset noise and improves linearity. As is often the case with image sensors, the schematics alone do not provide sufficient detail to describe the actual circuit or to permit analysis of its operation or performance. If the real details of sensor operation and performance are important, some understanding of device construction is essential.

It is often suggested that another 4T arrangement might provide for subtraction of reset noise. The proposal is to add a second row transfer transistor to permit transfer of the reset noise to a second row of readout capacitors so that the reset noise can be subtracted from the signal using a differential amplifier at the readout. Unfortunately, this works only if each row is separately exposed because saving the reset noise requires a separate capacitor row for each line in the sensor. Even if this were provided, the rows would need to be transferred one at a time so all rows but the first would have some exposure added to the noise signal. Subtraction of the reset noise has to be done in the pixel and this requires even more transistors.

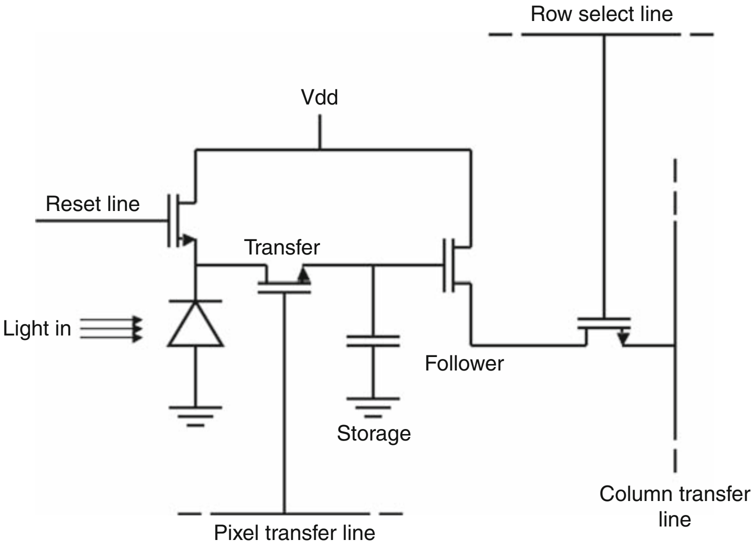


Fig. 10.13

By adding a fourth transistor to provide global electronic shuttering. This is achieved by separating the exposure and readout functions

5T and More

With five transistors, it is possible to configure a pixel circuit that stores the reset noise and the signal both. With six transistors, it is possible to do the actual noise subtraction in the pixel. With six or seven transistors, the dynamic range of the sensor can be increased by multiple sampling. More transistors can be added to allow collection of many images very close together in time. A sensor has been built that has 16 sample nodes per pixel that can be sampled only 1 μs apart, the equivalent of one million frames per second for a short time.

Unfortunately, all of these transistors and the lines to control them take space on the silicon die so adding functions either reduced fill factor or forces an increase in the pitch of the pixels. That is why CMOS sensor with a lot of functions tend towards large pixels. Large pixels drive increases in cost.

2T and Less

One the other end of the scale, where cell phones reside, the push is for tinier pixels to reduce both the cost of the silicon and the thickness of the lens-sensor assemblies while continually increasing resolution. In these sensors, configurations have been developed that allow sharing of some of the transistors between photodiodes. For example, if speed is not an issue, it should be possible to use the same follower and row select transistors for multiple photodiodes if the photodiodes have transfer transistors as in ➋ *Fig. 10.13*. These transistors could be turned off until each of the pixels is to be read out. If, for example, the readout circuit is shared by four photodiodes, the then the result is seven transistors for four photodiodes or 1.75 transistors per pixel. Many arrangements of this type have been designed and implemented for applications where space is at a premium.

Other Configurations

Many CMOS sensor engineers have designed other circuit configurations to provide specific advantages in particular performance measures. The active column sensor (ACS) architecture, for instance is intended to improve fixed pattern noise while reducing the space taken by transistors in each pixel. Sensors have been built with JFET switches instead of MOSFET to reduce noise. Photodiodes have been stacked one above the other to provide multiple spectral channels from the same area on the sensor. Pairs of photodiodes in two sizes have been provided to increase dynamic range. Comparators have been put in each pixel for direct digital output. The variety of configurations continues to expand to meet the diverse performance requirements of the many imaging market segments.

10.2.9 On-Chip Functions

While the transistors that must support each pixel are problematic because of the space they require, transistors outside the photosensitive area can be used to provide a wide variety of support functions, culminating in the complete system on a chip. Because essentially any analogue or digital circuit function can be implemented in CMOS, the capability of the circuitry that can be placed around the photosensitive area is essentially unlimited encompassing analogue-to-digital converters, microcontrollers, high-speed serial links and many other functions. In practical devices, four broad types of functions are commonly implemented –control, data conversion, processing and transmission.

10.2.9.1 Control Functions

One major advantage CMOS sensor offer in comparison to CCDs is the capability to include on-chip control functions for scanning and exposure. With CCDs, essentially all control must be provided externally to a set of pins that accept only very simple signals like phase drivers and tap selection. CMOS sensors, on the other hand, can include counters, registers and even microprocessor cores and so can execute complex sequences of operations at very high speed on the receipt of external high-level commands. Examination of any current CMOS sensor data sheet will reveal how far this capability has been taken. Many sensors now have hundreds of control registers to set internal clocking, scan configurations, power-saving modes, readout configurations bias voltages and almost anything else that could be controlled in a complex circuit. Most of these controls are useful only in the camera design process but some of them translate into very useful camera functions that can be set by users.

Scan Control

In the most common case, a camera is operated with a periodic scan of the entire area of the sensor. For general viewing or producing television shows, this may be all that is ever necessary. In many industrial, scientific and even viewing applications, changing the scan in some way from simple periodic repetition can provide useful benefits. Even in television, all of the cameras must scan together so that their signals can be easily mixed and switched. In television, though, the cameras all run at the same rate so that the timing for the next picture can be figured out from the last one.

Instrumentation situations are not so predictable so it may be necessary for the camera to produce images on receipt of random external commands. This is called triggering. There is, of course, nothing inherent in sensors that prevent them from starting the generation of images at any time. However, any imager will accumulate charge in its photodiodes when it is waiting so the black level of randomly triggered images will have black levels that vary as well. These could, in principle, be subtracted out if they were pure offsets but, unfortunately, sensor dark charge will contribute non-uniformities and shot noise and reduce the dynamic range available for the real image.

To avoid this, it is useful to be able to reset the imager rapidly upon receipt of a trigger so that the dark charge is zero when the exposure begins. While various techniques can be applied to CCDs to continuously sweep dark charge from the photosensitive areas and the transport registers, the problem remains that any stray light reaching the sensor will generate ghost patterns that are essentially impossible to remove because the entire array cannot be cleared at once. IT sensors are somewhat less susceptible but still cannot avoid the effects entirely. In CMOS sensors, on the other hand, all of the photodiodes can be reset rapidly and simultaneously to provide a uniform, near-zero starting point at any time. Many CMOS sensors can also reset specifically-selected rows. Other reset patterns can be readily implemented by providing separate sets of reset lines for the desired photodiode groups.

Scanning only part of the active area is sometimes desirable to concentrate data gathering in a particular part of the image or to speed up the frame rate. This is called region of interest (ROI) scanning. While rudimentary ROI scanning is possible with CCDs (where it is typically called partial scan) the complete independence of each pixel from the others in CMOS sensors allows very sophisticated selection of areas to be scanned. The typical CMOS sensor has as in its controls methods of setting the number of the first row to be scanned and often the number of rows to be scanned at once and the number of rows to be skipped before the next scan. The end of scanning is generally controlled by simply stopping the counters that select the rows for scanning. Similar controls can be applied to the row of output capacitors so that only the columns of interest are passed to the output stage. Using these controls together allows great flexibility in matching the scanned area and its configuration to the data requirements of the current scan. As an example, consider the following:

► Let us say we wish to make a camera that will rapidly sample selected areas of the scene to provide exposure and focus information. On command, the camera will then take two pictures, one at full resolution for use as the primary image and one at reduced illumination to display on a small LCD panel. To do this, we first command the sensor to scan a series of small areas in defined positions. This can be done rapidly because the areas are small. We have to design the camera to quickly change the row and column start settings so that the scanned area can be repositioned after each small scan. When the trigger is received, the entire sensor is reset and then scanned twice. First it is scanned with a raster in which we read only every fifth line and column (this is for the display) and then it is scanned again, without resetting, and all of the pixels are captured. All of the setting changes can be easily implemented with appropriately capable CMOS sensors.

Additional options are available. If the scan counters are reversible, then the sensor can reverse scan directions on command. If multiple start points can be set, then multiple ROI selections can be scanned at the same time. The options can be increased further if 4T or more pixels are used because these provide for storage of images in the array itself. It can be safely said that few, if any, image sensor manufacturers explicitly identify all of the possible scan combinations available on each sensor and it is certain that no camera manufacturers accommodate all of them in any existing design so engineers needing special operations are well-advised to raise them with the sensor or camera manufacturers to determine if some sensor is actually available that might meet the requirements.

Exposure Control

Since most CMOS sensors are 3T or some equivalent or, if they are 4T, have severe constraints on the use of the photodiode independently from the storage well, the availability of global shuttering is severely limited. What this means in practice is that the initiation of the exposure can be controlled electronically – it is just the end of reset – but the termination of the exposure cannot. The exposure for a particular row ends only when its contents are sampled and transferred to the row of readout capacitors. Therefore, the exposure time of each row as the scan moves down the sensor is one row longer than the previous row. If the exposure is set to match the duration of the scan, for instance, then the last row will get twice the exposure of the first row. There are some ways to mitigate this problem.

The simplest mitigation in instrumentation settings is to control the illumination so that the sensor is in the dark after exposure. A mechanical shutter can provide this darkness if it blocks the light from the entire sensor simultaneously. Such a condition is not necessarily easy to provide because any shutter near the sensor will obscure different parts of the sensor at different times in a circular or some sort of sweeping pattern. This lack of simultaneity may not be a problem if the time to close is short compared to the exposure time. Real simultaneous exposure can only be accomplished if the shutter is in the position of the iris in the lens or in some similar optical plane. In situations where the object to be viewed can be enclosed, the exposure can be controlled entirely by turning an illuminator off and on at the right times. Care must be taken to exclude stray light, especially if the exposures are short compared to the scan time. It is important to note that the onset of illumination, either by a shutter opening or a light turning on, does not have to be the start of the exposure because the sensor can be held in reset and used as the starting time. This can be very useful when an object is anticipated to arrive for capture but its exact time is not known. The illumination can be initiated slightly in advance while the exposure start can be held until the object is actually detected. Ending reset is generally much faster and more accurate than changing the illumination state.

CMOS can provide a fully electronic exposure method if the sensor is provided with two independent row counters. If one of the counters is used to command reset of the selected row and the other counter controls reading, then simply by establishing a fixed delay (usually measured in multiples of the row period) between reset and read, all rows can have the same exposure time. For example, if row 25 is reset as row 1 is read, then, in the next cycle, row 26 would be reset and row 2 read. After 25 repetitions of this, row 25 would be read after having accumulated exposure for 25 row periods. This spaced arrangement is moved down the array so that all rows see an exposure of 25 rows. The start has to be handled to be sure the rows there get the right exposure but this requires only a simple logical control. The effect, though, is of providing a variable, uniform exposure simply be setting the number of rows between reset and read. A little additional logic can stop the scanning to provide exposure of any length, not limited by the number of actual rows in the sensor. This process is called rolling shutter scanning.

The difficulty with the rolling shutter is that exposure is not simultaneous. Each row has an exposure time (in the absolute sense) that is slightly delayed from the exposure of the previous row. The total difference in starting times will be exactly the time needed to scan the sensor once. While the delay is not important if static objects are to be imaged, moving objects will suffer geometric distortion. Objects moving perpendicular to the rows will be stretched or compressed depending on their direction relative to the scanning and objects moving along the lines will be tilted one way or the other. The significance of this depends on relative speeds and the requirements for geometric accuracy in the images. Oddly enough, the digital still camera with a mechanical shutter is often offered as the ideal way to use a sensor that does not have electronic exposure control. However, the shutters in such cameras are of the curtain type, consisting of two metal leaves that move across the image – one to start the exposure and one to end it. At speeds above about 1/125 sec, the terminating blade starts moving before the initiating blade has completed its travel. By the time the shutter gets to 1/1,000 sec, the aperture the leaves form is a vertical slit that traverses the image, providing an exact mechanical equivalent to the electronic rolling shutter and producing the same geometric distortions.

To provide electronic exposure control at both initiation and termination, an extra storage node is needed in each pixel. This implies at least a 4T pixel and perhaps more. The extra transistors take space and will reduce fill factor at least until sensors can be built with transistors buried under the photodiodes.

Data Conversion

Even though the control and scanning of CMOS sensors is all digital, the output signal is still analogue. It begins as a charge packet, is converted to a voltage and is then passed along from one storage capacitor to another until it emerges from the sensor. There are a few exceptions to this signal flow but they are reserved for special applications. However, building an analogue to digital converter (ADC) in CMOS technology is not difficult so sometimes these are added to the sensor chips itself to provide a digital output. Usually, the sensor designer does not have to design the ADC because these are available under license as silicon intellectual property (IP) modules designed to be dropped into new designs. Several types of ADC are useful for on-chip incorporation

The simplest type is the common flash video ADC that is applied at the output of the image data path. Instead of being sent off-chip, the analogue signal is directed to the input of an ADC where it is converted to digital data which is then made available on package pins in either serial or parallel form. This is a direct match of the typical configuration in which a flash ADC is connected to the video output of the sensor. The requirements to use an ADC inside the package properly are essentially the same as those for using an external ADC so some additional on-chip circuitry must be provided. To accommodate the various ranges of signal level, a programmable analogue gain stage is needed before the ADC input to assure that the signal levels are matched to the full-scale input of the ADC. If this is not done, then the ADC input range has to be set to accommodate the saturation signal of the sensor. This is acceptable as long as the typical use of the sensor produces highlights that are near saturation. However, if the application only produces maximum signals that are, say, one half or one quarter of saturation then the full range of the ADC cannot be used. An 8-bits ADC with a quarter signal maximum is then functionally only a 6-bit ADC. To use the full 8 bits with this low signal, a gain of four is needed before conversion. A programmable gain amplifier will accommodate this. In addition, level-shifters, buffers, differential amplifiers or other circuits may be needed to match the analogue signal to the ADC input and to maintain stability over temperature and power supply variations.

In a very fast sensor, a single flash ADC may be insufficient to handle the required data rates so the sensor can be partitioned, typically into groups of columns, with each partition having its own ADC. This arrangement has three problems. First, flash ADCs take a lot of power, perhaps defeating one of the purposes of selecting a CMOS sensor in the first place. In addition, they generate a lot of heat. This is undesirable because heat raises dark current. Further, in CMOS sensors, multiple ADCs would have to all be positioned along one side of the sensor so the heating of the sensor would be uneven probably resulting in shading in the image. Finally, flash ADCs take up a lot of space and, in sensors as in all silicon devices, space is money.

The common solution for high-speed sensors is to use slow ADCS at the bottom of each column, then combine the outputs digitally. Since these ADCs can be of the compact, low-power delta-sigma type, they fit more easily and have much less heating effect than flash converters. Of course, there are many more of them. A 1k × 1k sensor would have 1,000 ADCs on-chip. These column ADCs have some performance advantages because they have such low sample rates. They are much easier to design because their clocks are so much slower than flash clocks. This leads to easier selection of a data sampling point and simpler calibration. Column ADCs can also more easily provide data with more bits because increasing the bit depth only requires increasing the ADC clock rate. At the highest frame rates, the column ADCs may need to include low-bit flash sections to keep the clock rates manageable.

Processing

CMOS sensors can include both analogue and digital image processing on-chip. The analogue functions are generally simple. As previously described, these might include reset noise subtraction, or adjustment for gain and offset. Digital functions can be more complex and are often aimed at reducing the data rate from the sensor or reducing the number of pins required. Of course, there is a tradeoff, more processing functions take up more silicon area and so the silicon area and the packages get bigger, increasing cost. Some of the more common on-chip functions are:

- Compression – Generally, the simple types like run-length encoding or delta coding are used. When these are operating, the camera designer must be prepared to reconstruct the original data before applying further processing.
- Automatic gain control – Rather than depend on the camera for exposure control, a sensor might include a circuit to measure the illumination in selected areas and adjust the exposure to keep the signal level optimized. Data from such a sensor does not provide any absolute measure of scene brightness unless the gain control signal is also made available as an output. A similar control might be applied to black level.
- Exposure balancing – Under different light sources, the relative amount of energy received by the colour channels can vary substantially. To optimize dynamic range, a senor could adjust the exposure time of the photodiodes in the three channels separately to produce outputs of similar amplitude. The sensor might even be made capable of remembering relative levels of the channels for white objects to simplify colour balance.
- Post-processing – If desirable, any digital operation can be included such as noise smoothing, gamma correction, edge enhancement or even operations as complex as retinal simulation or feature detection.

Fundamentally, the reason for incorporating processing on-chip is to provide adjustments at the earliest possible point in the data stream to minimize data loss. This is not quite the same as the camera-on-a-chip concept in which many functions, including some not directly involving the sensor, are included on one piece of silicon to minimize camera size and assembly cost. All additions to sensor functionality come at a penalty of yields, size and heating at the chip level and of flexibility at the system level. Once a function is added to a chip, its maximum capability becomes the capability limit of the system.

Data Transmission

Data transmission complexity is directly related to speed. In sensors with analogue outputs, higher speed means more taps an, as a result, more pins. The pins for multiple signals in analogue sensors must be carefully spaced so that there is no inter-tap crosstalk. Digital sensors also need more pains as speeds increase but the relationship is not so direct because of the variety of digital channel choices available.

Simple digital output sensors have an ADC that puts out data in parallel form, which is connected directly to a set of pins. For one tap, this is a good arrangement because it requires minimal circuitry to receive the data. Adding taps makes the pin count rise proportionally and adding bits to the data has a similar effect. While packages with hundreds of pins are available, the size of these would often be far larger than the sensor die so a better scheme is needed. Multiplexing can be employed. In the parallel multiplex scheme, the data from several taps (or from many column ADCs) is sequenced into a single set of output pins. This raises the data rate but digital transmission can be much faster than the typical maximum clock rate of a single tap. With this scheme, care must be taken to assure that skew in the data timing between outputs does not become so large that the data gets scrambled.

To avoid the skew problem, the data from one or more ADCs can be sent through a serializer and transmitted on a single pair of pins as a balanced high-speed (often LVDS) signal. Since the entire data stream passes through a single pin pair, the skew problem is eliminated. Even if multiple data streams are needed to handle all of the data, deskewing codes can be added to the serial data stream to support resynchronization. Serialized data sent through LVDS or other drivers can be sent much longer distances than can parallel data providing additional flexibility for the camera designer. If this technique is to be used, the selection of data format and driver type should be matched to some sort of commercially available receiver/deserializer to minimize the need for custom design.

10.2.10 Other Sensor Types

While the vast majority of sensors are of the raster-scanned, rectangular, monolithic, silicon type in either CCD or CMOS process producing a voltage that represents light converted to charge in depleted silicon, there are other types of devices made, mostly to server special purposes. Thousands of types have been made, many in only a few samples in sensor design labs but some have found real commercial applications. A selection of these is included to suggest the diversity of what can actually be made. One caveat – typically, sensors with special capabilities will be available from only one source.

10.2.10.1 Charge Injection Devices

The charge injection device (CID) is another form of MOS device. Unlike most sensors, it does not have photodiodes. Instead, it consists of a silicon layer overlaid with an insulating oxide with thin metal lines in a row and column arrangement as shown in ➋ *Fig. 10.14*. Voltages are applied to the lines to produce a charge storage well that can then accept incoming photons and convert them to charge. The odd thing about CID sensors is that since the row and column lines create a potential well around their intersection, the centre of each pixel is obscured. The boundaries of the pixels, however, are unobscured, just the reverse of essentially every other sensor geometry. By changing the voltages applied to the electrodes, the charge can be made to

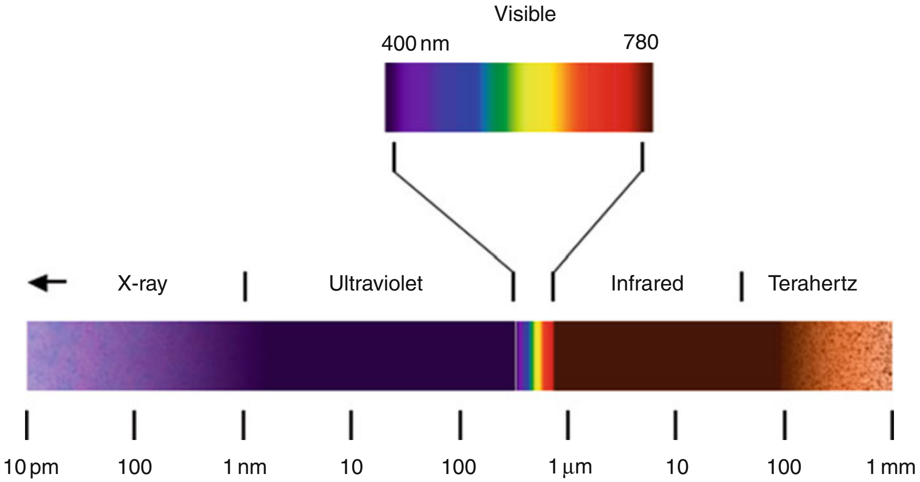

Fig. 10.14
The visible spectrum is shown relative to the near-infrared (NIR) and near-ultraviolet (NUV) bands. This suggests that these wavebands may be imaged using techniques similar to those in the visible part of the spectrum (VIS)

move and generate a voltage that can be read out at the ends of the row electrodes. The motion is non-destructive so it can be repeated to provide images showing the image as it builds up. When the exposure is over, the charge is injected into the silicon substrate, hence their name. The injection can be read as a signal as well if the pixel crossovers are injected separately in a raster sequential fashion for either the full array or one or more ROIs.

Because CID sensors have no junctions and no transistors in the imaging area, they are very resistant to radiation exposure. This makes them suitable for use in monitoring cameras in nuclear reactors and other high-radiation environment areas. In the CID structure, there are no communication paths from pixel to pixel even in heavy saturation so blooming is essentially non-existent. In addition, CID pixels can be made to store relatively large amounts of charge, making them suitable for spectroscopic applications. Unfortunately, the high capacitance of the row and column lines makes the conversion factor for CID arrays very low and contributes substantial noise. Nevertheless, the CID continues to serve several important niches.

10.2.10.2 X-Y Arrays

CID sensors are X-Y arrays because they have pixels that can be randomly selected. Pixels from any sensor can be randomly selected after the sensor is read out but in X-Y arrays, the scanning process itself can be random. In theory, any CMOS sensor could be operated as an X-Y array by allowing rapid setting of the row and column decoders to select individual pixels. In practice, this setting process is usually so slow that random readout doesn't produce enough data in a reasonable time. Real X-Y arrays tend to be relatively small simply because the applications for them do not require high resolution.

A typical X-Y array has either individual pins for each row and column (small arrays) or separate ports to load the coordinates of the next pixel rapidly. Most X-Y arrays built to date run in the current mode rather than the charge accumulation mode of both CCD and CMOS area arrays. To run in current mode generally requires that the light levels be quite high so that sufficient photocurrent is generated to produce an output signal with reasonable signal-to-noise ratio. Since the maximum signal level in current-mode operation is not constrained by well capacity, X-Y photodiode arrays can have extremely large dynamic range. One million to one is possible. An interesting advantage of the X-Y array is that the photodiodes can be of any type – not only simple silicon pn junctions but also p-i-n diodes, avalanche diodes and diodes made of other materials.

10.2.10.3 Non-Rectangular Arrays

Not everything to be viewed maps well into a rectangular array of squares with constant spatial resolution. Although nearly every scene is treated as if the rectangular geometry is good enough, there are situations where non-rectangular or non-periodic arrays are more suitable. The most obvious of these is the acquisition of round objects. Clearly, the rectangular array will produce widely varying angular sample rates from centre to edge of a round object and often fail to accurately image the object centre. In addition, the constantly changing angle of the pixel array relative to the slope of a round surface leads to very inconsistent estimates of edge position. One solution is to use more pixel so that the sampling is sufficiently fine to reduce the errors to insignificance.

Another solution is to use a sensor with the pixels arranged as either concentric circles or radial lines. The difference between these two geometries is that the concentric circle type has pixels of constant size at all diameters arranged so that the pixel edges are ether radial or tangential. The pixels do not overlap in the radial direction so each circumferential ring acts as a row would in a rectangular array. Such arrays are good for determining centration and deviations from roundness but they cannot measure individual radii accurately because the centres of the pixels do not form straight lines in the radial direction. In the alternative geometry, the pixels are arranged in radial rows. The distance from the centre of the pixel boundaries can be made uniform along all radii. These arrays will have gaps because the circumferential spacing increases with increasing radius and pixels can only be used to fill in when the space between adjacent radial lines is sufficient to allow insertion of another row. Sometimes the uncovered area can be minimized by allowing the diodes closer to the centre to be smaller than the nominal size but this generates shading that has to be compensated. Radial arrays can be designed with four or six lines beginning at the centre depending on the symmetries requires in the measurements. Reading out circular arrays is straightforward in CMOS types because the rows and columns can be easily mapped to increments in radius and angle

In addition to the reasonably obvious rectangular and polar geometries, many special configurations have been built for specific purposes. Some of these are arrays of arrays. Examples of these can be found is the instrumentation for particle accelerators where small sensor may be combines on curved surfaces to match a mathematical function of a focal plane. Arrays can be stacked for detection of coincidence or for suppression of background events. In production, the two most common special devices are both made for spectroscopic applications. In optical spectroscopy, light is spread by wavelength using a prism or grating so individual wavelengths can be detected. The light to be detected always consists of a spectrum spread in one direction and a long slit perpendicular to the spread to provide enough light for robust detection. To accommodate this configuration, spectroscopic sensors are built as single lines with pixels that are close together in the spread direction and very long, up to a few mm, in the slit direction. This not only matches the optical geometry but provides very large charge storage capacity, often in the hundreds of millions of electrons. These are always MOS arrays because shifting charge packets that large by CCD transport registers is not possible.

The other spectroscopic array is much more odd. In atomic emission spectroscopy, very specific emission lines, some very close together in wavelength, must be detected. Simple prisms and gratings cannot spread these lines out enough so a two dimensional grating called an Echelle is used. This spreads the emission lines into several rows rather than just one and leaves great unused spaces between many of them. Since the entire area to be covered can be large but very sparse, the economical sensor to build consists of a set of detection rows each arranged to cover exactly one emission line. Essentially, this is a two-dimensional array of small line arrays all connected to a central readout point. Most of the silicon is unused.

Many other non-rectangular arrays have been built to address one or more limitations of photodiodes at image detectors. In some arrays, dynamic range is expanded by providing two diodes per pixel. One arrangement for this is to use large octagonal pixels and fill the square holes left between them with smaller square pixels. The centres of all of the photodiodes form a rectangular array but the centres of the octagonal and square parts taken separately make two offset diagonal arrays. The mathematics for decoding such a structure, especially when colour filters are added, is complex. Another useful configuration is the hexagonal array. This has the advantage of representing both rectangular and circular objects reasonably well and it can provide a smoother representation of the image than rectangular arrays, especially when the fill factor is low but the output almost always must be mapped to a rectangular display or at least rectangular coordinates to be used so the advantages vanish quickly. In addition, designing a colour filter array for hexagonal arrangements is problematic because there is no minimal repeating cell.

10.2.10.4 Stacked Sensor Arrays

While two dimensional arrays of photodiodes are enough for most imaging applications, more and more three-dimensional arrays are being developed to support detection of scene features in addition to spatial variation in brightness. Some of these arrays are literally three-dimensional and others encode the third dimension by partitioning the two-dimensional surface much like colour filter arrays are used to produce colour (really two more dimensions) from a single plane of identical photodiodes. Taking colour as a starting point, consider the arrays of stacked photodiodes in which colour separation is accomplished by use of the inherent wavelength filtering behaviour of silicon. Three diode junctions stacked at appropriate depths in the silicon can separate visible wavelengths sufficiently to produce colour images. A device of this type must have complete sets of scan and readout electronics for each of the three layers in the diode stack so the pixel areas tend to become crowded with transistors. This structure can only be implemented in CMOS because the CCD process does not allow enough stacked wells to be defined for three layers. Two layers have been built in CCD structures but never commercialized.

Substantial work has been done in stacking arrays for infrared imaging as well. This is covered in detail below. As an introduction consider that every semiconductor material becomes transparent to photons with energies below the bandgap energy. In silicon, this occurs around 1,100 nm. A dual-band sensor can be readily made that has a long-wavelength detection array placed behind a silicon detector array. If the silicon is packaged so that radiation passing through it is not blocked, then the longer wavelengths can be detected by the second array. The problem here is generally optical – how to design a lens that will focus the two wavelength bands at the correct distances and transmit both bands.

Instead of supplying spectral information, arrays can be built to indicate distance. Several types of these have been built that rely on the demodulation of time-varying active illumination. In all cases so far, the structures required to detect the phase of the illumination use pixels that include at least two detection elements. Thus distance is detected using a partitioned planar array. The variety of special arrays that can be built is endless, limited only by the funding available.

10.2.10.5 Intensified Arrays

As described above, CCDs can be fitted with special high-voltage shift registers to provide on-chip gain for low-light-level imaging. Unfortunately, there is no equivalent for this in the CMOS structure. Nevertheless, methods of providing imaging with very limited illumination using CMOS do exist.

First, a small refresher on vacuum image intensification devices. Certain materials will emit electrons when placed in a vacuum and bombarded with light. This is the photoelectric effect that led Einstein to conclude that light could work as particles. In practical devices, the emitter (called a photocathode) is deposited on glass in a vacuum and fabricated so that photons arriving on the glass side of the photocathode cause electrons to be emitted from the opposite surface into the vacuum. For imaging, the photocathode may have a diameter of 18 or 25 mm. In a camera, a lens is placed in front of the photocathode so that the optical image is converted to a pattern of emitted electrons. By application of appropriate electric fields, the electron pattern can be focused on some material that will multiply the electronic charge and hold the charge for readout. Thus, the final signal is stronger than the original photon image could have produced if just focused on a silicon image sensor.

Silicon has an advantage as a receptor of electrons because for each 3.6 eV of energy carried by an electron arriving at the silicon surface one hole-electron pair will be produced. Silicon used in this fashion is called electron-bombarded. In typical operation, the voltage is set so that the electron gain is about 300. This multiplication process is essentially noise-free. With modern photocathodes made of semiconductor materials like gallium arsenide, nearly all the incoming photons in the visible can be converted to electrons so overall gain remains near 300. Of course, this device is not monolithic and may be susceptible to external effects due to it reliance on vacuum and electrostatic fields.

Monolithic CMOS sensors with gain have been built in small arrays. The silicon equivalent of the vacuum intensifier is the avalanche photodiode. Development of CMOS avalanche arrays is still in the early stages but arrays of 256 × 256 pixels have been produced. This remains a technology to watch for low light imaging.

10.2.10.6 Very Large Arrays

As machine vision imaging tasks become more complex and as larger fields of view and higher resolution are needed, the image sensors used need to have more and more pixels. Even arrays up to 4k × 4k can now be found in vision systems. Since the optics often limit how small the pixels can be, high-resolution often means very large areas of silicon. The size of individual sensors is usually limited by the maximum area that can be exposed in one shot in the photolithography systems used to lay down the patterns in silicon. In a typical fabrication facility, this size is on the order of 25 × 30 mm, more or less. While that may seem large for typical inspection applications using even megapixel sensors, it is not as large as a 35 mm film frame and it is much smaller than the latest line scan sensors used in LCD glass inspection, which are up to 90 mm long.

Three fabrication techniques are used to move beyond the constraints of the projection lithography aligners. The first is simply to use a different type of lithography system in which the masks containing the patterns are placed in contact with the silicon. Since these masks can be made as big as the silicon wafer, the sensors can be this large, too. In fact, many devices using wafers up to 125 mm in diameter have been fabricated this way. Unfortunately, this technique is completely incompatible with almost all device fabrication facilities so it is essentially relegated to specialty production.

A second technique uses small sensors designed to have their active areas placed in close proximity to each other to simulate a larger single device. This technique is called butting. Butting can be accomplished by either designing sensors with pixels very close to the edge of the cut silicon or by providing fibre optic bundles that connect slightly separated sensors together using a taper in the fibres. The fibre optic method supports easier sensor design but is subject to some distortion in the image and is very expensive. Area sensor designed for one, two or three sided butting have been made but are found only in specialty situations. Line scan sensors designed for butting, however, are found in every documents scanner and fax machine using a contact image sensor. The critical factor in successful butting is minimizing the dead space between sensors without damaging the outer rows of photodiodes. Typically, the gaps can be many tens of microns but some butted line scan assemblies have gaps as low as 15 microns.

For large monolithic sensors, a technique called stitching is used. Instead of being exposed in one shot, stitched sensors are exposed in many shots carefully aligned at the edges to produce a continuous array that has no gaps. To design an array for stitching, it is necessary to break the layout of the sensor into small parts that can be repeated on the silicon to build up the desired full array. For instance, if an 8k × 8k CMOS image sensor with 10 micron pixels is needed, the basic array might be just 1k × 1k and the registers and drivers and readout structures around the active part of the array are broken into centre and end and corner pieces that are put back together on the silicon. Because silicon exposure alignment can be done with sub-micron accuracy, the boundaries between exposures have insignificant effects on operation and performance when stitching is properly done. However, CMOS imagers are much easier to stitch than CCD imagers because CMOS does not require building charge transport registers that work across the stitching boundaries. Essentially in large CMOS imagers only the aluminium interconnecting wires need to be stitched.

10.3 Imaging Outside the Visible

Without optical or electronic aids, humans can see only a small portion of the electromagnetic spectrum, that part with wavelengths between 400 and 780 nm known self-referentially as the visible spectrum. In many situations, the use of wavelengths outside the visible band can reveal invisible features useful in measurement or monitoring. In ➋ *Fig. 10.14*, the visible spectrum is shown relative to it nearest neighbours, infrared and ultraviolet, which may be imaged using techniques similar to those in the visible and relative to its more distant relations, which require very different imaging techniques. A survey of these bands and their associated techniques will explain their usefulness.

10.3.1 Infrared

Infrared is that portion of the spectrum adjacent to the red end of the visible spectrum and extending to about 30 μm. In ➋ *Fig. 10.15*, the infrared region is expanded to show its various named components. The imaging requirements and detector materials for each of these bands is discussed below. Infrared imaging comes in two types – active and passive. Active infrared imaging is much like visible imaging in which an object is externally illuminated and the results of this illumination are imaged. In passive imaging, the object itself provides the illumination, in the form of emission of electromagnetic radiation. Of course, passive imaging of very hot objects is possible in the visible band but passive imaging of lower-temperature objects is much more common and more widely useful. Since detectors in each of the infrared bands is always

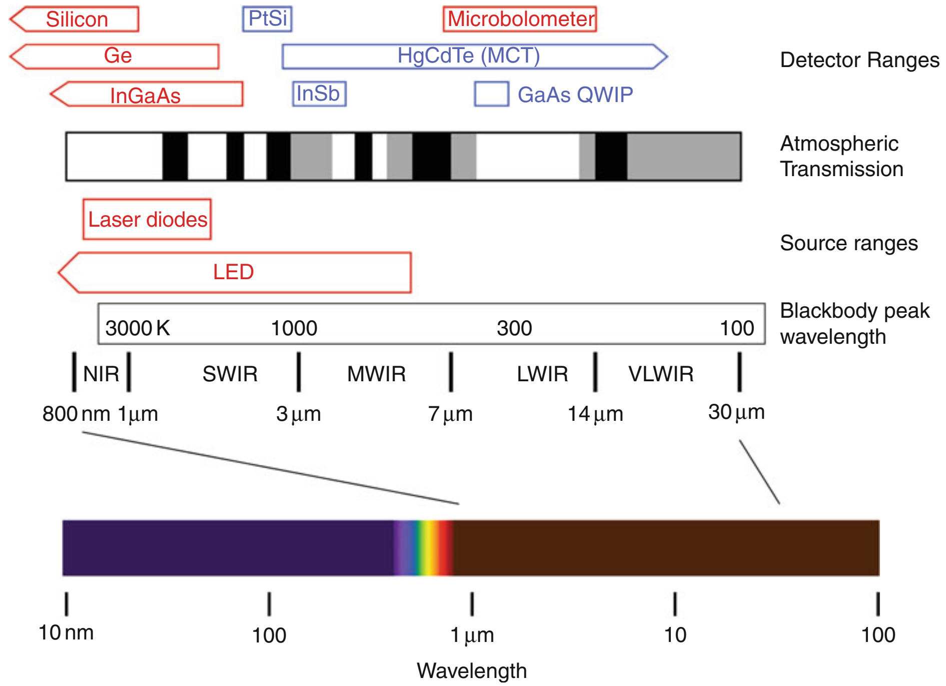

Fig. 10.15
Expanded view of the near-infra-red part of the spectrum

sensitive to emitted energy, careful design of cameras to minimize the effect of stray emissions, even from the camera itself, is essential.

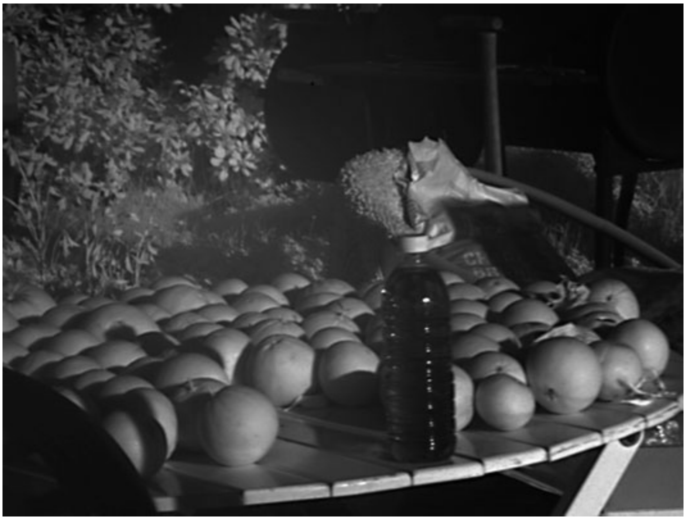
The optical absorption characteristics of the atmosphere have led to the separation of the infrared spectrum into bands. Near infrared is composed of wavelengths adjacent to the visible while the rest of the bands fall farther and farther away. Each band has its own set of useful detection and optical materials that are roughly as exotic and expensive as their relative distance from the visible band. One practical consideration in the implementation of infrared imaging is that essentially all sensors and cameras operating beyond the near infrared are export-controlled by the U.S. government.

10.3.1.1 Near Infrared

In spite of the first atmospheric transmission limit around 1,200 nm, the extent of the near-infrared band is essentially defined by the long-wavelength photon absorption limit of silicon – about 1,100 nm. Because the transparency of silicon increases rapidly beyond 800 nm, thick image sensors are needed to capture a significant fraction of photons beyond 800 nm. In most CCD and CMOS sensors, even though the silicon may appear to be several hundred micrometers thick, the actual photon collection depth is defined largely by the depleted region, which may only include a few micrometers at the input surface. Even those sensors constructed to collect photons through the full thickness of the silicon still only have a few percent efficiency at 1,000 nm.

The advantage of using the NIR band is that the same sensor, and sometimes the same optics, can also be used for visible imaging. This provides additional flexibility in selecting illumination or filters to produce contrast where different wavelengths the visible alone might not be sufficient. For example, bruises can be identified in fruit by NIR imaging. The photograph in ➲ *Fig. 10.16* taken using a CMOS sensor in sunlight through a 1,064 nm filter, shows several potentially useful NIR effects. Most significantly, the opacity of water at 1,064 nm is apparent. Even a few centimeters of water appears nearly black. In addition, the high NIR reflectivity of foliage is demonstrated as it the transparency of the PETE plastic used to make the water bottle. Another common use for NIR is imaging through dyes. Most coloured dyes are transparent beyond about 800 nm. Under NIR illumination all of the dyes disappear so that the underlying material can be seen. This is the principle used in film digitizing to remove scratches from the scanned image. Three colour channels detect the RGB components while a fourth channel with only NIR response sees through the colour dye layers and views only the film substrate material. When this channel is subtracted from each of the colour channels, the scratches disappear. Dye transparency in the NIR also lies behind the capacity for image sensors with colour filter arrays to see at night using NIR illuminators and imaging of lower paint layers in works of art.

NIR imaging allows imaging hot items by their own emissions, but temperatures of at least 800–900 K are required to produce enough energy in the NIR band. This is typical of soldering irons, some industrial processes and some invisible flames. Heated objects can be imaged by sensors extending to 1,000 nm at temperature below those where the eye will see a dull red glow. When the eye can see the glow, then any visible band sensor will do.



◘ Fig. 10.16
Near infrared image taken using a CMOS sensor in sunlight through a 1,064 nm filter

10.3.1.2 Short-Wave Infrared

Short-wave infrared (SWIR) overlaps with the boundary of the visible, starting around 900 nm, and extends to the atmospheric (and glass) transmission cutoff around 2.5 μm. While SWIR imaging has been in use for temperature profiling of boilers and other equipment and for some aerial surveillance for over 30 years, only the ascendance of infrared laser diodes in telecom applications provided sufficient funding of the technology, especially sensors, to advance the use of this band significantly. For many years, the detector of choice for SWIR was a lead sulfide (PbS) photoconductor in a vidicon-style image tube, but now the pre-eminent detector material for SWIR is the solid-state indium gallium arsenide (InGaAs – pronounced in-gas) array even though most InGaAs detectors respond only to 1.7 μm. The complicating factor in the use of InGaAs arrays for imaging is that InGaAs itself cannot serve as the substrate for the readout circuitry so that the detector array must be bump-bonded to a matched readout array made of silicon. This leads to relatively large pixels compared to those in silicon imagers. The typical range for InGaAs sensors is 25–50 μm but pixels as small as 12 μm have been put into production. The large pixels force larger sensor sizes and raise costs for both the sensors and their optics but they also allow the inclusion of complex silicon circuitry for each pixel to support pixel-rate correction of sensitivity, dark current and fixed-pattern noise and for complex control circuits similar to those found in sophisticated silicon CMOS imagers. The fill factor of InGaAs sensors can be quite high because the circuitry is not in the same plane as the detector. In addition to area arrays, line scan sensors are also readily available. These were originally designed to be used as channel power monitors in telecom systems but also serve well in line-scan cameras. Low-light-level SWIR sensors have also been built, using an InGaAS layer as a photocathode in an electron-bombarded intensifier structure.

InGaAs is actually responsive from the visible through the SWIR range but the visible is blocked from detection because the InGaAs layer is grown on an indium phosphide (InP) wafer substrate. When the InGaAs is bonded to the silicon readout circuit, the InGaAs layer faces the silicon so incoming photons must pass through the InP to reach the InGaAs. Unfortunately, InP blocks everything below about 900 nm so the visible response is lost. Devices have been made in which the InP is etched off after bonding of the InGaAs to the silicon so that the response can reach below 500 nm. These devices are difficult to make and expensive but can provide reasonable response from visible through SWIR, minus the wavelengths blocked by the atmosphere, of course. InGaAs is generally run at room temperature for industrial and surveillance applications but cooling can improve image quality for scientific use. Cooled cameras must include a cold reference plane that can be placed in front of the sensor on command to provide calibration.

Germanium photodiodes are responsive over the full visible-SWIR range but have not found use in imaging because the lack of an insulating germanium oxide prevents fabrication of MOS transistors on the germanium wafer. Germanium could be bonded to silicon for readout like InGaAs but the assembly would have to be cooled due to the high dark current of germanium diodes at room temperature. Another possible way to use germanium is to deposit it on silicon so it can function only to generate charge while the silicon provides the diode and readout functions. Devices of this type can be expected to become more available as the process problems are worked out.

One difficulty in using any sensor in the visible and SWIR simultaneously is the extreme burden put on the optics. Ideally, lenses for this application should focus over the entire

400–1,700 nm band simultaneously. Unfortunately, such a design cannot be realized with any combination of known glasses so techniques such as diffractive elements would have to be employed. At this writing, no such lenses exist. Even if only the 900–1,700 nm band must be imaged, the design options are limited. The large pixels in InGaAs imagers relieve the design requirements somewhat but large sensors mean long focal lengths, leading to large lenses. In addition, the curvatures of the surfaces must be constrained so that the required wide-band coatings function properly. All of this leads to relatively high cost for lenses specifically designed for SWIR use, especially in applications requiring operation all the way to the 2.5 μm band edge. Lenses intended for visible use can be applied in relatively undemanding SWIR applications, especially where only a narrow band must be imaged as in telecom testing.

Objects at 400 K and above produce enough emission in the SWIR band to be detected in contrast to the background. This makes SWIR imaging useful for detecting heating due to thermal insulation defects, electrical connection problems, and even passage of heated fluids. This temperature range is common in industrial processing applications so SWIR imaging has found wide use in both on-line and off-line inspection and in examining machines and facilities for incipient failures. SWIR imaging in surveillance applications is enabled by nightglow from the sky, which is concentrated in the 1.3–1.8 μm band. Nightglow is sufficiently bright, even on overcast nights, to permit passive imaging.

10.3.1.3 Mid-Wave Infrared

The next atmospheric window, extending over the range of roughly 3–5 μm, is home for the mid-wave infrared (MWIR) band. Three detector types are used in MWIR cameras, indium antimonide (InSb – pronounced ins-bee), mercury cadmium telluride (HgCdTe, but usually abbreviated as MCT) and microbolometer. The first two are narrow-bandgap semiconductors operated while cryogenically cooled and are built as bonded assemblies like InGaAs but the third can be operated at room temperature and is built in silicon using a MEMS process. The performance differences for industrial temperature measurement applications are rarely significant. While cooled detectors provide better temperature resolution in thermal imaging applications, they are much larger, more expensive and more difficult to operate. Even so, microbolometers are found less often in MWIR applications simply because the manufacturers who could provide them concentrate instead on LWIR sensors and because the MWIR band is used mostly in defence and research applications where temperature resolution is paramount. In laboratory applications, the choice between InSb and MCT often depends on the total range of wavelengths required rather than solely on MWIR performance. InSb can detect photons to below 1 μm with appropriate optics but MCT is limited on the short wavelength end to about 2 μm. On the other hand, MCT can detect out to beyond 12 μm, while InSb extends only to slightly beyond 5 μm.

In addition to temperature measurement applications, MWIR cameras are very useful in narrowband imaging intended for detection of specific substances. This has led to their wide use in hyperspectral imaging systems in which area images are taken of many narrow spectral bands simultaneously to allow real-time detection of the presence of several target substances. In spectroscopic terms, the range of detection for the MWIR band is about 2,000–3,300 wavenumbers (cm^{-1}), which covers the detection of CH_x, various C double and triple bonds, Nitrogen bonds and several other important identifiers for organic compounds. No other band capable of imaging through the atmosphere covers as many individual bond types.

As a result, MWIR can be used for imaging uniformity, purity and distribution of a wide variety of organic compounds.

Lenses for the MWIR band are generally made of germanium and silicon and protective windows are made of sapphire (aluminium oxide). All of the usual lens types can be made – fixed focal length, switchable field of view and zoom lenses. Since the ratio of the high and low wavelengths to be covered is relatively small, correction of aberration can be fairly accurate. Diffraction-limited designs are possible. However, lenses containing germanium must be used with care because germanium can experience thermal runaway. As germanium gets hotter, its transmission drops so if it is used in situations where energy arrives at a rate faster than it can be dissipated, then the lens can overheat and suffer permanent damage. In industrial situations, it is important to avoid allowing radiation in the range of 1.5 μm and beyond to fall on a germanium lens even if the radiation is not used to form an image.

10.3.1.4 Long-Wave Infrared

Beyond the next atmospheric absorption band, from 7 to 14 μm, lies the long wave infrared (LWIR) band. This is the band traditionally associated with thermal imaging because it is the band providing the best temperature discrimination for objects around 300 k. The first thermal imagers, built back in the 1960s, used MCT cooled with liquid helium. As MCT quality and readout circuits improved, the operating temperature could be allowed to increase until now liquid nitrogen is sufficient. MCT still produces the best temperature resolution in this band, down to 15 milliKelvins, and it is still the detector of choice in the most critical applications but is relatively complicated to support and expensive. As a result, MCT has been supplanted in all but the most critical applications by microbolometer arrays.

A bolometer was originally pair of metal strips, one blackened and exposed to the radiation to be measured, and the other shielded. Incoming radiation heated one strip and the difference in resistance was measured using a Wheatstone bridge. Microbolometer image sensors are essentially of the same construction except that the resistance measurement is typically single-ended – there is no reference strip. Commonly, the absorbing material, which must also have a substantial temperature coefficient of resistance, is amorphous silicon or vanadium oxide prepared to present a black absorbing surface. The strip is silicon etched by chemical micromachining so that it is suspended over an open space. This construction prevents rapid conduction of heat away from the resistive element and improves sensitivity at the expense of lengthening the time constant of the measurement. The tradeoff choice for most imaging applications is to match the time constant to the imaging frame rate, which results in temperature resolution on the order of 50 milliKelvins. The primary advantage of microbolometers is their ability to operate over a wide range of temperatures up to 60°C. This simplifies cameras design substantially. However, to avoid serious temperature-induced drift in image performance, microbolometers are often stabilized at some selected operating temperature with closed-loop thermoelectric plates.

LWIR imaging is primarily used for viewing temperature differences of a object only a few tens of degrees different from the background. The widely-known night-vision applications involving detection of people, animals, vehicles and shelters by their thermal signatures are still the most common use for LWIR cameras. However, the temperature discrimination of these devices is sufficient to reveal small differences in heat transmission by insulation or variations in industrial process temperatures or heating due to friction in machinery and vehicles. These tasks all involve detection of emitted radiation but active illumination is also involved in some uses. In industrial settings, LWIR cameras are used to monitor CO_2 laser radiation, especially for its presence in places where it is not desired because stray invisible laser beams, especially at the typical power levels used in industrial processes, can be extremely dangerous. LWIR radiation penetrates smoke well because its wavelengths are not scattered as much as is visible light. This has led to the use of LWIR imaging in monitoring processes that generate smoke and in firefighting.

Because the detector elements in LWIR sensors are essentially mechanical, they are typically larger that the silicon photodiodes in silicon visible sensors. Pixel pitches are commonly 25–50 μm although pixels down to 10 μm have been produced. The minimum pixel pitch is also constrained, as it is in InGaAs sensors, by the need to bond the detector array to an underlying readout device, which, for microbolometers, can be just a multiplexer since the signal is always available on the detector elements. LWIR line scan sensors have also been made for thermal monitoring of moving objects and panoramic thermal imaging.

Optics for LWIR incorporate primarily germanium. Because of the well-developed set of applications for this band, the selection of optics is quite broad, including fixed, multiple-field and zoom optics, in addition to reflective optics with long focal lengths.

10.3.1.5 Very Long-Wave Infrared

Beyond 14 μm the goal remains object detection and measurement but the objects are those colder than 300 K. Since most radiation in this band is absorbed by carbon dioxide in the atmosphere (the "greenhouse effect"), observation typically occurs in space where the targets are discarded shrouds, fragments of old satellites and other objects either in orbit or on space trajectories. MCT works as a detector over the shorter-wavelength part of this band, which extends to some indeterminate wavelength one side or the other until the radiation is more often termed "terahertz". At the longer-wavelength end, more exotics materials like microstructured quantum wells, QWIPs and even quantum dots are being explored for use in improved detectors. Outside space or the laboratory, little is seen of VLWIR imaging systems. Wider application will need to wait until significant industrial operations are undertaken in atmosphere-free locations.

10.3.1.6 Two-Colour Infrared Imaging

Accurate temperature measurement requires detection of radiation at two wavelengths. If only one wavelength is used, some assumption must be made about the emissivity of the material being measured. For many common materials, the assumptions are good enough to produce temperature estimates that serve the intended purpose or to produce useful images of temperature differences. Viewing leaks of heat around doors in a house, for instance, does not require an absolute measurement, only an indication that some places on the surface of the house are warmer than others. For industrial process control, though, accurate, non-contact, temperature measurements are needed. This requires measurements at two wavelengths, so a ratio of signals can be taken that cancels out the emissivity factor. Of course, if emissivity changes with wavelength then errors will occur but for most materials emissivity varies little within the range of wavelengths typically used.

While two-colour optical thermometers are common, two-colour line and area sensors are not. Various attempts have been made to supply two colours using essentially the same techniques applied to colour imaging, which is considered in detail below. Two-colour imaging is more difficult than true colour imaging with silicon detectors because infrared detectors require silicon readout circuits. Attempts to stack two imagers of different materials have been only marginally successful due to the need for the longer-wave radiation to pass through the first detector and its readout circuit and due to the large separation between the positions of the two focal planes. The recent refinement of this is the development of a single device that has two stacked layers of QWIP materials tuned to different wavelengths. This design allows use of germanium optics with simpler designs and eliminates the need to operate the two focal planes separately. Cryogenic cooling is required with these sensors but the performance is promising and manufacturing at reasonable cost is feasible. Quantum dots have also been used in prototype sensors. If these can be made to work commercially, they can offer improved selectivity and some relaxation of the cooling requirements.

The simplest way to make two-colour detectors ought to be to use HCT with different fractions of mercury and cadmium in two stacked layers. Theoretically, the results should be excellent. Unfortunately, no method to reliably fabricate devices of sufficient quality has yet been discovered. Also under development are LWIR microbolometers layered with InGaAs, arrays with alternating pixels that respond to two different wavelengths and numerous other schemes, all concentrated around defence and security requirements.

10.3.2 Terahertz Imaging

What was previously known at the sub-millimeter microwave band (and considered part of the radio spectrum) has been moved to the imaging camp and renamed the terahertz band. This term roughly identified the band starting at the high end VLWIR and extending to down to a few hundred GHz – about 0.3–6 THz, corresponding to wavelengths of from 50 μm to 1 mm. Imaging at frequencies from around 100 GHz up has a long history. 94 GHz, for instance, has been used for passive imaging through fog because atmospheric attenuation is low at that frequency. The optics used are spherical structures of graded refractive index polyethylene foam called Luneberg lenses. However, the molecular bonds in materials have no signatures at this frequency so the images tend to show featureless shapes of objects. While this may be sufficient to monitor movement of aircraft around airport concourses, it is insufficient to support identification of smaller objects.

At higher frequencies, especially above 1 THz, the composition of objects begins to become visible in images. Unfortunately, the self-radiation of the objects has insufficient power to provide these images so active sources are required. Unlike 94 GHz, where high-powered sources using standard microwave components and techniques are readily available, terahertz frequencies have no easily-implemented generators. Quantum cascade lasers and other devices are used but better sources are the continuing subject of research. In addition, atmospheric absorption is very high in the terahertz band, so the applicability of terahertz imaging is limited to short-range situations.

Terahertz radiation can be detected with a variety of small-geometry antenna arrays or by wavelength-independent detectors. Pyroelectrics and thermopiles, for instance can detect radiation at any wavelength. Unfortunately, the sensitivity of these is too low for practical imaging systems. Microbolometer arrays can be used as can more esoteric detectors such as

Pockels cells, which convert electric field strength to polarization, essentially converting the terahertz image into a visible one. Research on better, faster detectors continues.

The varying signatures of organic materials have made terahertz imaging valuable in security screening. Clothing is largely transparent while metal objects are opaque and many plastics, including those used in explosives, have unique terahertz signatures. In addition, the relatively long wavelengths of terahertz radiation make detection of phase feasible. This may enable measure thickness or other properties not easily detected just by transmission amplitude.

Although many potential industrial inspection applications have been suggested, little implementation is yet in evidence. Aside from the cost and size of the detectors necessary for terahertz imaging, the relatively low resolution, fractions of a millimeter, stands in the way of qualifying this technique for detailed inspection tasks. Perhaps, there will be important applications in detecting materials below other materials, such as in laminates or in detecting organic contaminants in surface treatments. If an application seems intractable in the visible or infrared, considering the contrast the might be generated with terahertz illumination is worth considering.

10.3.3 Ultraviolet Imaging

Imaging in the ultraviolet is full of complications – more and more optical materials stop transmitting as the wavelengths get shorter until, finally, only reflectance works. But, because more and more image sensors are capable of UV imaging and because UV imaging reveals many interesting industrial, medical and scientific phenomena, the need for high-performance, cost-effective UV camera designs in steadily increasing. Successful execution of these designs requires careful consideration of the characteristics of optics, sensors and the radiation itself.

10.3.3.1 What is UV?

Ultraviolet is the range of electromagnetic radiation occupying the wavelength range from just shorter than the visible (about 400 nm) to about 10 nm, where the photons begin to penetrate materials enough to be called soft x-rays. The UV range is further subdivided by certain practical effects into the five bands in ➲ *Fig. 10.17*. The wavelength boundaries between these bands are based on photobiological activity and may vary in different references.

- UVA is the tanning and blacklight ultraviolet. It passes through most optical materials like visible wavelengths and can generally be detected by visible light detectors. Although it is invisible to humans, many insects use UVA images to identify certain plant materials, which are highly reflective in this band. UVA above 340 nm is commonly used to stimulate visible fluorescence in paints and the like.
- UVB is the sunburn and “solar blind” ultraviolet. Most UVB is blocked by ozone in the earth’s atmosphere. In small does, it produces vitamin D but more exposure causes sunburn and other skin damage. Any intense UVB must come from local sources. Solar blind imagers, which respond only to the UVB band, permit monitoring of local sources like hydrogen flames and electrical corona in daylight. Some local sources, like quartz halogen bulbs, can emit enough UVB to pose significant UV skin hazards.

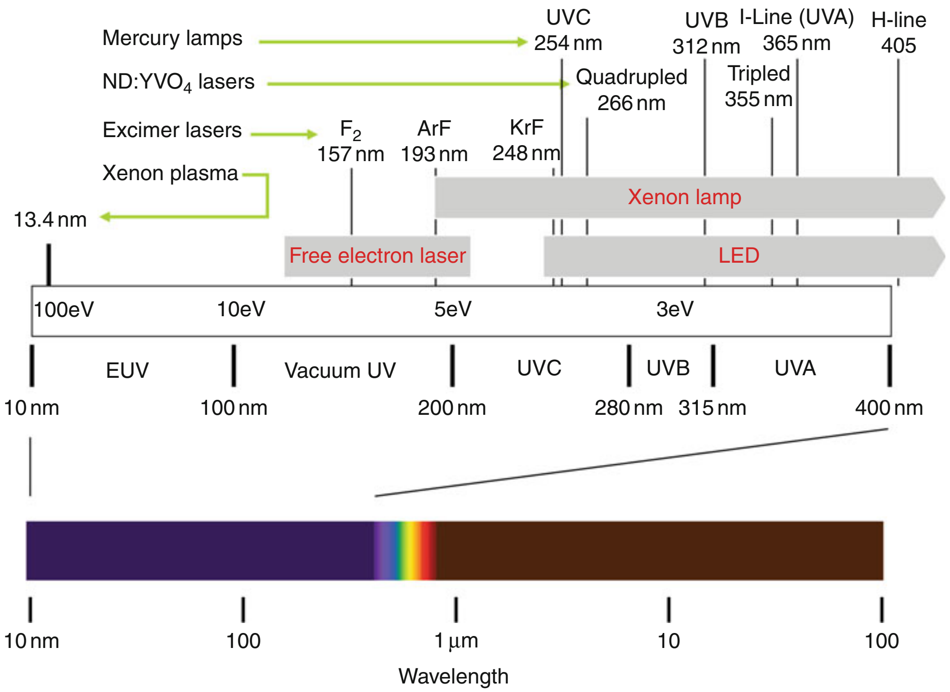


Fig. 10.17
Expanded view of the near-ultraviolet part of the spectrum

- UVC is the industrial and germicidal ultraviolet. Solar UVC is almost entirely blocked by ozone but large amounts of UVC are produced artificially, primarily by mercury lamps at emitting at 253.7 nm. This UV is used extensively for curing, sterilization and erasing EPROMS. Glasses largely block UVC so quartz or other materials are needed in optics for this band.
- Vacuum UV begins below 200 nm, where water vapour and oxygen begin to absorb ultraviolet strongly, relegating use of such wavelengths to evacuated systems. Absorption of similar magnitude continues down to about 10 nm by one or more atmospheric gases so this entire band is called vacuum UV.
- Extreme UV is the designation of the below-100 nm band to indicate that there are no transmissive optical materials useful below 100 nm.

Mirroring the infrared, as UV wavelengths move farther from the visible, fewer and fewer optical materials are available and managing the radiation becomes increasingly difficult and expensive.

10.3.3.2 Sensing UV Images

Fortunately, silicon can be made to work well as an ultraviolet detector across all of the UV bands. However, as the wavelength drops, so does the characteristic penetration distance of the radiation into the silicon before absorption occurs. Ultimately, the distance gets so short that surface effects on the silicon can draw a substantial proportion of the charge towards the surface instead of allowing it to travel inward to the collection point. The minimum distance, about 25 nm, occurs around the 254 nm wavelength. Treatments have been developed to provide an electric field in a favourable direction at the surface of the silicon to force the charge away from the surface where it is generated to a junction where it can be collected. These treatments can use very thin silver layers or chemisorption techniques but only work where the unoxidized surface of the silicon can be presented for treatment. As a result, they can generally only be applied to backside thinned scientific imagers.

Careful design of photodiodes can extend useful response below 200 nm for applications in spectroscopy but these design techniques are used primarily in line scan devices where the process constraints are generally more relaxed. Frontside area imagers with useful UV response below 350 nm are rare. In typical CCD imagers, the photosites are covered with polysilicon electrodes needed to move the charge. The polysilicon is thick enough to absorb essentially all radiation below 400 nm before it reaches the photodiode. In frontside CMOS imagers, the photodiodes are buried under multiple layers of silicon dioxide and plastics that severely attenuate the UV. Techniques have been devised to provide electrodes without covering the entire photosite or to replace polysilicon with less UV-absorptive materials to improve UV response. With these, the response can be pushed below 400 nm.

One time-tested technique for detecting UV radiation that cannot reach the silicon surface directly has been to coat the sensor with a transparent phosphor film that converts incoming UV into visible radiation that the sensor can readily detect. This technique, illustrated in ➔ *Fig. 10.18*, can extend the response of the typical sensor to below 200 nm. In general, however, these coatings will absorb some incident visible radiation, reducing overall quantum efficiency slightly and increasing response nonuniformity.

Because the reflectance of uncoated silicon can rise to more than 60% in the 200–300 nm range, the maximum possible external QE can be quite low. ➔ *Figure 10.19* illustrates the problem. Generally, the surface of the silicon is covered by silicon dioxide, but that helps little

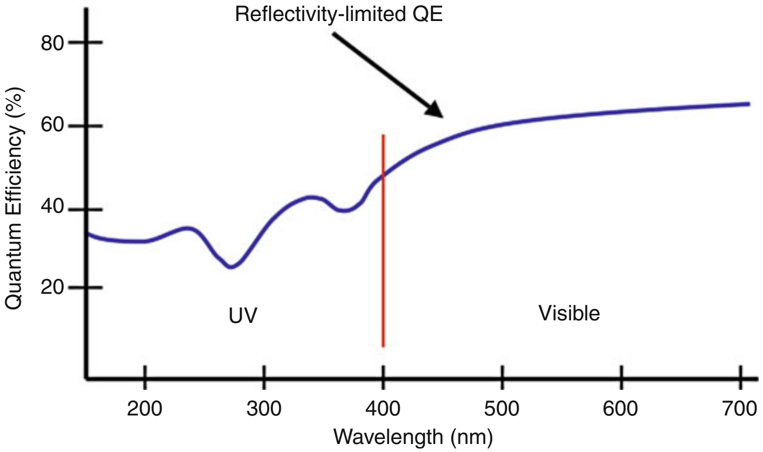

Fig. 10.18
Quantum efficiency of a silicon photo-sensor collecting charge all the way to the silicon surface as a function of wavelength

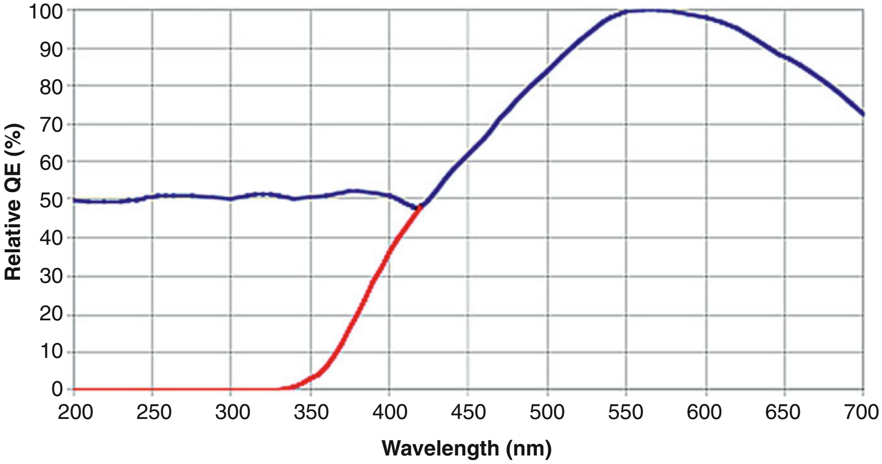

Fig. 10.19
Quantum efficiency of silicon sensors (which do not collect charge well at the surface) can be increased in the UV waveband by applying a UV-fluorescent phosphor (*Red curve*: uncoated silicon)

because it has an index of refraction too low to form a matching layer. Hafnium oxide (HfO_2) is a higher-index material that works well but is practical only in large area applications to backside-thinned sensors. With both field generation and antireflection applied, sensors with external QE in excess of 50% at 300 nm can be routinely accomplished.

Around 340 nm the photon energy equals the pair creation energy in silicon so that at shorter wavelengths two electron-hole pairs are generated and the internal QE exceeds 1. A second extra carrier pair is generated at 170 nm and an additional pair for each incremental 3.7 eV of photon energy. Since this extra charge does not improve the shot noise statistics, it can use up well capacity in sensors without delivering the S/N expected of strong signals. As a result, well capacity must be carefully considered for imaging in the VUV.

10.3.3.3 UV Optical Materials

Many transmissive materials used in visible optics will also transmit in the UVA band but exhibit a higher index of refraction. This displaces the focal plane forward in most commercial lenses, perhaps a tolerable accommodation. However, most currently manufactured commercial lenses do not transmit well in the UVA band because their antireflection coatings reject wavelengths below 400 nm quite strongly. This is intentional, intended to avoid fogging of film or bleaching of colour separation filters in still and video cameras. For best performance in the UV, optics must be carefully selected or specially built.

Lenses of many standard glasses can be used down to 300 nm if the AR coatings are designed for UV transmission. Below 300 nm, the choices become much more limited. The primary material used below 300 nm is fused silica, which has useful transmission to below 190 nm, which includes the ArF laser emission at 193 nm used extensively in semiconductor photolithography. Fluoride-doping can extend transmission of fused silica to nearly 150 nm. All of the other useful materials are crystalline and birefringent to varying degrees.

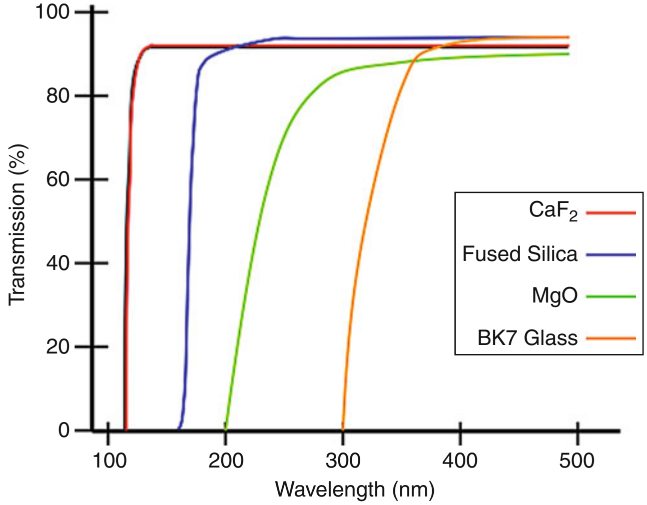

Fig. 10.20
Transmission through materials used in UV optical devices as a function of wavelength

Figure 10.20 shows some common materials that can be used below 200 nm. Other fluorides, chlorides and bromides are also useful. Since most of these are soft and hygroscopic, they must be handled very carefully and shaped using special techniques. Optical designs using these materials must include compensation for birefringence.

Reflective optics are also useful in the UV. Below 100 nm, they are mandatory, but even at longer wavelengths, they have a place. Two of the common reflecting materials used in the visible and infrared, gold and silver, perform poorly in the UV. Aluminium is the material of choice. Typical aluminized mirrors used for astronomy will reflect about 85% of UV light as long as they have not been coated with protective layers that absorb UV. Objectives for UV microscopy incorporating two aluminized surfaces have long been available. High-performance reflecting lenses can also be built in catadioptric designs with fused silica corrector plates but the lower wavelength limit on these is about 180 nm.

10.3.3.4 UV Imaging Applications

The most widespread applications for UV in industry are in the production and inspection of semiconductor masks and devices. Essentially all exposure of photolithographic resists used in defining patterns on semiconductor wafers use ultraviolet illumination. In the past, the 254 nm mercury arc lines was used, followed by KrF laser output at 248 nm for higher intensity. Currently, the vast majority of semiconductor production lines use 193 nm ArF laser sources. A substantial effort was made to implement systems using the 157 nm F_2 laser for finer geometries but the optical problems proved overwhelming. Even though the optical problems are much worse for even shorter wavelengths, it is still believed that a switch to the 13.4 nm wavelength from Xenon plasma must be accomplished to allow continuing reductions in device geometry. These same sources are also used for the production and inspection of the exposure masks and for inspection of fabricated wafers for proper geometries.

More generally, UV is used to image materials that fluoresce. Of course, in such applications the UV serves only as an illumination source and the actual images are made using the fluorescent output, usually in the visible, so no special optics are needed except perhaps a UV blocking filter. Images of UV emissions are valuable primarily in monitoring of dangerous situations such as the presence of hydrogen flames and the occurrence of electrical corona discharge from high-voltage transmission lines. Special-purpose cameras that provide UV images of the hazards and overlaid visual images for context have been developed for these applications.

10.3.4 X-rays and Gamma Rays

At the extreme short wavelength end of the spectrum lie the overlapping X-ray and gamma-ray bands. (➋ Chap. 12) Both x-ray and gamma rays are electromagnetic radiation but x-rays are generally produced by electrons falling to lower energy levels and gamma rays are produced by events in atomic nuclei. Perhaps the most important practical difference between these two types of radiation is that x-ray sources can generally be turned off with a power switch but gamma ray sources, radioactive nuclei, can't. X-rays cover the range of wavelengths from just below the extreme ultraviolet, about 10 nm, where the photon energy is about 100 electron Volts (eV) down to about 10 femtometers (100 MeV). This is a much wider range of wavelengths and energies than is covered by any other band. The gamma band extends from about 500 keV to beyond 500 GeV, also about six orders of magnitude. Radiation of these energies is generally referred to by the photon energy rather than wavelength, a practice that is followed here. However, in some circumstances, especially those involving diffraction imaging, the wavelength designation is more appropriate. The x-ray band is sometimes further split into two bands, with the lower energies designated as "soft" and the higher energies as "hard". The boundary is roughly 10 keV, corresponding to the highest energy photons that will penetrate only the soft tissues in the body.

Because of the extremely broad range of energies in these bands, a wide variety of techniques and materials must be employed to enable imaging. At the lowest energies, direct detection is possible but as the energies increase and the radiation becomes more penetrating, more complex assemblies of converters are required to stop enough radiation to create usable images in reasonable times. It is important to always keep in mind that the noise statistics of x-ray images, like any other images formed by photons, are limited by the number of photons initially absorbed. This is not confusing when the ratio of electrons produced to photons absorbed is less than one, as in visible imaging, but in x-ray imaging this ratio is often greater than one, perhaps up to several hundred. These large signals are the equivalent of adding gain, but they do not have statistics better than the original absorbed photons and, in many cases, actually have worse statistics because multiplication can be a noisy process. Thus, it is essential to assure that the photon flux is sufficient to provide the statistics needed to support the measurement required in each application. The simple amplitude of the detector output signal is not sufficient to assure that this requirement is met.

10.3.4.1 X-ray Absorption

To detect x-rays requires that arriving x-ray photons interact with some material capable of initiating a process that ends up with charge being stored in an image sensor. In all cases, detection requires absorption of incoming x-ray photons, a process that is strongly dependent on the atomic number (Z) of the material. X-ray absorption curves are generally expressed in terms of μ/ρ, the mass attenuation coefficient. This form is used to allow the curves of various materials to be compared on the basis of the mass per unit area of material intercepting the x-ray beam, a formulation convenient for both detecting and shielding calculations. If the density of the material is known, then a useful plot can be made of the attenuation length of the material. This is the distance an incoming beam will travel in a material as its intensity is reduced to 1/*e*, 37%, of the incoming intensity. The two examples of attenuation lengths, for carbon and lead, shown in *Fig. 10.21* convey the wide distance ranges involved.

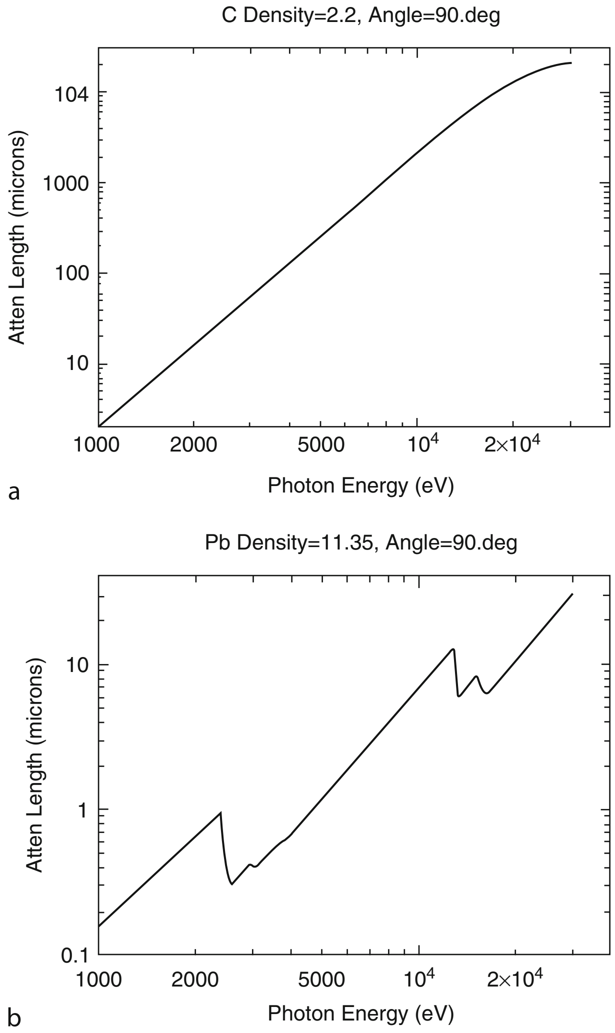

Fig. 10.21
Attenuation of x-rays plotted against photon energy (a) Copper (b) Lead. [3]

In order to produce an x-ray image, enough x-rays need to penetrate the material under examination for collection by an image converter or sensor. Generating and filtering an x-ray beam with the right mix of energies to produce sufficient contrast in the image while minimizing the dose absorbed by the material under examination is an art and science unto itself. A clear understanding of the materials to be examined and the methods by which x-rays are absorbed and scattered is essential to production of good image quality. Five interactions between x-rays and materials are possible as described below.

The Photoelectric Effect

When the energy of an x-ray photon is transferred to an atom, it dissociates by emitting an electron with a kinetic energy equal to the excess of the photon energy over the binding energy of the electron. The probability of this occurring is highest if the incoming photon energy is only slightly larger than the binding energy. This leads to the characteristic sawtooth shape of x-ray absorption curves as seen in ➲ *Fig. 10.22*, the curve for cesium iodide, a common x-ray to visible light converter. The absorption falls as the photon energy approaches the binding energy of electrons in a particular atomic shell and then rises rapidly at the binding energy only to slowly fall again. The fine-structured peaks occur where many several electron binding energy levels exist close together. The highest binding energy (resulting from electrons pulled from the innermost K shell) for all elements is 142 keV for Fermium 254 but most elements commonly used in x-ray imaging have K transitions in the range of 55–70 keV. The iodine K transitions

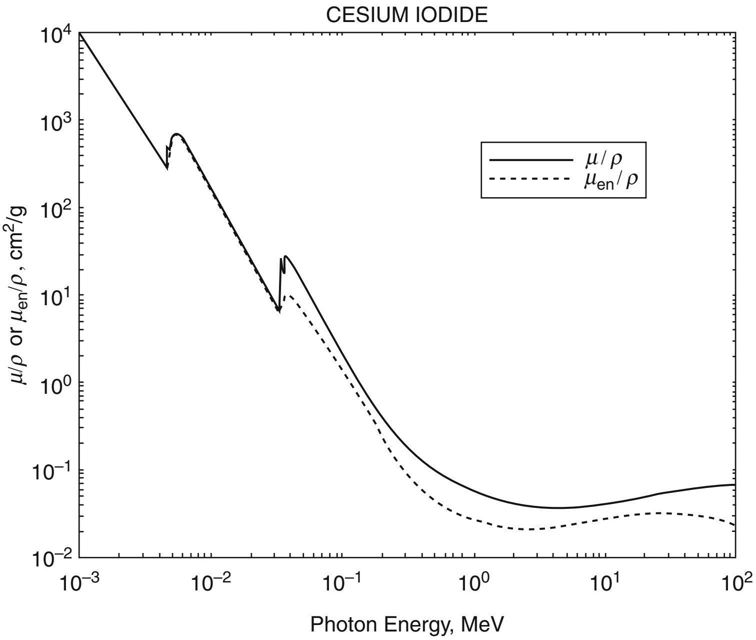

Fig. 10.22
x-ray Absorption curves for cesium iodide showing the characteristic sawtooth shape (See ➲ Chap. 12 for more examples) [4]

around 33 keV and the cesium K transitions around 35 keV are visible on the solid curve in ➲ *Fig. 10.21* as are the large number of L shell transitions in both elements around 3–5 keV. When x-ray photons knock electrons from their shells, other electrons fall into these, emitting secondary x-rays at the characteristic energy and generally these will be reabsorbed before leaving the material. The dashed curve represents the net effect of the reabsorption. The photoelectric effect is dominant in all materials at lower energies but provides a rapidly diminishing contribution to the total absorption above the K shell range.

Compton Scattering
In which the x-ray photon is not completely absorbed by an atom but glances off it at an angle, thereby transferring some of its energy to an ejected electron. After deflection, the x-ray photon energy is reduced by the amount of energy transferred to the ejected electron, which depends only on the deflection angle, not the type of material or the incident photon energy. The deflected photons are absorbed more readily than the incoming photons so most will not escape the scattering material. Compton scattering dominates in the part of the absorption curve where the slope transitions from steeply falling to flattening out where its contribution roughly equals the contribution of the next component.

Pair Production
X-ray photons with an energy of at least 1.022 MeV can produce electron-positron pairs if they strike the atomic nucleus. The positron is very short-lived and soon annihilates with an electron, producing two 511 keV secondary photons, which may then interact in other ways with the material or escape. Pair production can cause difficulties in imaging systems because the secondary photons can emerge from the material in any direction, causing a general background fog. Pair production dominates with x-ray energies above about 10 MeV.

Coherent Scattering
In coherent (or Rayleigh or Thomson) scattering, the incident photon escapes the atom without giving up energy but may emerge in any direction. This phenomenon contributes only a small fraction of the absorption and is confined to the energies of the photoelectric effect. Like pair production, coherent scattering adds to the overall background haze.

Activation
At very high energies, photons absorbed by an atomic nucleus may provide sufficient energy to activate a decay event. Since decay events may not occur immediately, the result of activation is that the nucleus becomes radioactive. The energies required are generally above 15 MeV – copper, for instance, can be activated at 16 MeV – and even at those energies, the efficiency is very low due to the small cross-section of the nucleus compared to the diameter of atoms. However, once a material is activated by x-ray exposure, the resulting radioactivity cannot be neutralized so energies this high should be avoided in industrial applications.

10.3.4.2 X-ray Image Converters

X-rays may be converted to charge for collection by electronic means using several conversion methods. These fall broadly into categories of direct, in which the electrons generated by the photoelectric effect are collected directly and indirect, in which the x-rays are first converted to visible photons and then to charge. At megavolt energies, more complex methods using build-up layers are used to assure that a sufficient number of x-ray photons are collected to assure statistical significance while providing properly-sized signals for detection but only the simpler methods used at lower energies are described here.

Phosphor Screens

The same screens used for film intensification can also be viewed by a video camera. Light leaving the screen is captured by a lens and focused on an image sensor. Since the collection of the light by a lens is much less efficient that direct film exposure by a screen, higher x-ray doses are generally required for electronic imaging with this arrangement. Nonetheless, this rather simple screen-camera combination has been used for many years in industrial imaging where dose rate is not a concern. To maximize the light collection, very fast optics (i.e. with low f-numbers) are commonly used and intensified imaging devices may also be employed.

One additional material, cesium iodide (CsI), is used for imaging with a camera. CsI has the advantage that it can be grown in a columnar structure, called acicular, much like a group of soda straws. This structure keeps any light generated inside its original column, directing the light to the end. As a result, CsI screens can be much thicker than granular phosphor screens resulting in an increase in x-ray absorption efficiency without loss of resolution. CsI also has a higher density than the phosphor materials, further adding to its x-ray stopping power.

Direct Converters

The photoelectric effect releases electrons into the material absorbing x-rays. These electrons will reattach themselves to an atom in the material sooner or later. However, if an electric field is applied across the material, then many of the electrons can be forced to leave the material before they recombine. If those electrons can be collected, they can form an image of the received x-rays. The material most commonly used for this purpose is selenium (Se) because it is a reasonably good x-ray absorber, especially at lower energies and because it is sufficiently conductive to allow collection of the liberated electrons. Substantial work has gone into the preparation of selenium for x-ray imaging so the image quality it can produce is quite high. Several other materials, most notably mercuric iodide (HgI_2) and lead iodide (PbI) have higher x-ray absorption than Se but both of these are more difficult to prepare in the large-area film forms useful for imaging.

X-ray Image Intensifiers

For most real-time (fluoroscopic) applications, screens optically coupled to cameras will not work because the demands on the x-ray generator tubes would be too high. In these applications, image intensifier tubes are most often used. In these tubes, the x-rays enter a vacuum envelope through a thin aluminium window coated with a CsI scintillator having a photocathode on its back side. Incoming x-rays make the CsI emit light, which is captured by the photocathode that then emits electrons into the vacuum. These electrons are focused by an electrostatic lens on an output phosphor which emits green light suitable for viewing by a camera. The output image is typically several thousand times brighter than a directly irradiated phosphor screen would be. This allows operation with much lower x-ray flux but, of course, produces noisier images because of the smaller number of arriving x-ray photons. Image intensifiers have round input surfaces with diameters in the range of 150–400 mm. The output phosphors are most often 25 mm circles.

10.3.4.3 Coated Sensors

Image sensors can be devised to detect light and convert it to charge or to collect arriving charge directly. Both of these techniques are widely applied in the detection of x-rays due to the need to adapt to the wide variety of converter materials available. When phosphors are used to convert x-rays to light, the direct deposition of the phosphor on the sensor array is optional. A very small separation, such as that resulting from a plastic protective layer, may still allow the phosphor to be close enough to the array to preserve the resolution. However, direct converters must be in electrical contact with the array so the interfaces between the converter and the silicon and the possibility of contamination, poor bonding and other deleterious effects must be very carefully controlled.

In addition, placing the converter directly in front of the sensor almost always results in the direct exposure of the array to x-rays because the converters rarely absorb all of the incoming radiation. In some cases, this can be alleviated by using a fibre optic coupler between the phosphor and the sensor. Unfortunately, couplers are limited to use in low-energy exposures and relatively short coupling distances with areas exceeding a 125 mm image diagonal only in extremely expensive equipment. As a result, the lifetime of the sensor under the expected exposure needs to be considered. The typical maximum dose before significant effect for CCD and CMOS imagers is in the range of 30,000–70,000 kRad. CID imagers are more radiation resistant, working often beyond 1 MRad.

Silicon Image Sensors

Standard CCD and CMOS sensors can be phosphor-coated and used for x-ray detection since they have SiO_2 passivation layers on top to protect the silicon from the phosphor materials. Sensors without microlenses are preferred because the microlenses have little effect on collection efficiency when the light source is in contact with them and the binder in the phosphor may react with the lens plastics. Of course, since x-rays travel in divergent paths, the sensor must be larger than the object to be viewed. Tapered fibre optic bundles can increase the input area somewhat but in any case the coverage for a single sensor is not likely to be more than about 125 mm. In very expensive cameras intended for x-ray crystallography, four or nine reducers may be bonded together to increase the input area but this produces extremely expensive assemblies.

The coverage area can also be increased through the use of buttable arrays designed with photodiodes that go right to the edge of the silicon on one or more sides. One, two and even three side buttable arrays have been produced to permit assembly of large x-ray imagers. Four-side buttable arrays have also been produced but these must be mounted on a second silicon wafer to provide paths for power and signal connections. By designing the support wafers so they are also buttable, very large imagers, with uses confined mostly to nuclear physics experiments, have been built and put in operation. Stitched arrays can also be made up to the size of full silicon wafers. Arrays up to 200 mm square have been made in this fashion using whole 300 mm wafers. X-ray sensitive line scan arrays of any length can be made using the same assembly techniques common in the production of contact image sensors.

Amorphous Silicon Panels

For large-area, radiation-resistant imaging arrays, hydrogenated amorphous silicon (aSi:H) is often the most suitable material. Amorphous silicon is the material used to make the switching transistor arrays in LCD panels. The transistor array alone, with the addition only of metal storage capacitors, is sufficient to provide the backplane functions for direct converters like Se. In panels coated with Se, some additional protection is required because the applied voltage used to drive the charge to the capacitors is 5 kV, however, these problems have been long solved. Se panels are most useful for radiographic applications because of the need for a recharge cycle after exposure. Selenium is most useful at lower x-ray energies, up to about 30 keV, due to its low atomic number, but it is in common use with sources up to 100 keV or so.

To use phosphors with amorphous silicon panels requires the addition of photodiodes to convert the light to charge. These are more complex than the panels for direct converters but are also in regular production. Both common phosphor screens and acicular CsI are used with these photodiode panels. Since the CsI can be made quite thick, up to 500 μm, the absorption of x-rays up to 70 keV or so can be high. CsI and the other phosphor screens can be readily used, with reduced efficiency, to image with industrial x-ray sources of up to several hundred kV. With added build-up layers, these panels are also usable with megavoltage sources for medical portal imaging and inspection of very thick materials. Unlike panels for selenium, phosphor panels can be readily operated as fluoroscopic imagers.

Amorphous silicon panels are much more compact than either optically-coupled or intensifier systems and have zero geometric distortion. However, the prime advantage of amorphous silicon panels is their radiation resistance, which extends to doses beyond 5 MRad.

10.3.4.4 Other Radiation Imaging

While radiation generated by x-ray tubes or, in rare circumstances, by gamma radiation from radioactive sources dominate the applications for imaging with penetrating radiation, other radiation modes and particles are useful in special cases. In nuclear imaging, for instance, an object is examined using its own gamma emissions through the use of a radiation collimator and a detector array. The collimator essentially restricts the radiation emerging from the object to angles that line up with the collimator holes, producing a one-to-one correlation between the position of the radiating source and a point on the sensor plane. A single exposure of this kind can only produce two-dimensional data but multiple exposures from different angles allow mapping the distribution of emitted radiation over a volume. Since emitted gamma rays will always have an energy characteristic of the emitting atoms, filtering out background radiation and secondary radiation from the object is straightforward. The most common detector for large areas is a scintillating sodium iodide (NaI) crystal monitored by an array of photomultipliers. This combination works well because the rate of arrival of gamma rays at the detector is usually quite low, generally no more than a few thousand per second. Cadmium zinc telluride (CZT) is also used as a detector for smaller areas. Because the radiation levels are low, the time required to accumulate an image containing enough photons to define the areas of interest can be many minutes, even hours in some situations.

The only particle used regularly for imaging is the neutron. The neutron is useful primarily because the cross-section for its absorption is so different, element by element, than for x-rays. With x-ray, the cross-section is roughly proportional to atomic number but for neutrons, cross-section is determined by the much more complex nuclear potential, which varies substantially depending on the energy of the incoming neutron. The scattering cross-section is especially high for hydrogen and low for metals, making neutron radiography especially useful for examining organic materials inside metal casings. Neutrons are always detected as a result of the decay products (gamma rays and alpha particles primarily) resulting from their absorption into an atomic nucleus. This means that as neutrons are detected, the detection material wears out. At some point so much of the detector will have been converted to the element resulting from radioactive decay that the original neutron-stopping element will be too low in concentration to be useful. Materials with large cross-sections that also emit light include lithium, gadolinium, boron and a large number of both solid and liquid organic scintillators. The most commonly used detector in industrial applications is a layer of gadolinium oxysulfide used as a film intensifying screen, a convertor for silicon detectors or as the input phosphor in image intensifiers.

Proton radiography, after languishing for decades after its initial development in the early 1970s, has again raised interest. For protons, the advantages are that the deposited dose for image quality comparable to x-ray images is much smaller than the x-ray dose and that the absorption length of protons can be accurately tuned by changing the proton energy. Thus, lower-energy protons (<1 GeV) are suitable for examining soft tissue and other organics, while high energy protons (up to 50 GeV) produce high-quality images of thick metal objects. Of course, since protons are charged particles, they can be focused allowing small objects to be examined at high resolution. Proton imaging detectors use phosphor screens of CsI and rare-earth orthosilicates.

10.4 Sensor Performance Measures

The capability of an imaging system to provide the information needed to a computer or a viewer depends fundamentally on the quality of the data that the image sensor can produce. In some applications, reproduction of fine detail is paramount. In others, accurate detection of colour is critical, in still others, precise rendering of small changes in brightness. Success in most applications requires some minimal level in a variety of performance measures so that the cumulative effect of limitations in each measure still permits extraction of the necessary image features. Although the task of converting a flat optical image to an equivalent electronic representation seems straightforward, implementation of this function involves a large number of choices and limitations that should be made with careful regard to the application.

Unfortunately, there is no standard yet for the acquisition or presentation of sensor performance data. Much effort has been and continues to be expended on such standards development but the results, while useful, still fall far short of facilitating universal direct comparison of the performance of one sensor against another. As a result, those faced with selecting sensors must understand sensor performance in terms of individual factors as they relate to specific sensors to support calculations that can lead to satisfactory sensor selection.

10.4.1 Spatial Resolution

Essentially all image sensors now in use break the image plane up into discrete areas, generally approximating rectangles, often squares. As a result, the signal from the sensor is not continuous, but rather sampled. While sampling has only a small effect on the signal when intensity variations in the image occur only over many samples, the effect on the signal when the signal changes by large amount from one sampling location to the next can be substantial, producing results to do not resemble the original intensity variations. Understanding these effects requires a brief discussion of sampling theory.

If a pattern of intensity is projected on the sensor which is a series of parallel black and white lines of equal width and spacing as shown in ➲ *Fig. 10.23*, then the distance between the

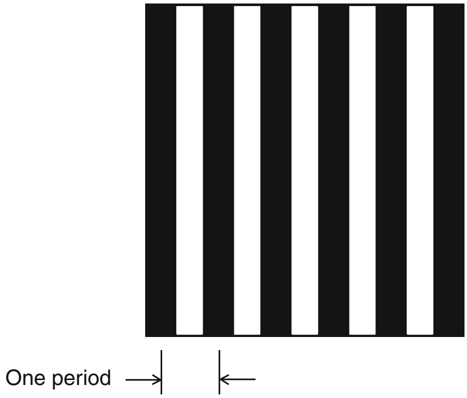

Fig. 10.23
Pattern consisting of parallel *black* and *white* lines of equal width and spacing

centre of one black line and the next (or one white line and the next) is called the *spatial period.* The combination of one black line and one white line is called a *line pair.* Comparing the distance across one line pair (equal to the spatial period) to some standard linear measure, typically 1 mm, produces the ratio of line pairs per millimeter, abbreviated lp/mm and called the *spatial frequency.* Using the same calculation, the maximum spatial frequency that can be detected by an image sensor is just the extent of two sampling locations in the sensor matrix compared to 1 mm. For instance, if the sampling locations are 10 μm apart, the two of them cover 20 μm or 0.02 mm and 50 of these pairs will fit in 1 mm. Thus, the *limiting resolution* of the sensor is 50 lp/mm.

10.4.1.1 Aliasing

In sampling theory, the spatial frequency corresponding to the limiting resolution is called the *Nyquist limit.* Any spatial frequency presented to the image sensor above the Nyquist limit will produce a signal, but it will be an *alias*, that is, a difference frequency between the spatial frequency of the illumination pattern and the Nyquist limit of the sensor. For spatial frequencies in the image just above the Nyquist limit, that alias will have a low spatial frequency that appears in the sampled data as if it were real information at that low frequency. Since the alias has a frequency between zero and the Nyquist limit, it overlays the true image information and cannot be removed by computation once it is generated. It is very important then to minimize the generation of aliases by restricting the spatial frequencies in the image to those below the Nyquist limit. Controlling lens resolution or adding spatial filters, called anti-aliasing (AA) filters, are typical methods of restricting alias generation.

10.4.1.2 CTF and MTF

When a black and white set of bars (a square-wave pattern) is imaged on the sensor, the amplitude of the signal generated will depend on the spatial frequency of the pattern. Plotting the signal amplitude as a function of the pattern spatial frequency produces a curve called the *contrast transfer function* or CTF. If the pattern image on the sensor retains full black and white at all spatial frequencies, then the shape of the CTF curve will be the sinc (sinx/x) function as shown in ➋ *Fig. 10.24*. The horizontal axis is the number of cycles (black/white line pairs) that is imaged on each sampling location. The one (full amplitude) occurs at low spatial frequencies where it is assured that each sample is either black or white so that the difference between these is 100%. The zero occurs when exactly one pair fits in each sample location because the signal from all samples will be the same, the average between black and white, so that the difference between the largest and smallest signals from the various samples will be zero. Between one and zero, the situation is more complicated.

Consider the situation when the pattern bars are exactly the same width as the sample spacing. As ➋ *Fig. 10.25* shows, there are many possible resulting signals, from a full-amplitude square wave to a flat 50% grey level, depending on the relative position of the bars and the sampling locations. Although the signal amplitude is a linear function of the relative phase, the calculated theoretical amplitude when the bars and sample spacing just match (0.5 cycles per sample on in ➋ *Fig. 10.24*) is about 63%, not 50%.

In practice, the plot of signal amplitude vs. spatial frequency is often called the *modulation transfer function* or MTF. True MTF measurements require that the test target bars be sinusoidal in transmission, not square wave. In most practical systems, the distinction is not significant because of the effect of the camera lens on a square wave target. The MTF of the lens is typically limiting compared to the theoretical CTF of a sampling device so MTF and CTF can be used interchangeably with little risk of significant error. In fact, in real systems it is important that the lens or some other optical element limit the MTF to minimize aliasing in the sampled image.

➋ *Figure 10.26* illustrates the situation when the lens is not limiting. In the figure, the entire curve to the first zero is shown. The top curve (blue solid and dashed) shows the natural curve

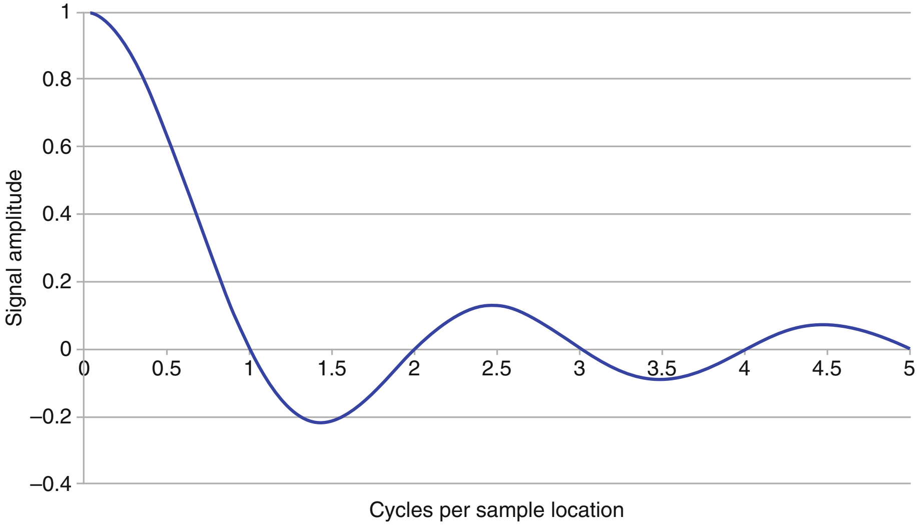

Fig. 10.24
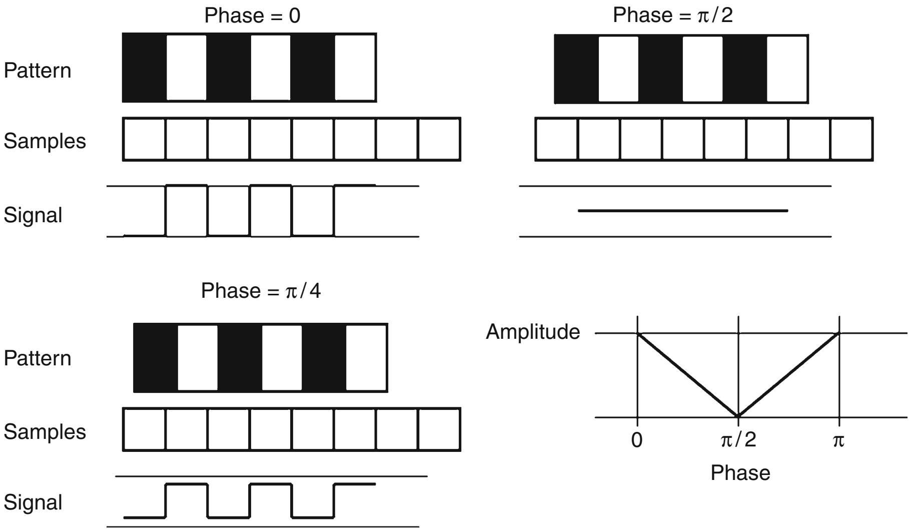
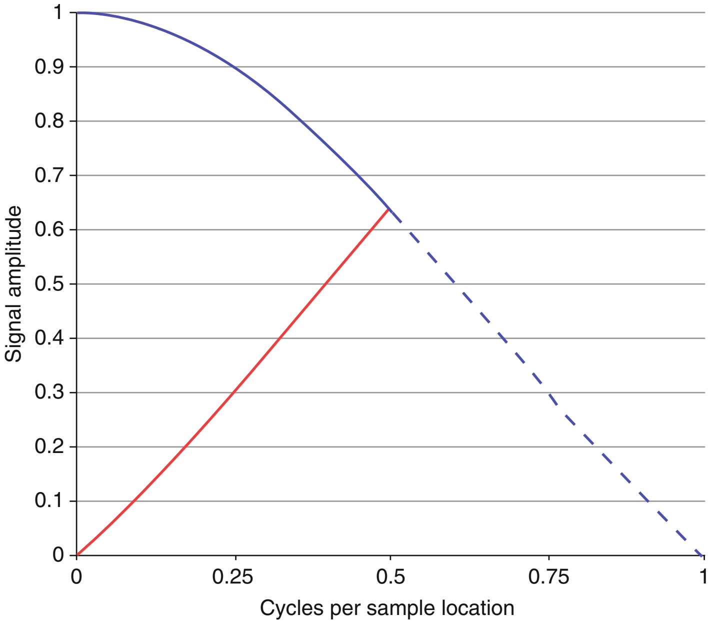
The function sinc(X) (= sin(X)/X) for positive values of X



■ **Fig. 10.25**

Pattern bars of exactly the same width as the sample spacing. The resulting signal depends on the phase (i.e. relative position of the bars and the sampling locations)



■ **Fig. 10.26**

Aliasing when sampling a bar pattern. The solid blue curve indicates the amplitude when the sampling frequency is above the Nyquist limit. When under-sampling occurs, the curve is effectively "folded" about a vertical line (cycles per sample = 0.5); the dashed blue maps into *red curve*)

and red curve shows how the alias from bars with spatial frequencies above the sampling cutoff fold back into the real frequencies of the sampled signal. If the bars are permitted to arrive at the sensor with full amplitudes beyond the sampling cutoff, the amount of aliased signal is a significant portion of the signal as a whole. The image signal becomes even more confused when frequencies above twice the cutoff (1 sample per cycle) are allowed through because the aliases generated there are negative, that is, reversed in phase, from the bars that generate them.

10.4.1.3 Aperture Effects

The curves in previous section apply only when the sampling areas are contiguous, that is, when the fill factor in an image sensor is 100%. When the fill factor is lower or the aperture is smaller than the sample interval, the aliasing situation gets worse. Essentially, the x-axis scales with the reduction in fill factor. So, for instance, if the fill factor is 50%, the bar width equals the aperture at the 0.25 point on the spatial frequency axis. This increases the amplitude response to about 83% at cutoff but the curve will fold three times before reaching the first zero rather than once. Controlling the spatial frequencies reaching the sensor becomes even more important when the fill factor of the sensor is low.

10.4.1.4 Resolution Nomenclature

Resolution can be expressed using several absolute and relative terms. The choice depends on the application and situation. The absolute term typically used is line pairs per millimeter (lp/mm) in the object plane. Measuring resolution in this way allows direct relation of the measured resolution to feature sizes in object to be viewed. The most widely used test chart intended for object-plane use is the US Air Force 1951 Resolving Power Test Target shown in ➲ *Fig. 10.27*. The original target has square-wave bars (white on black) at various spacings. The spacings change by a factor of two for each group (large numbers) and by the sixth root of two for each element in the group. Group 0, element 1 is 1.0 lp/mm. The original chart covered 0.25–645 lp/mm but larger, lower resolution charts have been made for use in outdoor settings.

Resolution may also be expressed in lp/mm either on the image plane or on the object plane (field-of-view). Since resolution is more often useful when related to field of view, it is common to see an expression of resolution relative to an image dimension. Originally, the universal expression was TV lines per picture height (TVL/PH), now often abbreviated just TV Lines (TVL). Since this is a relative measurement, the test charts can be any size and the lines can be any width as long as reference marks on the chart are fitted to the height of the image. A typical chart of this type, the EIA 1956 Resolution Chart, is shown in ➲ *Fig. 10.28*. This type of chart has now also been adopted for characterization of digital still cameras where the resolution is expressed as Lines per Height (LPH). These figures can be converted easily to lp/mm at the image plane by dividing the resolution number by twice the height of the sensor in mm.

10.4.2 QE & Sensitivity

The purpose of an image sensor is to convert incoming photons into an electrical signal. The first step in this process is conversion of photons into charge. This is generally accomplished by

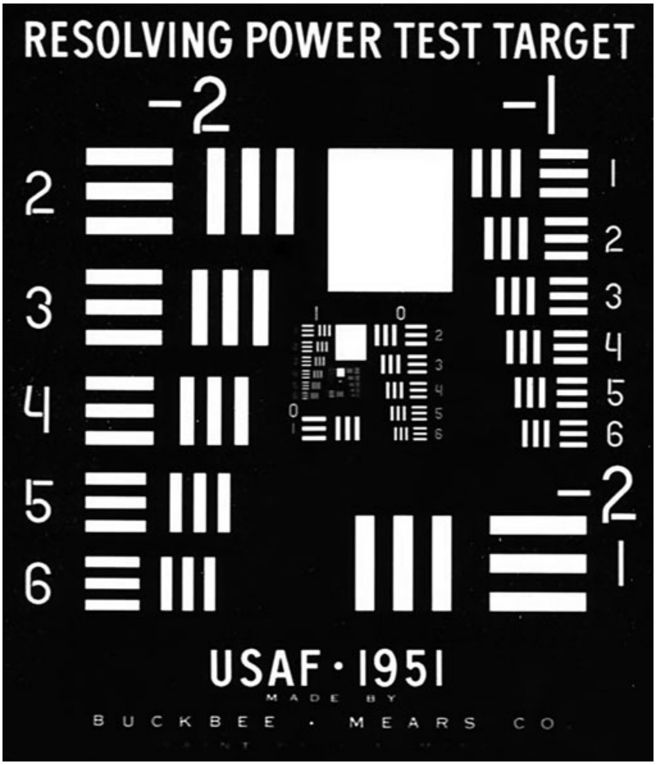


Fig. 10.27
US Air Force 1951 resolving power test target [5]

capture of photons in a photodiode in which electrons or holes are liberated in proportion to the arriving photons and collected for readout. The ratio of the number of collected electrons (or holes) to the number of incoming photons is called the *quantum efficiency* (QE). If a sensor can convert every incoming photon into one collected charge, then the QE is 100%. Unfortunately, some photons are lost because they are reflected from the surface of the sensor or absorbed outside the photodiode or cancelled by effects caused by the wave nature of light. Some charge is also lost, by recombination before it can be collected or by moving to an isolated area under the influence of electric fields or even by arriving at the collection point too late to be counted. The net result is that the QE is always less than 100%.

Due to variations in the photon absorptance of the sensor material and the performance of various layers on top of the photodiode with photon energy, QE is usually expressed as a function of wavelength. Each detector material has an underlying characteristic QE curve that is modified by the thickness of the device, the characteristics of overlayers and various enhancement processes that may be applied. Using silicon as an example, *Fig. 10.29* shows the typical internal QE of silicon in its top curve. This is the QE that would be measured if all of the incoming photons could be delivered to the photodiode in a place where they could generate collectable charge. This curve is essentially the absorbance of a 1 mm thick layer of silicon.

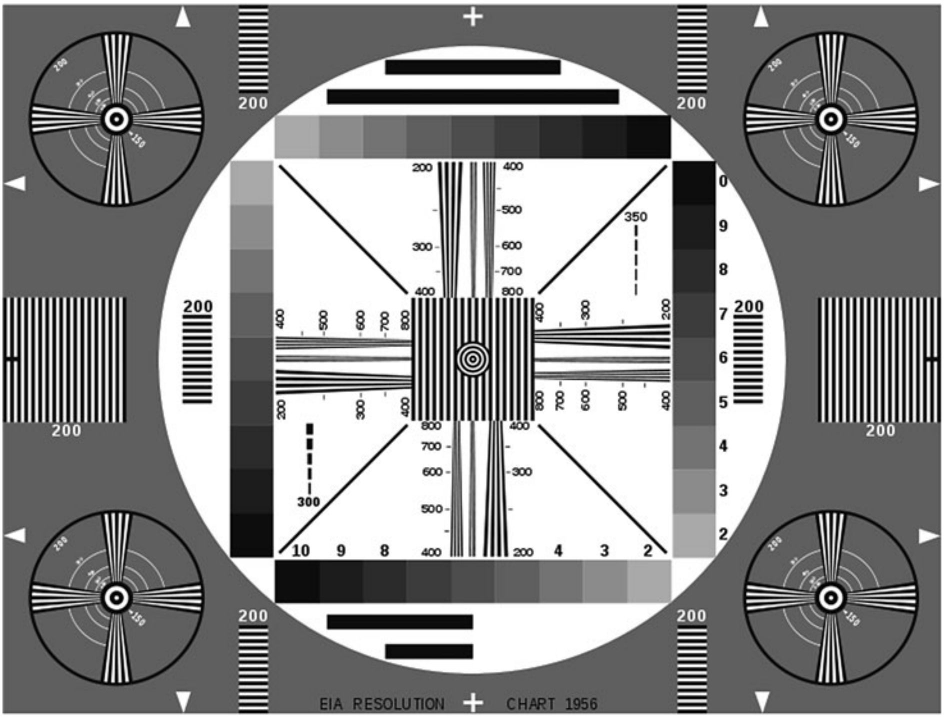

Fig. 10.28
EIA 1956 resolution chart [6]

In a typical sensor, many factors intervene to reduce the QE. *Figure 10.29* shows typical effects in an interline CCD sensor but similar effects are present in other sensors as well. Losses occur due to the reflectance of silicon. In devices with thin enough top oxide to permit use of an anti-reflectance coating, ripples in the QE curve will generally be present as a result of optical interference in the various overcoat layers. The QE is further reduced by loss of photons that strike the aluminium shields and conductors on the sensor. This is the effect of fill factor. Some charge may be lost by conduction to structures intended to provide isolation or to prevent overloads. Finally, the spectral extent at shorter wavelengths is typically reduced by absorption in the overlayers and recombination of charge generated too close to the surface to be collected. At the long wavelength end, the limited thickness of the photodiode will prevent a larger and larger proportion of the photons from being absorbed as silicon becomes increasingly transparent with wavelength. Of course, each of these problems suggests it own solution and many of these have been implemented in sensors where higher QE is required.

Some sensors report QE numbers greater than 100%. Two ways this can occur are by detection of very energetic photons or provision of charge gain on the sensor. Energetic photons, those with more than about 3.6 eV of energy in silicon, will generate more than one electron per photon due to ionization. Charge gain can be provided through the use of impact ionization shift registers. However, although these techniques can increase the signal amplitude, they do not improve the statistical noise in the signal itself so even in such devices converting every photon into collectable charge remains important.

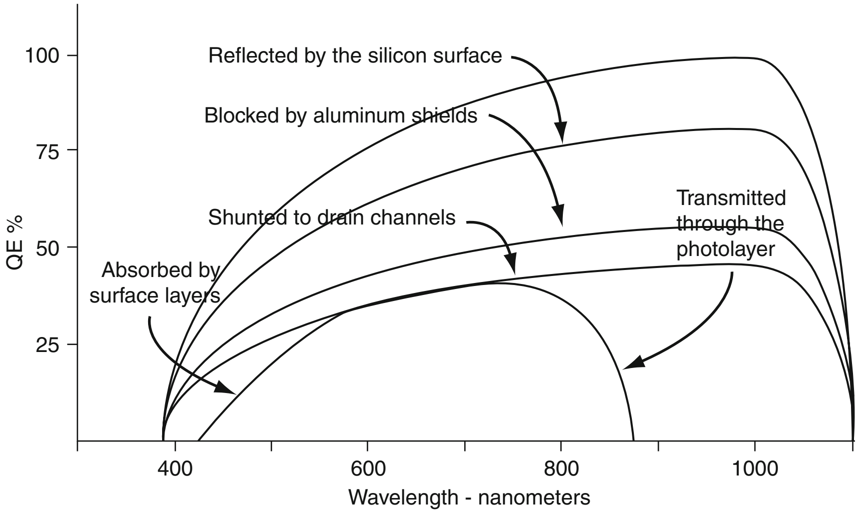

Fig. 10.29

Quantum efficiency of silicon (*top curve*). This is the QE that would be measured if all of the incoming photons could generate collectable charge in a photodiode. Other curves show the performance of various layers above the photodiode

The effectiveness of the photon to charge conversion may also be expressed by *sensitivity*, the ratio of the generated photocurrent to the incoming optical energy expressed in Amperes per Watt (A/W). Equivalently, this measure may be expressed statically in Coulombs per Joule (C/J). The significant difference between the QE expression and the sensitivity expression is that in sensitivity the photons are each weighted according to the energy they carry using the expression e=hc/λ. This means that if the QE is the same at two different wavelengths, the sensitivity will be higher at the longer wavelength. Equivalently, if the sensitivity is equivalent at two different wavelengths, the quantum efficiency will lower at the longer wavelength.

10.4.3 SNR and Dynamic Range

Signal-to-noise ratio (SNR) and dynamic range (DR) are related but must be carefully distinguished to be used and compared properly. SNR is a spot measurement, that is, it is taken with a specific signal level while dynamic range is a multi-point measurement that has meaning only when taken as the ratio of signals at two different levels. To see the difference the makeup of the output signal of a sensor must be understood at different signal levels. For simplicity, a sensor that responds linearly to input photons from zero to some maximum (the saturation exposure) is assumed.

When the input photon level is zero, the sensor signal will consist solely of the sum of noise components either generated within the sensor, such as reset or transistor noise or shot noise from dark current, or received from the outside, such as clock, conducted power supply or radio frequency noise. This total is the dark noise as shown by the line labelled "Sensor noise" in ❯ *Fig. 10.30*. Since the signal from the photon input is zero, the SNR is also zero. Note that, strictly speaking, the SNR with no signal cannot be expressed in decibels. As the exposure rises,

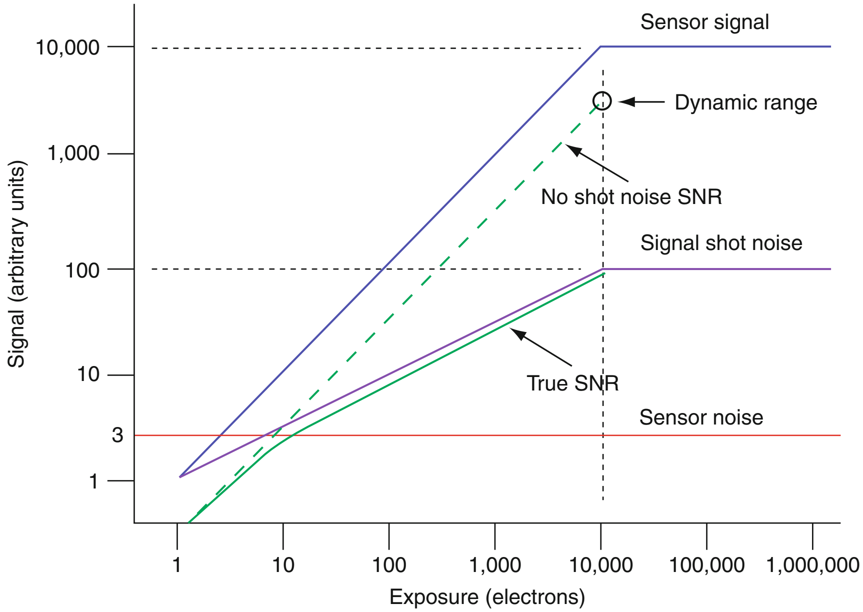

Fig. 10.30
Noise and signal components which taken together define the sensor output

the signal rises with it until the maximum signal handling capacity (usually sensor full well) is reached.

It is often assumed that the SNR of a sensor is just the signal divided by the sensor noise. This is unfortunately not true, since the signal consists of discrete packets, photons or electrons. This characteristic gives rise to shot noise, a statistical variation in the actual number of photons or electrons captured when some average exposure is measured. Since photon arrival follows a Poisson distribution, the shot noise is simply the square root of the signal . That is, if the average number of photons arriving at the sensor is 10,000, then the standard deviation in the arrival number is 100. Thus, at exposures above the square of the sensor noise, shot noise predominates. Below this point, the SNR curve parallels the exposure curve while above this point, it parallels the square root of the exposure curve as does the shot noise itself.

Shot noise is often the limiting factor in detecting low contrast objects. Generally, two signal amplitudes must be separated by at least three standard deviations of the noise to be reliably discriminated. If a signal 90% of maximum is generated using the sensor of *Fig. 10.30*, then the signal is 9,000 electrons and the standard deviation is 95 electrons. Three times this is 285 and 9,000/285 is about 32. This means that that maximum number of separate levels that can be reliably discriminated with this sensor is only 32. This implies that if 256 levels were needed (8 × 32) the maximum signal would need to be at least 8 × 8 × 9,000 or 576,000 electrons. Of course, these signals and the noise are measured on a per sample basis so detection can be readily improved by averaging over a number of samples either spatially or in time.

Dynamic range is a much simpler calculation because the denominator in the calculation has no signal and therefore no signal shot noise. In the sensor in *Fig. 10.30*, the maximum signal is 10,000 and the noise is 3. The DR is 10,000/3 or 3,333. This is much higher than the

SNR but the utility of a signal equal to the noise at the low end, where the SNR is only 1, must be considered in light of the application. A requirement for ten times the noise is not uncommon, reducing the usable DR to more like 300:1.

10.4.4 Speed

Just as the number of sampling elements in an imager determines its spatial resolution, the frame rate of the imager determines its temporal resolution. Frame rate is important whether a single object is to be viewed multiple times for monitoring of changes of individual objects are imaged only once as in high speed industrial inspection. Calculating frame rate is rarely as simple as it seems. In the simplest case, it is only necessary to multiply the number of sample elements in an image times the time per sample period and add any dead time in the scan cycle to determine the frame period. The frame rate is then the inverse of the frame period. However, complications arise even in the simplest situations so the details of the scan cycle must be knows to assure a propoer calculation.

10.4.4.1 Line Scan Rates

In the earliest line sensors, the photodiodes were active all the time and no charge integration took place in the sensor. Readout simply consisted of sequentially connecting to each of the photodiodes and reading the instantaneous current. Although, this configuration requires a lot of illumination, readout is very simple and the speed is determined simply by how long each photodiode must be interrogated to produce an integrated signal with the necessary S/N. In addition, the exposure of the photodiodes in imagers of this type is not simultaneous. Each pixel is sampled in a different time interval, so moving objects appear as a series of tilted lines. Whether this is significant or not depends on the application.

When the integration function was moved to the sensor, the timing rules became more complicated. The important distinction between the two types of line scan imagers is the capability for storing an integrated signal in a location separate from the photodiodes so that a new image acquisition can be started during the readout of the previous image. Those without separate readout will produce tilted lines similar to those from the sampled photodiode scanners except that the exposure periods are overlapped rather than sequential. In this case, the line scan interval is determined solely by the time required to read out all of the storage locations unless the exposure time is set longer than the minimum scan time. In that case, the readout time will be almost the same as the exposure time. To avoid tilted lines, a strobe may be used which illuminates all the photodiodes simultaneously and then permits scanning in the dark. The scan time is then the strobe time plus the calculated time to read out all of the photodiodes.

In sensors with storage structures separate from the photodiodes, the integrated photodiode signals are all transferred at once into the storage structure and then the contents of the storage structure are read out while the next exposure takes place. This arrangement eliminates tilted lines even with continuous illumination. The scan time is still some minimum set by the number of photodiodes and the clock rate that will be increased if the exposure used is longer than the minimum.

In all cases, repetitive scanning will guarantee the shortest periods. Individual triggered scans often add setup time to the cycle. Attention to determining all elements required to complete a timing cycle for a particular sensor or camera are critical to understanding the actual speed that may be attained.

10.4.4.2 Area Scan Rates

Fundamentally, an area scan is just a sequence of line scans with some time added between lines and some time added before or after the complete scan. As with line imagers, some imagers are still arrays of photodiodes without integration. Similarly high illumination levels are required and images of moving objects suffer similar tilting. Most imagers use one of the schemes described in earlier sections so appropriate precautions should be taken to assure that the image content is as expected. As with line scanners, the scan period in area scanners has some minimum that may be increased by long exposures or by the necessity to operate in an individually triggered mode. Full knowledge of these effects is similarly important.

Many area scanners offer options for region of interest (ROI) scanning or binning to provide tradeoffs of field of view or resolution for speed. Rarely is there a direct inverse relationship between the reduction in elements scanned and speed because of the fixed times that have to be added to lines and frames regardless of the ROI or binning settings. In some sensors, these added times are even longer in the reduced area or resolution modes than in the full modes so, again, a complete understanding of the timing requirements of each needed mode is essential to avoid erroneous assumptions about the efficacy of the tradeoffs.

10.4.4.3 Temporal Limitations

While complete isolation between sequential frames is desirable, some possibilities for interframe correlations need to be considered. The most common interframe effect is *lag* or image persistence. While the amount of one image left behind to become part of the next is small in modern imagers, it is not necessarily zero. In some imagers, it is still on the order of 1% so if large variations in brightness are expected from one frame to the next great care should be taken, perhaps even by scanning dark frames, to avoid leftover signals. Lag can be especially severe in some imagers if the sensor is allowed to saturate because saturation can drive charge into areas not used for normal imaging. Upsets caused by this stray charge can persist long after one frame. If the charge is forced into traps (undesirable energy levels in the bandgap of semiconductors), typically by very large multiples of the saturation level, it can emerge seconds or even hours later.

Interframe problems are not limited to simple retention of image signal. Charge in the wrong places can change the operation of transistors in the signal chain, modulating gain or offsets or even affecting noise performance. In thinned sensors, bright spots can cause localized heating, raising dark current. In some sensors, even moderately oversaturated spots can interfere with charge transfer in later frames or pull down power buses. Many of these effects are small but only testing under real conditions can assure that they are insignificant in a particular situation.

10.4.4.4 The Effect of Taps

Taps are additional outputs on image sensors intended to permit increases in readout speed by providing parallel readout of sections of the sensors. In a simple case, the sensor might be split into left and right halves with each half provided with an output. To a first approximation, this will double the readout speed. Three taps triple the speed, four taps quadruple it and so forth. However, suppose that a sensor with left-right taps is to scan an ROI of half the sensor height and width centred on the sensor as in ➋ *Fig. 10.31*. It is clear that the speed can be roughly doubled by reading out only those lines in the ROI. However, along the rows, there is no gain in speed because the scanning of the taps runs in the same sequence on all taps. That is, columns 1 and 5 must be read at the same time. So too, 2 and 6, and so forth. As a result, all columns must be accessed at the normal clock rate, the same situation that would occur if no ROI had been designated in the horizontal direction. Only if the ROI is completely contained within one tap (and is smaller than the number of columns serviced by the tap) is any speed improvement realized. Of course, if the taps can be separately addressed, a very rare feature, then a speed advantage may be available.

10.4.5 Causes of Degradation

The possible ways that the transformation from an optical pattern of photons arriving at the sensor into an electrical signal can be adversely affected number in the hundreds. Fortunately, most of these factors are subject to control or improvement by good engineering. A few are not – shot noise, for instance – but those which are should be carefully considered lest they degrade the signal sufficiently to render it useless. What is important is to understand where in the build-up of a system each of these factors can be influenced.

Some may occur inside the sensor and be uncorrectable outside it. Others might also occur inside the sensor but be correctable by later processing. Usually, the later in the chain that a negative effect can be corrected the better because the resources required to implement correction are generally more accessible and flexible downstream. For example, reducing

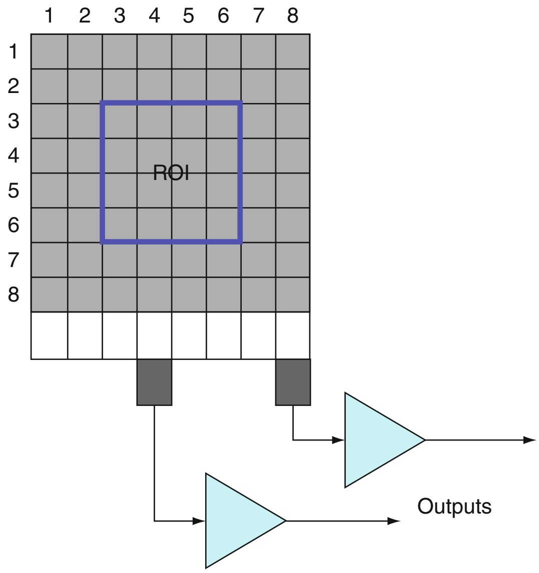

Fig. 10.31
Tapping the sensor array to sample a region of interest (ROI)

noise in a sensor requires modifications of design in silicon and perhaps even process development. Reducing noise for visual display proposes can be implemented in post-processing software.

Some effects are irreversible or, at best, only approximately reversible. Reversing such effects often demands large amounts of processing power and very close matching of the reversing algorithms to the original effects to avoid generation of artefacts that can be more troublesome than the original effect. Better to avoid as many of these effects as possible.

10.4.5.1 Optical Interactions

Interactions between the sensor and its optical environment fall in the category of difficult to reverse without sever artefact generation. In a simple case, lens vignetting can be reversed by careful application of variable gain across the image. Unfortunately, varying the gain also varies the noise, introducing noise gradients in the image that are often harder to deal with than the original shading. Better to just use an optical system designed for low vignetting. Other interactions may be both more difficult to correct and easier to avoid.

Oversize Image

With the large variety of sensor sizes and lens image diameters available matching these is not always possible. An image diameter smaller than the sensor causes an obvious problem – dark edges on the image – but image diameters much larger than the sensor can lead to a different type of nonuniformity. In most cameras, there are reflective surfaces around the active area of the sensor, some, like bond wires, inside the sensor itself and others, like solder pads on the sensor pc board, in the camera. Care must be taken to assure that light does not reflect from these structures and ultimately end up as scattered illumination in the image. It is generally good practice to surround the active part of the sensor with an optically-absorbing material minimize the possibility of scatter.

When large-format lenses, like those for 35 mm film cameras, are used on adapters – c-mount being the most common – additional optical baffling may be needed to assure that the substantial amount of light that can arrive outside the sensor active area is absorbed. One further precaution needed with such lenses is careful monitoring of bright illumination that may be present outside the sensor field of view. A bright light out at the edge of the lens acceptance angle can cause substantial glare in the image even though the source may not be imaged by the sensor.

Interference Patterns

As mentioned above, the various overlayers on a sensor can act as interference filters and produce ripples in the QE as a function of wavelength. In applications where absolute illumination levels must be measured, these ripples can make reliable measurements with narrow band sources difficult due to variations in the ripple positions from sensor to sensor and even in various positions on a single sensor. Variation in the interference patterns across the sensors can also generate significant non-uniformity when narrow-band illumination is used. Interference effects can be very strong at longer wavelengths where, as silicon becomes more transparent, reflections from the back of the silicon die interfere with incoming light. The effect is to produce broad light and dark contours in the images that map variations in the thickness of the die.

Backside Reflection

Also at longer wavelengths, the entire image can be reflected back through the die and detected a second time. Such a reflected image will be out of focus and generally slightly larger than the incoming image. This effect can be avoided by filtering out longer wavelength light before it reaches the sensor. If a particular wavelength that falls in a low QE part of the response curve is essential to the desired image, watch carefully for spreading of small bright spots due to backside reflection.

Crosstalk

In sensors with smaller pixels, the pixel spacing begins to fall inside the typical absorption length for visible photons in silicon. This can allow photons arriving at large angles from the normal to pass through the first pixel area where they arrive only to be absorbed in a neighbouring pixel. Microlenses can ameliorate this effect somewhat by forcing more photons to arrive near the normal. Users can control the effect by selecting lenses with longer back focal distances to minimize the larger angle rays in the arriving image.

Angular Dependency

The high index of refraction of silicon makes all the QE of all sensors somewhat angle sensitive but this is a minor effect and can be minimized through the use of lenses that cover an image area slightly larger than the sensor. Microlenses make the angle dependence worse because they become less and less effective in directing incoming light to the photodiode as the angle of the light deviates further and further from the normal. In many cases, the angular limitation is different in the horizontal and vertical directions because the photodiodes are not square. While the typical acceptance angle (where 50% of the incoming rays hit the photodiode) is about 20°, half on each side of the normal, the range for various sensors can be 10–30° even reaching these extremes on the same sensor for the two axes.

In an attempt to accommodate lenses with short back focal distances, some sensors now have radially offset microlenses, aligned in the centre of the imager and progressively more offset toward the centre as the radial distance of the pixel increases. Such sensors can produce mild vignetting when used with lenses having large back focal distances because of the loss of rays near the normal in outer pixels.

10.4.5.2 Charge Spreading

After photons have been converted to electrons the charge must be controlled to assure that each carrier remains associated with the photodiode where its generating photon was absorbed. Charge spreading through overflow, called *blooming*, can be minimized through the use of photodiode isolation techniques and provisions for rapid removal of excess charge. A variety of structures have been developed for CDD an CMOS imagers to manage blooming so this has becomes less of a problem. Often now, sensor blooming is not at fault when bright objects appear larger than they are because the real problem is reflections in the optics or one of the optical interactions described above.

Even without overloads, charge diffusion in the sensor can put charge carriers in the wrong location. The likelihood of diffusion is very small in most sensors because of the isolation techniques now almost universally employed. However, diffusion remains a consideration in those sensor types which use the bulk silicon for charge storage.

10.4.5.3 Spurious Signals

The large number of potential spurious signals fall into two rough categories, those that affect the offset of the signal by raising or lowering it level independent of the signal amplitude and those that modulate the signal, effectively changing the gain on a pixel by pixels basis.

Offset Noise

Overall variation in offset is typically stated as Dark Signal Non-Uniformity (DSNU). Here are some typical types of offset noise and their effects:

- Reset noise – As discussed previously, this is an uncertainty in the reset level of the sample node. It can raise or lower the signal from its true value and changes with each new sample.
- Circuit noise – this can come from any of the components in the sensor signal path. It has the same effect as reset noise but is usually much smaller in amplitude.
- Telegraph noise – This is due to individual charge carriers moving in and out of traps in the semiconductor bandgap. It is especially significant in sensors with small well capacities or at very low signal levels. The offset can be positive or negative depending on the direction of the charge jump and shows up as transient whiter or darker points in the image.
- Dark current – this is charge accumulation in photodiodes due to reverse leakage current. The major effect is a unidirectional offset in the signals of all pixels. Dark current has shot noise, however, which causes pixel to pixel variations in the dark offsets.
- Column noise – Found only in CMOS imagers, column noise is caused by variations in the threshold voltages in the column storage transistors. Since the signal from all rows in a column pass through the same transistor, column noise appears as vertical stripes. Column noise does not typically vary from frame to frame so it can usually be removed through subtraction of a dark image which contains the column noise signal. Temperature changes can sometimes upset the accuracy of this subtraction. In the extreme, columns can appear completely white or black. Column noise generally makes up the bulk of the measurement called Fixed Pattern Noise (FPN) but other static sources may contribute.
- Power supply noise – This is noise generated in power supplies and conducted to the sensor through internal power buses. The appearance depends on the nature of the noise. Low-frequency noise from feedthrough of AC power can show up as horizontal bars. Square waves from switching supplies can appear as periodic bright or dark points.
- Thermal noise is indistinguishable from similar noise generated in the sensor and can be hard to identify.
- Clock noise – Clock noise that is not synchronous with the scan timing can appear very similar to switching power supply noise. Synchronous clock noise will generally have either the same effect on every sample or inverse effects on alternate samples. The polarity of the offset depends on the details of clock phasing. While clock noise may be considered benign if it affects every sample identically, any instability in the clock timing or amplitude will directly affect the sample offset so precautions should be taken to minimize the presence of clock signals in the image data at the time of sampling. If the image data is not digitized but rather displayed as an analogue signal, clock noise can appear as very strong vertical lines in the image.

Modulation Noise

Overall variation in response is typically stated as Photo Response Non-Uniformity (PRNU). Here are some typical types of modulation noise and their effects:

- Geometry variations – Image sensors are produced by semiconductor manufacturing processes which overall are quite uniform but still contain variations that can affect the QE of individual photodiodes. These variations can take place in essentially any process step resulting in variations in the sizes of the photodiodes, the depth of the junctions, the shape of microlenses, the spectral characteristics of colour filters or in a large variety of misalignments. In the extreme cases, photodiodes may be completely inactive, appearing as dark spots, or shorted, appearing as white spots.
- Transistor variations – Primarily affecting CMOS sensors, variations in the gain of the various transistors in the signal chain can affect the signal amplitudes generated by the charge packets from individual photodiodes. If these differences result from localized problems like particles only small numbers of pixels may be affected. Variations across a sensor can also be present. With small sensors, these variations are more likely to be seen as gain differences from one sensor to the next.
- Temperature changes – The absorption of silicon to various wavelengths decreases with increasing temperature. As a result, the gain of an entire sensor may be noticeably affected by temperature shifts. This shift can be large enough to produce chromaticity errors in colour cameras.
- Nonlinearity – This is a secondary effect caused by the effective change in gain at different signal levels in sensor with nonlinear transfer curves. The effects of nonlinearity can be difficult to sort out because noise sources introduced before the nonlinear element will have amplitudes that are dependent on the signal level while noise sources introduced farther along will be signal amplitude independent. Nonlinearity can make cancellation of other noise effects quite difficult. Correcting the nonlinearity with processing will approximately reverse the effects of the early vs. later noise sources.

Other noise problems can arise from the digitization process. These are considered below.

10.4.5.4 Reciprocity Failure

Contrary to expectations, image sensors do not necessarily respond to a total integrated flux independent of the integration time. That is, a very short exposure from, say, a laser, will not necessarily produce the same signal as the same total flux from a continuous source collected over a longer time. Generally, the shorter pulses will produce smaller signals due to local exhaustion of carriers, and the inability of generated carriers to get out of each other's way. The minimum pulse width at which this effect begins to occur varies widely among sensors. In addition, some sensor may not produce the same signal level even with continuous illumination as the exposure time and illumination intensity are varied inversely.

10.4.6 X-ray Camera Performance

X-ray cameras have one additional performance parameter to consider. Since the quality of x-ray images is often defined by their S/N due to the limitations in available x-ray photons, a measure of the degradation of the S/N by x-ray imaging systems called Detective Quantum Efficiency (DQE) has been devised. DQE is the ratio of the S/N of the signal from the x-ray imager divided by the S/N of the incoming x-ray beam (just the shot noise in the x-ray flux). DQE is generally expressed as a percentage so the maximum DQE is 100% when the imaging device adds no noise. Since the noise spectrum of the x-ray beam and the imaging device are generally not flat, DQE can also be plotted as a function of spatial frequency. Note that DQE can be calculated for any part of an imaging system beginning with the image detector. Electronic conversion is not even needed so the DQE of x-ray image intensifiers with optical outputs can be calculated. DQE typically varies with x-ray dose rate and x-ray energy spectrum for any imaging device so full characterization can require a family of curves.

10.5 Colour Imaging

As image processors become increasingly fast and powerful, one of the increasingly complex tasks they are asked to undertake is detection and measurement of colour. Colour has been a small part of machine vision for many years, applied to sort fruit or detect wire colours, but as the quality of the colour camera equipment has improved and the prices have come down, the tasks now can include colour matching and control that were formerly possible only with off-line instruments. While early colour applications could be successfully implemented with just a little common sense and experimentation the newer applications require some familiarity with the formalities and terminology of colour science and some basis on which to select appropriate camera equipment. Herewith, a brief introduction.

10.5.1 Requirements

The fundamental requirement for production of colour images, that is, images that can be presented in such a way that the eye perceives them as having colour characteristics reasonably approximating the colours in the original, is that at least three spectrally-separated samples of the original must be taken. The reason for this requirement can be seen in ➜ *Fig. 10.31*. In the left diagram is shown a sample task, sorting oranges. If a detector is set up that measures the amount of red light reflected from the object, then it can distinguish from unripe oranges – which reflect only green – and ripe oranges, which reflect both red and green. The red signal can be represented as a grey scale, which can be used to automatically select ripe oranges. Unfortunately, this single colour method cannot distinguish ripe oranges from dead ones, which are yellow. To distinguish orange from yellow requires measurement of green reflected light so this simple task already requires two detectors. Similarly for the task in the illustration on the right, two detectors are required. If we want to measure the brightness of blue emission from an LED, we need one detector sensitive in the blue range. However, this detector tells us nothing about the emission out of the blue range so another detector, which measures everything except blue, is also needed. With these two detectors, we can assure that the ratio of blue to not-blue is suitable.

Now, let us assume that we want one system to perform both tasks. For the oranges, we need red and green detectors, and for the LEDs, we need blue and not-blue detectors. This seems like four detectors, however, with a little experimentation, we might notice that the sum of the red and green detector signals tracks well the signal from the not-blue detector and that the blue detector signal doesn't change much as we look at the three classes of oranges oranges. This could lead us to believe that three detectors are both necessary and sufficient to define colours. We would turn out to be right but with a few important constraints. After all, what about purple?

10.5.2 Colour Matching

Early on, it was decided that the useful thing to know about colour would be some rigorous description of colour as seen by human eyes that could be used to produce any colour at any time with some assurance that the various colour samples produced would all look the same. In the 1920s several experiments were set up as shown in ➋ *Fig. 10.32* to determine a colour matching function. An observer was positioned in a dark room so that a colour sample subtending a 2° circle, while illuminated by a 5,000° Kelvin incandescent source, could be viewed on the left side of a screen. The viewer was given control of a projector pointed at the right of the screen containing three monochromatic sources at 435.8, 546.1 and 700 nm that illuminated a 2° circle with amounts of light from the sources set by three knobs. Various colour discs were inserted on the left and the viewer was asked to set the knobs so that the projected colour matched the colour sample.

◘ Fig. 10.32
Colour matching is conducted a dark room. The surface whose colour is to be analysed is illuminated by light from a standard 5,000 K blackbody source. (An incandescent filament lamp will normally suffice). The observer controls the intensities of three monochromatic sources, wavelengths 435.8 (B), 546.1 (G) and 700 nm (R). Their beams are merged, by projecting them onto a white surface. The observer adjusts the brightness of each of these three primaries, until he/she judges that the colour of the merged beam matches that of the sample surface

Almost immediately, it was discovered that some of the matches were impossible. In order to match some of the colour samples, a second projector had to be added to the left side so that the viewer could project monochromatic light from one or more of the sources on the sample while those same sources were set to zero on the right. By simple algebra, this meant that to avoid using projectors on the left, projectors that would subtract light from the right were needed. It had turned out that the colour matching function had negative parts, as shown in ➲ *Fig. 10.33*. That finding confirmed that it is not possible to duplicate the appearance of all spectral colours with three monochromatic sources. Since the concept of negative light is inconvenient, some other solution for matching needed to be found.

10.5.3 Tristimulus Values

The solution came again from algebra. It was decided that if three spectral primaries would not work, perhaps a different set of primaries might. To make new colour matching curves that can be combined linearly to form the measured curves, it is only necessary to combine the experimental curves algebraically to produce a set of three that are all positive. Since this process has more degrees of freedom than are necessary, one of the curves was preassigned the shape of another key curve, that which plots the luminous efficacy of the eye. This is the plot of the apparent brightness of equal-energy spectral colours. This was designated the $\overline{y}(\lambda)$curve and the other two computed curves were designated $\overline{x}(\lambda)$ and $\overline{z}(\lambda)$. These curves are shown in ➲ *Fig. 10.34*. Note that the negative parts are gone. With this set of curves, however, the primaries are imaginary, that is, they are physically unrealizable. What they form is a colour space that is larger than that required to produce all physical colours, thus defining a space that provides positive numbers describing every possible colour.

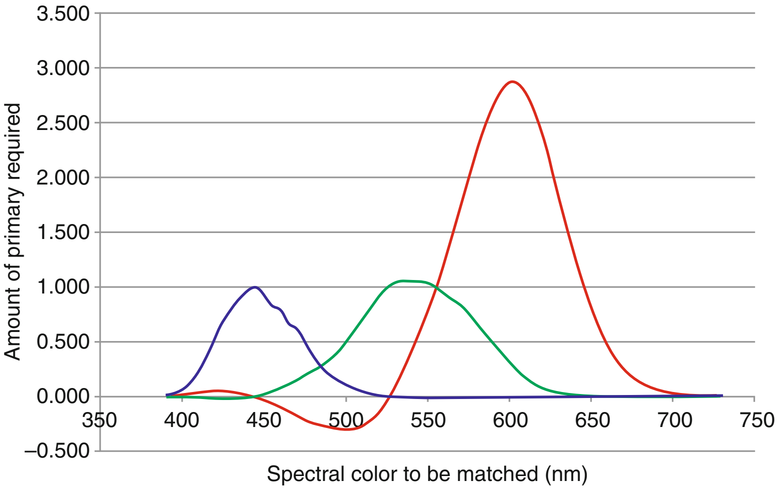

Fig. 10.33

Results of colour matching. The fact that negative contributions are needed from the three primaries is explained in the text

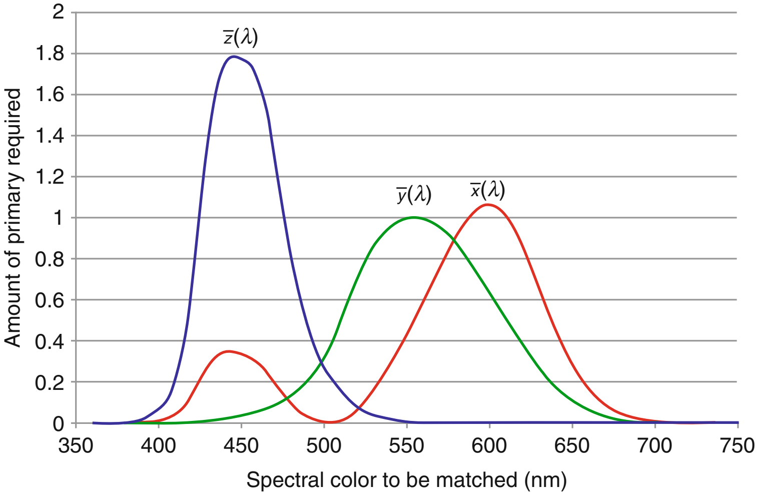

Fig. 10.34
Imaginary primaries (i.e. not physically realizable) can avoid negative spectral values

It is essential when using these curves to understand that they have two separate but equally valid meanings. Assume that it is desired to produce the perception of 500 nm spectral illumination. To do this, the colour matching curves require that 3 units each of the "blue" primary and the "green" primary are required. Conversely, if we had detectors with spectral response curves shaped like these colour matching curves, then applying a 500 nm spectral illumination to them would produce equal signals in the "blue" and "green" channels and no signal in the "red" channel. To extend this principle, if we have a source that is a mixture of spectral colours (which, of course, is what any colour is), then the signal it produces will just be the sum of the amount of each of the spectral colours multiplied by the value of the curves at each colour. This leads to the generalization in which we take the integrals over all wavelengths of the products of the applied spectral distribution and the three colour matching curves. The results of these integrals are designated *X, Y* and *Z* and called the tristimulus values.

10.5.4 Chromaticity Values

One further simplification was implemented. Since brightening or darkening a colour in the XYZ space simply means that all three values are made proportionally larger or smaller, it is possible to remove the brightness variable simply by normalizing the curves. To do this, each of the three curves is divided by the sum of X, Y and Z to produce a new set of curves designated x, y, z. The sum of x, y, and z is always 1 in this calculation so only two numbers are needed to specify a colour (independent of brightness). These are the chromaticity values and can be plotted in a plane to generate the chromaticity diagram shown in *Fig. 10.35*. This plane shows only the colour or chromaticity. The brightness is indicated by the Y value, which is the integral of the product of the luminous efficacy curve and the spectral power distribution of the colour being measured. This combination is called the CIE *xyY* colour space.

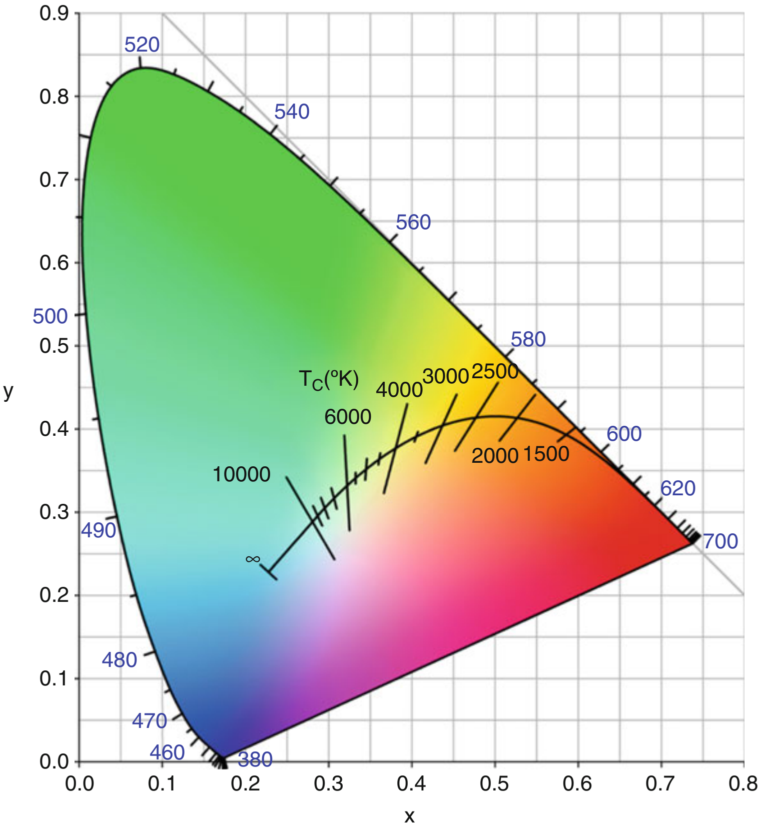

Fig. 10.35

CIE chromaticity diagram. The position of the peak in the spectrum of a blackbody radiator varies with its temperature (See black arc.)

Several important points about the chromaticity chart need to be understood.

- Imaginary primaries – The chromaticity chart shows all visible colours within the central horseshoe shape. The black space around the horseshoe indicates the rest of the space created by the imaginary primaries at $x = 1$ and $y = 1$.
- Spectral locus – The curved portion of the boundary of the horseshoe is the spectral locus. It represents all of the spectrally pure visible colours. The numbers on this line indicate the spectral wavelengths. Part of this locus falls along the line connecting the primaries because these colours have no z content. This can be seen from the tristimulus curves.
- Magenta line – The straight line connecting red and blue shows the non-spectral mixtures of these two real colours.
- White point – Since the three curves have been normalized to sum to 1, the equal energy point, called the white point is at $x = y = z = 0.3333$.
- Blackbody locus – The black line with the numbers indicates the visual colour of a blackbody radiator at the temperature indicated by the number.
- Colour differentiation – moving from any point on the chart to any other point requires changing two of the coordinates; if only x or y are changed, then z will also change. This means

that if a colour change is to be visible, the change must result in the change of two chromaticity values. At the red end of the horseshoe the chart indicates 650 nm but the eye is sensitive out to about 780 nm. However, beyond 650 nm, the x and y curves are nearly proportional. This is equivalent to having a change in only one value so the change in wavelength from 650 to 780 nm will result only in a decrease in brightness, not a change in colour.

The actual visible colours cover a much wider range than can be displayed or printed so the chart must be taken only as a rough representation. Violet at 400 nm, for instance, is missing completely because it cannot be displayed or printed using standard phosphors, dyes or inks.

10.5.5 Colour Spaces

A colour space is a numerical model with a specified mapping, usually involving three or four values, which provides convenient methods of describing or transmitting colour information in specific applications or environments. A common example is the sRGB colour space, used in almost all computers, that maps tristimulus values to the colours capable of reproduction by the phosphors in CRT displays. The numerical representation for sRGB is the familiar 0–255 scale for each of the three RGB channels. Generally, one colour space may be converted to another through the use of a set of simultaneous equations. (➋ Chap. 4) This process may, however, produce negative values, indicating that a colour that can be represented in one colour space is out of range for another.

10.5.5.1 Colour Space Conversion

Sets of simultaneous equations for colour space conversion are often expressed in matrix form. Where the conversions are linear, as in the conversion of XYZ values to sRGB, the matrix is of the simple 3 × 3 element type as shown in ➋ *Fig. 10.36*. Clearly, this can produce both negative values and values greater than 1 for the sRGB coordinates. In practice, those values are discarded because they cannot be reproduced by typical displays. The sRGB colour space can be shown on the chromaticity chart by finding the extremes of x and y that produce sRGB values between zero and one. These will map a triangle, as shown in ➋ *Fig. 10.36*, which has vertices that correspond to the primaries used to define the sRGB colour space. Only those colours inside the triangle can be displayed on a device using the sRGB colour space but in practice, the real primaries on a display may not match the colour space primaries and so the displayable colours may be further restricted. Colour standards also generally specify a white point, the colour generated when the three values in the colour space are equal. For sRGB, this is D65, approximately the colour of a 6,500 k blackbody.

10.5.5.2 Colour Spaces

A wide variety of colour spaces have been developed to provide convenience in different applications. Selection of a proper colour space depends on understanding the various ways in which each colour space represents what the eye can see and on evaluating the suitability of each colour space to simplify colour image data in a way that reduces the computation complexity of the required machine vision tasks.

$$\begin{bmatrix} R,_{RGB} \\ G,_{RGB} \\ B,_{RGB} \end{bmatrix} = \begin{bmatrix} 3.2410 & -1.5374 & -0.4986 \\ -0.9692 & 1.8760 & 0.0416 \\ 0.0556 & -0.2040 & 1.0570 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$$

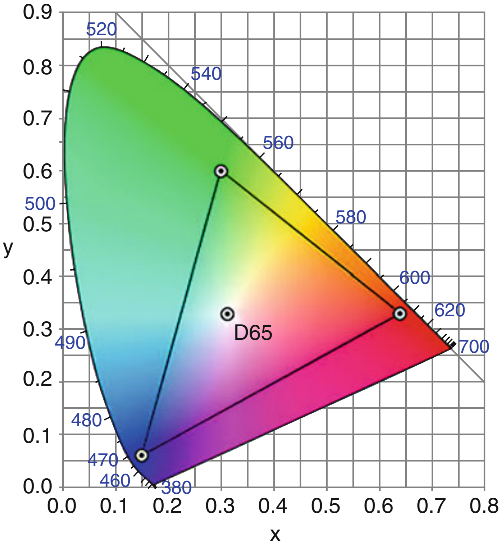

Fig. 10.36

Converting from one colour space to another. (a) Equations for mapping XYZ colour coordinates into sRGB parameters. (b) CIE chromaticity diagram The vertices of the triangle represent three primary light sources. Only those colours within that triangle can be approximated by mixing light from those primaries. This is called the gamut for that particular set of colour parameters

RGB Spaces

All RGB spaces are designed to support a direct representation of the data sent to the three colour sources in a display. (➜ Chap. 4) Originally, these data were three analogue voltages but now they are almost always digital numbers. In the typical RGB space, zero indicates that a particular colour source is turned off and 255 (in 8-bit systems) indicates that it is all the way on. Although the original RGB space was defined based on real CRT phosphors, newer RGB spaces have corners in the triangle that are far enough apart to accommodate a variety of different phosphor sets, LCD filter dyes or DMD colour wheels [7, 8]. In addition, RGB spaces may include gamma correction that may or may not match the characteristics of a particular display. Since sending the same data to these different devices will result in different displayed colours, ICC profiles should be used wherever colour matching among displays is critical. sRGB, Adobe RGB, RIMM, ROMM, xvYCC and others are spaces of the RGB type with different gamuts. (The *colour gamut* is a certain subset of colours. The most common usage refers to the set of colours that can be accurately represented in a given circumstance, for example within a given colour space or by a certain output device.)

Other spaces with structure similar to RGB are:

- $L^*a^*b^*$ – This space uses a highly nonlinear set of matrix equations to create colour charts that are more perceptually uniform than the XYZ space. This means that moving equal numerical distances in different parts of the colour space produces the appearance of equivalent change to the eye. This type of representation conserves data because it does not pack more values into one part of perceptual space than into another.

- CMYK – This space is used to specify colours for print. C, M and Y are cyan, magenta and yellow, the subtractive primaries. K is black, which is substituted for equal amount of CMY in dark areas to prevent putting down too much ink. Because CMYK actually has a relatively small gamut, much high-quality printing now uses six or seven inks to expand beyond the space that CMY can cover.
- YUV – This is one of several colour spaces that use special colour axes rather than *x* and *y* to provide immunity from various types of misadjustment in the colour rendering chain. YPrPb and YCbCr are newer examples.

Chromaticity/Brightness Spaces

These colour spaces separate the chromaticity of the colour signal from its brightness. Whereas RGB spaces may be thought of in terms of Cartesian coordinates, these spaces use a polar coordinate model. Typically, the angle around the cylinder will represent the chromaticity, the radius will represent how much the pure colour is mixed with white and the height will represent brightness. The most common space of this type used in machine vision is HSI for Hue, Saturation and Intensity. Hue is the colour angle, saturation is the distance from the axis (white on axis and pure colours at the outer boundary) and intensity is the brightness running from black at the bottom of the cylinder to full brightness at the top. This sort of space has the advantage that the base colour can be measured without regard to brightness so uniform illumination is not essential. HLS, HSL, HSB and HSV are similar spaces.

10.5.5.3 Colour Gamut

Each colour device has a range of colours over which it can operate. This range is termed the gamut. Printers, displays and most other output devices have colour gamuts that cover perhaps the central 30% of the chromaticity chart; they are not capable of reproducing saturated colours due to the fairly broad spectral characteristics of the inks or phosphors used. Since no two output devices have exactly the same gamut, an additional process, colour profiling, is often applied. Colour profiles are developed for each device. These are typically non-linear lookup tables that map the standard colour space into the actual colour gamut of the specific device so that every value presented to the device has some output. Attempting to get the colours in these actual outputs to resemble one another is the science of colour management. Colour profiles are generally defined according to a format developed by the International Colour Consortium (ICC).

10.5.5.4 Detector "Gamut"

Strictly speaking, a detector alone does not have a gamut because the definition of gamut requires presentation to the eye. However, detectors do have ranges over which they can produce accurate data representing colours presented to them. Except in rare cases, detectors used for imaging do not have spectral response curves that are designed to match the tristimulus curves directly. Instead, the signals from detectors may have a conversion matrix applied of the same form as those used for output devices and may also have colour profiles applied. In fact, the entire ICC colour effort is focused on supporting the concept that all input and output devices should communicate through a common colour space. The colour space of choice is, of course, the tristimulus space because it incorporates all colours discernable to the eye. Thus, the capability for accurate colour reproduction for detectors rests on their ability to produce signals that can be accurately transformed (preferably by linear simultaneous equations) into XYZ tristimulus values.

10.5.5.5 Illumination Effects

When the tristimulus values for a viewed object are calculated, the spectral power density received carries no distinction between the spectral reflectance properties of the object and the spectral emission properties of the illuminating source. The received distribution is merely their product. To separate the object from the source requires either specifying the source or illuminating the object with spectrally flat energy. Because blackbody illuminators follow the theoretical emission curves reasonably well, specifying the source is generally easier so this practice was long ago adopted. This leads to the requirement that measured colour data be supplied with an illuminant tag like D50 or D65, which specify 5,000 and 6,500 K illuminants. Colour data taken with one illuminant can be transformed into data as it would be under another illuminant through a linear 3 × 3 matrix. This process is applicable for any illuminant, not just blackbodies.

10.5.6 Colour Detection

Specifying both chromaticity and brightness requires three numbers regardless of the colour space chosen. The function of a colour detector, in machine vision often a camera, is to determine these three numbers from an incident optical image. The type of detector required depends on the accuracy of the colour data required. Generally, this accuracy is stated in the L^*a^*b colour space because that space was designed to be perceptually uniform. The error in each of the three dimensions could be stated separately but common practice is to combine them as the length of a Cartesian vector from the true colour to the measured colour. This value is reported as ΔE, pronounced delta-E, and is defined so that a ΔE of 1 is the smallest variation that the eye can see. The error in professional colorimeters can be as low as 0.001 while the error in high-quality digital cameras is typically in the range of <1–10 with an average over all colours of about 5–6.

In practice, three detectors with realizable colours filters will not achieve average errors below about 5 if the entire XYZ tristimulus space is to be measured. In real cameras, improved colour accuracy in one colour region – skin tones, for instance – might be traded for larger errors in a less critical region like blues. To reduce the error to the neighbourhood of 1–1.5 for all colours, about six channels are needed. This is why most commercial colorimeters for tasks like monitor calibration have seven or so filtered sensors.

10.5.6.1 Colour Separation

Fundamentally, accurate colour measurement requires that the spectral response of the various detector channels, however many there are, can be linearly combined to approximate the tristimulus curves. For any detector, except a few very expensive colorimeters in which the tristimulus curves are replicated very closely, there will be some error in colour measurement based on the mismatch between the detector and tristimulus curves and some uncertainty based on the S/N of the detector. In cameras, there can also be non-uniformities in the measured colour due to the same problems that appear in monochrome imaging and due to glare in the optics.

The techniques to approximate the tristimulus curves fall in two broad categories, those which try do it with exactly three detector channels and those that use more. Those that use many more channels are essentially hyperspectral imagers, using 10 or 20 or 50 narrowband channels to provide accurate spectral distribution curves for the objects being viewed. With these systems, matching the tristimulus curves becomes a purely mathematical operation in which the spectral sensitivities of the numerous channels are linearly weighted and combined. Increasing the number of channels can bring these approximations arbitrarily close to the normative tristimulus curves. Of course, this technique carries substantial burdens of cost, complexity and speed.

In imaging, cost is still very much the issue so techniques using one or three image sensors account for virtually all commercial implementations. These have been of three basic types: one-sensor sequential, one-sensor simultaneous and three-sensor.

One-Sensor Sequential

Sequential colour imaging is simply an extension of the usual method of monochrome frame scanning. For colour acquisition, three successive frames are taken, each with a colour filter inserted in the optical path. Several varieties of filters can be used. Historically, these have been three Kodak gelatin filters – Wratten types 25 (red), 58 (green) and 47B (blue) are a widely used triplet – that separate the spectrum into three relatively non-overlapping sections. Other dye and interference filters sets with this spectral behaviour have also been developed. Alternatively, the filter set may use complementary colours – cyan, magenta and yellow – each of which takes in two of the RGB colour bands. The CMY scheme is more light-efficient that the RGB but requires calculating strong differences between channels to produce the tristimulus approximations. Which technique is better depends on a variety of image sensor characteristics and the relative importance of various image quality measures.

In so-called *tri-linear* sensors, a variation on this technique uses three lines, each with its own filter, to sample each line on the object three times as it moves past. This operation can be executed at the same speed as monochrome line imaging but carries the risk of slight changes in the object being viewed due to the scanning time separation.

One-Sensor Simultaneous

The most common method of colour separation uses a monochrome image sensor provided with a colour filter array (CFA), with one colour filter per photodiode. Various CFA configurations are possible but the most common is the Bayer arrangement in which a four-pixel group is provided with two green filters and one each of red and blue in a diagonal configuration. A complementary version of this design and other filter arrangements are also used as shown in ➋ *Fig. 10.37*.

Luminance resolution in cameras with colour filter arrays is approximately 70% of what would be produced by a monochrome sensor with the same pixel count. This results partly from the not having direct luminance samples from each pixel and partly from the anti-aliasing filters that are needed in CFA cameras to control colour artefact generation. Colour resolution is lower. As a result, aliasing from undersampling begins at different frequencies for the various

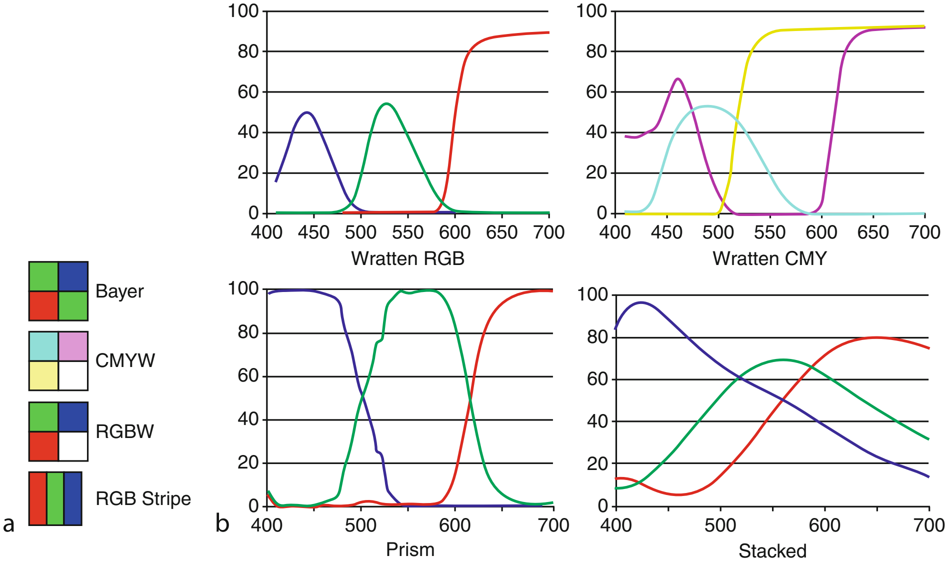

Fig. 10.37
Colour filter arrays (a) Filter configuration. (b) Spectral transmission curves

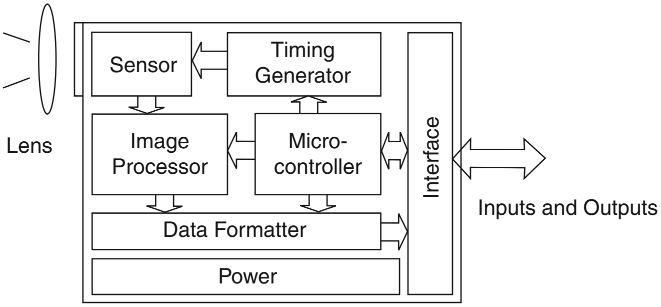

Fig. 10.38
Camera block diagram. The organization of particular cameras may vary but this is a useful conceptual aid

colour components and the direction of strong aliasing components varies by colour. This nearly always results in visible colour artefacts when significant energy at spatial frequencies above the various sampling limits is allowed to reach the sensor. Typically, the missing colour information is filled in with estimates made from close neighbours. This can generate colour errors due to mismatches in the estimates from pixel to pixel. In some implementations, no attempt is made to fill in the missing information; each colour signal is simply treated as complete but of lower resolution. This procedure avoids generation of reconstruction artefacts but reduces perceived resolution and can cause ambiguities in determining the positions of colour edges.

Sensors are now also available in which each of the locations has three photodiodes built in a stack inside the silicon. Since silicon has an absorption curve that allows photons to penetrate farther as their wavelength increases, the silicon itself can be used to separate colour. Charge generated at each level can be separately collected by the three stacked photodiodes to provide three spectrally-separated colour signals. This arrangement assures that the colour channels are optically aligned.

Three-Sensor

In order to combine full resolution and simultaneous colour imaging, three sensors can be used. Most commonly, these sensors are fitted on a prism assembly incorporating internal colour filters to direct the R, G and B bands to the three sensors. In these imagers, the monochrome and colour resolution are identical except for any errors, generally small, in the alignment of the sensors to each other. Separation prisms of this type must be carefully designed to provide identical optical path lengths for the three bands. (➋ Chap. 4) Often, special optics are required for low colour aberration because the lens design must take into account the thick glass region between the lens and the imager. Because dichroic multilayer filters are almost universally used in prism-based imagers, overlap in the colour bands is minimal.

10.5.6.2 Spectral Characteristics

Typical curves for several sensor filter sets are shown in ➋ *Fig. 10.37*. The first three sets show filters alone but the stacked set necessarily includes the spectral response of the sensor. All of these sets would need auxiliary ultraviolet and infrared blocking filters to restrict the light arriving at the sensor to visible wavelengths.

Each filter set when used with a sensor makes up a detector with its own colour space, producing a set of readings for each colour presented to it. This colour space will be different for every detector type and even, in a minor way, for each individual detector. For the output to be useful for anything except comparisons using only one sample of the detector, the colour space for the detector must be transformed into a standard colour space. This can be accomplished using a 3×3 matrix or some other colour coordinate transformation technique. Such matrices are generally developed by imaging a standard colour chart and computing the matrix values that fit the measured values to the true values most closely. While all of the three-sensor separation techniques can produce similar colour accuracy performance, the errors generated by each tend to fall in different locations on the chromaticity chart.

Each of these filter sets has advantages and disadvantages. Mildly overlapping curves enhance the detection of wavelength shifts in narrowband sources better than strongly separated curves while the separated curves are better able to discriminate between narrowband and wideband sources with the same central wavelength. Separated curves often have difficulty accurately detecting changes in wavelength near the transitions. However, if the curves overlap too much, then the numbers in the transformation matrix become large, adversely affecting the S/N of the transformed data. In typical implementations, filters with overlapping curves have high light losses as well because the light not used is absorbed. This does not apply to the stacked sensor because all of the light is absorbed in the silicon. In the three sensor designs, essentially all of the light passes through one of the channels in the colour separation prism so minimal light is lost although some designs incorporate trim filters which will reject or absorb some light.

One example using the Wratten RGB set will serve to illustrate the problems with particular types of curves. Let us assume that we have two monochromatic stage lights, one emitting around 420 nm (clearly violet) and one around 460 nm (deep blue). If we observe the stage with a camera using the Wratten RGB set, we will find that both of these sources produce a signal only in the blue channel. This means that our camera would not be able to tell the difference and would report both of these sources as having the same colour. When this colour data is displayed, it will appear as whatever has been assigned to a blue-channel-only signal. So, there will be no violet in the picture. Of course, this is just as well because there is no violet inside the sRGB display gamut anyway. Next time you are at a concert, wait until the violet spots come on and then look at the video monitors.

In some cases, two objects with different reflectance spectra can generate the same colour coordinates. This phenomenon is called metamerism. In imaging systems, metamerism is locked in at the time of detection. Once the detection channels produce the same signal set with two different stimuli, there is no way to distinguish these cases by subsequent analysis. This is a case similar to that found in aliasing because like aliases, once the confusion is generated it cannot be removed. Metamerism can be minimized through the use of an illumination source with a high colour rendering index (CRI) like halogen lamps. White LED illuminators have generally low CRIs (➜ Chap. 4).

Often, the colour images are not displayed; the goal is instead the accurate measurement of colour. In such systems, the colour separation requirement is unchanged because the accurate measurement of colour requires that the detector channels produce signals that can be combined to produce a three signal set that is the same as the set that would be produced by detectors with the spectral characteristics of the tristimulus curves. To some extent, this is an easier task than colour reproduction because the colour gamut constraints of the display are removed. Fundamentally, though the requirement remains: can the spectral characteristics of the sensor channels be combined to approximate well enough the tristimulus curves?

10.5.7 Multispectral Generalization

The technologies used to produce three channels for colour detection can also be applied to other wavelength bands. One longstanding example is the four-channel scanners used to digitize colour film. Three of the channels are tailored to match the spectra of the three film dye layers and the fourth detects near-infrared. Since all of the dyes are transparent in the infrared, the fourth channel contains only an image of irregularities on the plastic film base – scratches, discolorations and the like – so the fourth channel can be used as a reference to correct these same marks on the images of the colour channels to produce a digital image that is cleaner than the film original.

Near-infrared is also useful as an adjunct in inspecting agricultural products. In some cases, the channels may be just one narrowband visible and two near infrared. Making these changes is relatively straightforward in prism cameras because changing the spectral characteristics in these is precise and reliable. CFA (Colour Filter Array) [9] cameras allow much less flexibility due to the limited selection of the filter dyes available and the need to incorporate the filter deposition into the semiconductor fabrication process. For larger pixel spacings, dichroic filter arrays can be fabricated to provide substantially more options but these sensors still have the same geometric limitations of Bayer CFA sensors. The current limit for one-piece prisms is five channels but the number of different filters can be quite large if the spatial considerations are not important.

10.5.8 Hyperspectral Imaging

A camera with a large number of colour channels can produce hyperspectral images, that is images that detect the complete spectral energy distribution over a particular band for each resolution element at the object. The simplest hyperspectral cameras use some sort of spectrally-dispersive element like a grating or a filter in which the wavelength transmitted changes from one value at one filter edge to another values at the opposite edge. In both cases, an area sensor is presented with an image of a line on the object so that one direction resolves elements along the line and the other direction resolves the spectrum coming from each element on the line. If an entire area must be imaged at once, then the camera can be fitted with a variable filter which can be swept through the wavelength range of interest. Such cameras usually have high-speed sensors so the wavelength sweep, which may include 100 or more images, can be completed as quickly as possible.

In dynamic hyperspectral imaging, the data forms a four-dimensional hypercube – x, y, wavelength and time so the data rates can be high and data volumes can be large. Often, hyperspectral imaging is used as a tool to quickly determine which bands contain useful information for a particular task. Those bands can then be designed into a fixed channel camera matched to the task.

10.6 Cameras

Thousands of camera models are available so selecting the right one for a specific task can consume significant time and resources while still producing a sub-optimal match. Information on cameras is useful but often so much information is available it further complicates the search. Further, each camera seems to carry a few specifications that are based on assumptions that do not match those of any other camera so direct comparisons often require substantial additional research. Testing the candidate cameras would seem to be a useful way of making a selection but interface differences in everything from power to software make such comparisons tedious and often, at the end, unenlightening. Further, testing requires simulation of the expected conditions in the real application. This is rarely achievable in any way approaching completion simply because support, lighting, optics and other systems considerations are usually also undetermined during the camera selection process. The rate of new sensor and camera introduction is so high that the best selection may not even exist at the beginning of a search. It is thus imperative that the important criteria for the success of an application be carefully determined and that all camera selections be measured strictly against those criteria so that new candidates can be quickly accommodated.

Camera configuration and performance specifications begin with a relatively simple set of requirements on which are built layers of increasingly specific details [10]. It is of no use to focus on a detail unless the foundation for and effects of that detail are understood. The camera should be thought of at the beginning as a black box that is required to perform a set of functions. Then the implications of those functions on the camera specification can be considered. Then specific cameras meeting those specifications can be identified. Tradeoffs may be necessary, so the relative importance and range of tolerance on the required functions must be determined to allow ranking of the candidate cameras. Factors external to the camera, such as the reputation of the supplier, may also need to be taken into account but delaying this step until after the candidates are identified is recommended.

Finally, it is extremely unwise for systems designers to take on faith the performance of cameras without understanding in some detail the sensors inside them. Finding examples of cameras that use sensors incorrectly or claim camera performance that exceeds published sensor capabilities or fail to take advantage of sensor functions carefully implemented by their designers is not difficult. As a result, those selecting cameras need to be able to detect these discrepancies and understand the explanations provided by camera vendors. Sensors don’t do mysterious things when run properly and camera electronics do not perform magic so the explanations should be clear and rational. The material below is intended to provide a basis for such rational analysis.

10.6.1 Requirements for Visible Cameras

Strictly speaking, this section applies to cameras with silicon sensors operating in the wavelength band of approximately 350–1,100 nm. This omits something like one part in 10^{10} of all cameras, including primarily various types of infrared cameras, a few ultraviolet models and all high-energy imaging. The important requirements for those bands can be very different from both visible cameras and from each other and can be driven by very specific applications. As a result, generalizations become much less useful and guidance requires much more specific applications engineering. Some of the present discussion is relevant but should be tempered by acknowledgement of the significant differences.

10.6.1.1 Analogue or Digital?

With computers everywhere, this question almost always is really, “Where should the analogue to digital conversion occur”? Even security cameras are rapidly turning digital because Ethernet links compared to analogue coax are:

- Much less susceptible to noise
- Easier to provision with camera power
- Inherently bidirectional
- Easier to use for camera control
- Cheaper and simpler to extend
- Much easier to access from multiple viewing points
- More directly convertible to fibre optics
- More compatible with transmission of compressed or encrypted data
- The winner in the time-certainty vs. signal-delay tradeoff

Digital cameras are not even necessarily more complex than analogue cameras because of the availability of on chip digitization in CMOS sensors. Broadcast television is now digital, consumer camcorders are digital. The only analogue cameras left are single-board types and the heads in some two-piece cameras. Even in these, very little processing is done in the analogue domain. Interestingly, what processing remains in analogue cameras is also still present in digital cameras as part of the signal preparation for digitizing.

10.6.1.2 Mechanical

The basic camera for industrial applications is a metal (usually aluminium) box with holes for mounting, a big hole to let in light, some electronics inside and connectors for power and signals. It is unlikely that anything but metal can serve as an appropriate enclosure due to the requirements for rigidity, thermal stability, electronic shielding and tolerance for holes. Occasionally, users will supply their own boxes and need only to buy the electronics, thus assuming responsibility for the items just listed. In more explicit form, the mechanical requirements are:

- Sufficient mounting provisions and adequate rigidity to assure that the camera will remain pointed accurately in the desired direction and attached securely to its platform.
- Lens mounting fixtures that secure the selected optics, locate them correctly, exclude contaminants and provide lens orientation and back focal adjustments where necessary.
- Enclosure construction that provides appropriate protection against the environment, sufficient radiation of internally-generated heat, easy access to internal assemblies as needed and accommodation for non-interfering attachment, retention and removal of any electronics cables.
- External finishes meeting requirements for durability, electrical conductivity, optical reflectance and compatibility with other system elements.
- Size, shape and weight conforming to any optical and physical constraints.

Some specific design features to look for are:

- Separation of covers from support members. While consumer products are usually satisfactory if they fall apart when the covers are removed, industrial products built this way are at risk of falling apart on their own due to vibration. Of particular concern is the possible misalignment of the mountings for optical components when a camera is disassembled.
- Solid connections between the camera mounting surface and the lens mount. This requirement assures that the camera and the lens point in the same direction. Many industrial cameras are designed to mount using the same plate that holds the lens, using front surface or peripheral threaded holes. Those that mount on the base generally have a single casting for front and base or very sturdy mates between the two pieces. The mate should include a positive alignment feature and not depend solely on pressure applied by fasteners.
- Adjustable back focal distance. Not essential because extenders and shims can be used with threaded mounts, but convenient. Generally not necessary if photographic lenses are used because these are carefully calibrated unless, of course, the cameras are not. Many industrial lenses have built-in adjustments.
- Rugged, reliable cable connections. Not strictly part of the enclosure but very important mechanically. Screw-retained cables are always preferred and non-locking cables like consumer power connectors should be avoided. All cables should be supported separately from the camera anyway. Check to make sure the connector fasteners are installed correctly so the cables fully mate.
- Non-rotating camera mounts. Tripod mounts are discouraged unless they include an anti-rotation pin. Two screws will work but separate pins for location and screws or quick-release fasteners for retention are better.
- Positive board retention. All internal circuits need to be anchored to something solid. Connectors cannot be relied upon for mechanical support. Boards should not provide

support for anything except electronic components. Large components should be individually retained.

- Adequate heat paths. Verify that all components with significant heat dissipation are adequately cooled. Some cameras may require external heat sinking through the mounting surface. Be sure to understand any such requirement and implement them properly. Ask about required air flow rates over finned heat sinks.

Keep in mind that many optical systems need support separate from the mount. Many lenses are now bigger and heavier than the cameras using them. However, it is never acceptable to let the lens support the camera.

10.6.1.3 Electrical

Providing power to a camera seems simple enough since most run on a single DC supply. Unfortunately, many opportunities for injection of noise to the camera signal relate to power provisioning. Because of the wide variety in power and grounding schemes internal to cameras, universal recommendations are not possible. Here are some things that should be determined for each camera under consideration:

- Grounding scheme. In some cameras, the case is grounded to the external supply return but in others the case floats. The importance of this in a system depends on whether the camera mount or the lens are grounded or isolated and the configuration of the grounding on the supply providing external camera power. The battle here is between ground currents and electrical interference. The situation can be even more complicated depending on the way analogue and digital grounds are connected in the camera.
- Power supply noise rejection. Some amount of the noise on the power supply line can find its way into the image data. How much depends on the rejection ratio. Typically, the rejection gets worse as the frequency increases so switching power supplies can be problematic. Simple arithmetic tells how much rejection is needed. If the sensor puts out 1 volt full scale and 12-bit data is needed, then the maximum allowable conducted noise is about 250 μV. If 250 mV (peak to peak) is present on the power supply output, then the rejection needs to be at least 60 db. Higher rejection ratios will be needed if the camera is operated with additional gain.
- Input voltage range. Long power supply runs can reduce voltages at the camera below the camera tolerance range. Many cameras on the same power bus can cause voltage fluctuations. Know what tolerance the camera has and understand what changes at the camera output when the input voltage changes while the camera is running. Putting anything else on camera power buses is a risky practice.
- Overvoltage tolerance. Determine the effect of applying voltages, both DC and transients, above the recommended range. Ask what is necessary to change blown fuses or other protective elements.
- Reverse voltage tolerance. Cameras should not blow up if the power is connected backwards. Some of them will run either way. However, see the point above about grounding.
- Inrush current. Determine if the camera draws significantly more current during turn-on. This is especially important if many cameras are on the same bus because turning them all on can result in a supply voltage below the tolerance.

- Transient recovery. Some cameras will not start properly if the voltage is brought up slowly from zero. Some can even be damaged by this. Others lock up if the voltage drops below the minimum for a short time. These behaviours should be understood for each candidate.

10.6.1.4 Optical

The bulk of optical information will be found elsewhere in this book. In this section, the goal is to discuss the significance of a few optical characteristics that cameras may have. Warnings have been given about the need for controlling light behind the lens and for accommodating microlenses. Here are a few more potential problems:

- Front reflection. If the front of the camera is not hidden behind the lens from the perspective of the object being viewed, then ensure that the exposed surfaces are not reflective. At the least, this can increase stray light problems, especially where uniform illumination is desired. At the worst, the front of the camera can appear as a reflection in the image to be measured.
- On-axis reflection. Any optical element perpendicular to the optical axis of the lens has the potential to reflect light back through the lens and have this return to the image plane out of focus and in a different location. Possible sources for such reflections include the sensor surface, the sensor window and any filters or other optical elements between the back of the lens and the sensor. Reflections should be minimized by choosing optical components that have appropriate coatings (➲ Chap. 5).
- Light leaks. Assure that all materials surrounding the cavity behind the lens are opaque. Most cameras have LEDs inside which can provide opportunities for stray light at any time. Most sensors are silicon so they can detect radiation in the near infrared that won't be obvious to the eye. Some dyes used to make plastic black will still transmit NIR. Small leaks around the lens mount may not show up until a bright strobe is used.

Lens Mount Characteristics

Lens mounts come in three general types: threaded, such as the C-mount, bayonet, such as the Nikon F and breechlock such as the Canon FD. Each type has certain mechanical advantages and disadvantages but these are rarely significant in machine vision use. For compatibility with sensors and cameras, two factors are important: flange focal distance, to indicate how much space may be available for accessories that may be needed behind the lens, and image diameter to assure that the sensor can be covered with minimum vignetting. The JIIA LE-002-2008 lens-mount standard and its companion JIIA LE-001-2007, which defines specifies image sensor sizes, are currently gaining in popularity [11].

➲ *Table 10.1* provides details on some common lens mounts. Note that for all lenses, the flange focal distance is the distance from the reference surface on the lens mount, to the image plane in air. In most lenses, mechanical or optical elements will protrude behind the reference surface into the space between the lens mount front surface and the sensor. It is thus imperative to know the actual mechanical configuration of a lens to assure that no interference will be caused by protruding elements. Image diameters are nominal. Some photographic lenses have mechanical masks that limit the illuminated area on the image plane to slightly larger than the active area on the digital sensor or film. Discovering this is part of lens selection.

Table 10.1

Lens mount	Flange focal distance (mm)	Mount type	Image diameter (nominal – mm)
C	17.526 (0.69 in.)	1-32 UN 2A thread	20
CS	12.52	1-32 UN 2A thread	10
Canon EOS	44	Bayonet	33

Nikon F	46.5	Bayonet	43
Pentax K	45.5	Bayonet	43
T2	55	42-0.75 thread	43

Sensor Size Designations

Sensor sizes are designated according to three different systems: camera-tube equivalent, focal length multiplier and named. The camera-tube equivalents are all calculated from the ratio between the image size and glass envelope diameter in television camera tubes. The original vidicon tube had a one in. OD glass envelope and a 3/8 × 1/2 in. (5/8 in. diagonal) image area. Later, 30 mm (1.2 in., 2/3 and ½ in. tubes were made. The sizes have since been converted to metric so the 1-in.size is now 9.6 × 12.8 mm (16 mm diagonal). Sensors come in many sizes from 1/13 to 1.5 in., most of which never existed in image tubes. As the sizes get smaller, the real sensor dimensions deviate from the calculated ratios.

The scale for focal-length multiplier sensors sizes is based on the field of view of a 35 mm film frame (24 × 36 mm). The size number indicates the change in effective focal length of a lens when used with a sensor that is a different size from film. For instance, an imager with dimensions of 16 × 24 mm would be designated as 1/1.5 because that image size is the 35 mm frame divided by 1.5. The number is called a focal length multiplier because a 50 mm lens on the 35 mm frame would appear to be a 75 mm lens on the smaller frame if the field of view of the two cameras were compared. Unfortunately, the two designator scales overlap so the actual sensor dimensions must always be verified.

Some sensors have only names assigned by manufacturers or trade associations, presumably for commercial advantage. These are almost always sensors for digital still cameras. ➋ *Table 10.2* shows the commonly available sensor sizes. Many others without designators are available.

Sensor Matrix Designations

The number of pixel locations in available area sensors can be anywhere in the range of tens of thousands to tens of millions. At least one sensor with over 100 million locations is now available. The frame rate required and the number of pixel locations determines the volume of data that must be processed in each image. This product must further be multiplied if stacked photodiode sensors or multisensor prism assemblies are used for colour or multispectral

Table 10.2

	Designator	Width (mm)	Height (mm)	Diagonal (mm)	Notes
Image tube scale	1/13	1.120	0.840	1.400	All 4:3 aspect ratio
	1/10	1.440	1.080	1.800	
	1/7	1.850	1.390	2.300	
	1/6	2.150	1.610	2.700	
	1/5	2.250	1.910	3.200	
	1/4	3.200	2.400	4.000	Other sizes have been used
	1/3.6	4.000	3.000	5.000	
	1/3.2	4.536	3.416	5.680	
	1/3	4.800	3.600	6.000	
	1.2.7	5.270	3.960	6.592	Other sizes have been used
	1/2.5	5.760	4.290	7.182	
	1/2	6.400	4.800	8.000	
	1/1.8	7.178	5.319	8.932	
	2/3	8.800	6.600	11.000	
	1	12.800	9.600	16.000	Nominal starting point
	30 mm	17.100	12.800	21.360	
	4/3	18.000	13.500	22.500	Not the same as four thirds
Focal length multiplier scale	1/1.7	21.176	14.118	25.471	All 3:2 aspect ratio
	1/1.5	24.000	16.000	28.844	
	1/1.3	27.692	18.462	33.308	
Designations by name	HDTV	9.600	5.400	11.000	16:9
	Four thirds	17.300	13.000	21.640	4:3 AR (approximately)
	APS-C	21–29	14–19	25–35	3:2 AR, not cine APS-C
	Full frame	24.000	36.000	43.266	3:2 AR
	APS	25.100	16.700	30.148	3:2 AR
	APS-H	28.700	19.000	34.419	3:2 AR, not cine APS-H
	645	60.000	45.000	75.000	4:3, also smaller sizes

applications. While there is no reason why any particular number of locations is better or worse for fabrication, some sizes show up repeatedly, mostly for historical or other non-technical reasons. ➲ *Table 10.3* shows common pixel matrix sizes. These arrays can be made to match sensor sizes shown in ➲ *Table 10.2* within the constraints of manufacturable pixel pitch. As

smaller and smaller pixel pitches become more feasible, the number of locations in any particular sensor size increases. Care must be taken to assure that the resolution spatial resolution requirement at the array does not exceed the resolution capabilities of the optics. Here are explanations of a few terms in *Table 10.3*:

- Name. Most of these array sizes correspond to designators for video display resolution. These need to be used with care because in displays, the names refer to displayable white points, usually implemented with RGB triads. This means that the number of addressable elements in colour displays is actually three times the stated matrix count. This is not the case with CFA sensors, where the matrix stated is the total number of photosites which are partitioned into colours. Stacked diode sensors and RGB prism assemblies are categorized according the matrix size of a single photosite plane; however, the total data rate must take into account the multiple photosite planes.
- H count and V count. These are the number of active matrix locations in the horizontal and vertical directions. All of these are nominal because even the display manufacturers are not perfectly consistent and the display standards allow a range for many of the designators.
- Matrix aspect ratio. Originally, television images had an aspect ratio of 4:3 and computer displays followed suit. Later, widescreen displays were added to both television and computers but with different shapes. All along, some displays have had unique characteristics. Some of these decisions still affect compatibility of software and hardware in imaging systems.
- Point aspect ratio. While most displays and sensors now are arranged with equal horizontal and vertical pitch, those based on television standard are not symmetric due to the original accommodation of the unequal horizontal and vertical resolution of the eye. Arrays with non-square point aspect ratios will be squeezed in one direction when viewed on equal-pitch displays.

Matrices are listed in order of increasing horizontal count.

Decoding the names requires extensive reading on the history of displays. Here are presented the words that form the mnemonics, but not the historical background.

- Names ending in CIF. CIF means Common Interchange Format and is a reduced resolution matrix based on PAL digital video resolution. CIF is 1/4 of the PAL matrix. QCIF is 1/4 of the CIF Matrix, SQCIF is 1/9 of CIF. 4CIF is the same as the PAL matrix and 16 CIF is 4× PAL or 16× CIF. All of these are defined in the ITU H.261 and H.263 standards.

- Names ending in “GA”. GA means Graphics Array of which there are many types – C = Colour, E = Enhanced (except that for these two, A means adapter because it refers to actual hardware), V = Video and X = eXtended, There are modifiers H – which has two meanings: “Half” (approximately) when used with VGA and “Hex” (16×) when used with everything else – Q = Quad S = Super, U = Ultra, W = Wide and + for a few array sizes that don’t follow simple arithmetic.
- Video formats. These are really abbreviations using either the name of the standard that defines them, like NTSC, or the actual number of rows in the display as in 1080p.
- Interlacing. All formats are assumed to be scanned progressively unless the name ends in “i”, meaning interlaced.

Although square arrays (512 × 512, 1,024 × 1,024, etc.) have no names, they are also common in industrial and scientific imaging. Square displays are rare.

10.6.2 Environmental

Environments for industrial camera can include essentially every potential hazard, from electrical discharge to heat to mechanical shock. The fundamental requirement for successful implementation of any machine vision application is assuring that the image collected adequately captures the required information from the object being viewed. The straightforward implications of this are that the view cannot be obscured or significantly distorted, the camera cannot move relative to the object and the acquired image must be accurately translated to a signal for transmission. The first two of these relate primarily to concerns external to the camera. Here are some important considerations regarding the third:

- Vibration. Cameras must be isolated from high-frequency (more than a few hundred Hertz) vibration. The amplitudes of such vibrations are usually too small to cause substantial blurring in the image but they will eventually disassemble the camera regardless of the care taken to secure fasteners. Worse, they will likely lead to fracture of solder joints on the boards and even failures inside some components. Lower-frequency vibrations cannot be tolerated because they will move the camera relative to the object causing loss of resolution.
- Shock. Typical cameras now are relatively immune to shock because their masses are so small. Shock during operation can set up resonances that blur the image but isolated shock during handling and even operation are not likely to result in serious damage. Even so, stay within the limits established for specific cameras because striking a camera just the wrong way can damage the sensor window. Of course, if the camera needed for a particular application is large or contains devices like image intensifiers, shock should be carefully avoided even in shipping.
- Temperature. The insides of cameras can be much warmer, perhaps 30°C or more, than the ambient temperature. The specific issue with this is that the sensor is not running at ambient temperature so any calculation of sensor performance must use the real sensor operating temperature. Most other components and properly-designed circuits are not susceptible to temperature changes in ways that affect the camera signal more than the changes from the sensor will. Perhaps the most important non-sensor change involves timing of the sensor drive signals and the digitizing clock. In CCDs, for instance, relatively

minor shifts in the transport register drivers can have significant effects on CTE, causing image blurring in the line direction.

One other concern is condensation at low temperatures. Few cameras are sealed against moisture so falling temperatures can lead to condensation. The absolute temperature is not important. At high relative humidity, condensation can occur during falling temperatures even if the camera is hot. Condensation often shows on the sensor first because the sensor window may be the coolest place in the camera. It is useful to understand how each camera type will behave if condensation occurs and what should be done subsequent to a condensation event.

One extreme case of a temperature effect is the permanent conversion of amorphous selenium x-ray detection layers to a different phase that is not sensitive simply by exposure to the low temperatures encountered during air freight transport. Such devices cannot be air shipped.

- RFI/EMI. The camera body is essentially a Faraday cage for the interior components except for the perforations for the lens and connectors. However, these small holes can still allow reception of significant RF interference, especially if the lens or the cables are acting as antennae. Proper shielding and grounding can mitigate these problems but if a big motor contactor sits right next to the camera, it will generate white dots in the image no matter what is done. Protection is not impossible. Cameras on can coating lines can endure hundreds of what are essentially lightning strikes without failing because the system is designed to accommodate those. There is likely no substitute for testing candidate cameras in the target environment to uncover EMI/RFI problems.
- Ionizing radiation. When a camera is to be used in a system where radiation is used to form images, candidate cameras must be evaluated for their resistance to radiation at the expected exposure levels. Even where cameras are heavily shielded, random hits on the sensor and camera electronics are to be expected. Even in some applications away from main radiation beam, such as monitoring inside radiation therapy treatment suites or monitoring reactor processes, significant exposure can occur. The transient and cumulative effects of any exposure should be understood, especially if those effects are irreversible.
- Pressure. Changing pressure can have disastrous effects on some electronic components, not the least, image sensors. Most image sensors, unless in hermetic packages, use epoxies to secure the window. Gases can flow through epoxies, especially under the influences of pressure differentials. Pressure higher than the pressure under the window can force in water vapour, which can later condense on the inside of the window and the sensor surface. Generally, this occurs when the external pressure is first lowered, as during flight, long enough for the pressure under the window to drop so that subsequent return to normal atmospheric pressure forces water vapour in. Plastic bags and desiccants are recommended whenever cameras are air shipped.
- Cleaning materials. On food lines especially, the cameras must be protected from washdown and sterilization requirements. It is unlikely that many cameras are suitable for operations in such environments without additional protective enclosures. Nevertheless, it is wise to understand before an accident happens what effects contact with the cleaning materials would have on the camera so appropriate service actions can be ready to execute.

The various environmental factors can interact to produce higher susceptibility to poor operation or failure inside what would be normal tolerances for a single factor. In cameras intended for repeated flight, for instance, repeated temperature, pressure and humidity changes can lead to condensation problems even if none of the specifications have been exceeded.

10.6.3 Regulatory

Regulatory compliance requirements vary by application. Laboratory applications may require no compliance at all, while medical applications involving control or life support may require complex compliance including formal verification of software. The most common requirement is third-party safety certification such as that required to get UL certification or a CE mark. Lack of required compliance documents can result in stop work orders, especially in jurisdictions where safety signoffs by the fire department, for instance, are required to allow system turn-on. Regulatory requirement that may apply to cameras include:

- General safety. These certifications address primarily fire and shock hazards. Different classifications exist for various types of equipment and sophistication levels of target users. Specific responsible agencies are usually geographically determined. Each country may have its own agency with some deviation from universal requirements. Be sure any camera selected meets the requirement of the planned final installation locations. In some cases, entire systems may be submitted for certification by the system builder even if not all of the components are certified.
- EMI/RFI. Certification may be required to demonstrate both immunity to external electromagnetic interference and freedom from excessive radio frequency emissions for cameras and other active electronic equipment. Testing can include cables and require measurement of both radiated and conducted energy. Different standards of performance and methods of certification may apply based on application and equipment type.
- Ionizing radiation. While cameras do not emit ionizing radiation, they may constitute part of the shielding in radiation imaging systems or they may form part of an imaging chain that must meet certain performance requirements. Testing in shielding applications is nearly universal but image quality verification usually only applies to medical systems.
- Design and production control. Most medical equipment must be designed and manufactured under written control procedures certified by a third party or regulatory agency. Records must be kept for extended times and, in some cases, components and even materials must be traceable to the origin. Personnel training is generally required and even marketing literature may be subject to vetting of any claims of efficacy they state.
- Space and defence. Equipment supplied for space or defence purposes may be subject to stringent specific test requirements, third-party certification and inspection by the buyer. For purchasers of cameras, the requirements of flow-downs of this type from customers must be completely understood and specifically addressed.
- Quality systems. Many customers now require vendors to be certified to ISO9001:2008 or to demonstrate existence of a comparable quality management system. This may require that each vendor in a supply chain require the next vendor up also to be certified. Other certifications, such as ISO14000 or industry standards such as ISO/TS 16949:2002 (for automotive suppliers) may also apply.

If any of these regulatory requirements appear to apply, the vendor must take responsibility to determine applicability and assure compliance. Contracting qualified experts is sometimes necessary.

10.6.4 Block Diagram

The purpose of a camera is straightforward: convert a flat optical image into an analogue or digital signal containing the image information. However, there are myriad details of this conversion process to consider when selecting a camera. Each of the steps in this process must have a particular set of controls and ranges and formats. Comparing these with the requirements of an application is often tedious on account of the divergence of the names and operation of various functions. Those presented here are in common use but cannot be considered universal.

A representative camera block diagram is shown in 38 The organization and operation of particular cameras can vary substantially but this diagram can serve as a starting point for understanding and comparing them. The blocks should not be taken as descriptive of individual parts or boards in any camera. In many designs, especially with CMOS sensors, all of the control, processing and interface functions may be contained in a single FPGA. It is worthwhile, however, to understand how the functions are implemented because the choice of parts may have an influence on reliability, maintenance and updating of cameras in the field.

10.6.4.1 Microcontroller

Except in the very simplest cameras, setup and operation are managed by a microcontroller, whether as a separate component or as an IP core realized inside an FPGA. The microcontroller is itself controlled via a typically EIA-232 serial, CameraLink, USB or IEEE 1394. Responsibilities of the microcontroller can include:

- Managing the external communications port.
- Conveying control data to registers in the sensor or to a register set in an FPGA.
- Monitoring the operation of the camera – determining its health and taking action or reporting.
- Executing commands not requiring real-time synchronization.
- Calculating camera settings based on commands and status.
- Sequencing turn-on or mode changes.
- Loading RAM-based FPGAs.
- Storing settings for power-on states or rapid configuration switching.
- Illuminating status lights.
- Running general-purpose software.
- Doing essentially anything else a controller can do.

If a camera has a microcontroller, it also has firmware. Firmware may need to be updated, so it is wise to know what is required to implement updates. In some cameras, updates can be applied through the control port. Others have a special connector to which a programming board must be attached. Still others require return to the factory. If updates are a significant concern, the update method should be understood.

10.6.4.2 Timing Generator

All timing for a camera is usually is generated by a timing generator built inside an FPGA or an integrated timing circuit designed for a specific sensor. Typical timing waveforms provided by the timing generator include:

- Accurately timed pulses to operate all sensor functions. In some CMOS sensors part of the timing may be generated inside the sensor and so the inputs may be a mixture of waveforms and clocks. CCDs may require separate power drivers for the transport registers. Sensor may also have additional inputs for mode switching that are not time-sensitive.
- Sampling pulses for analogue to digital conversion. Some sensors have internal ADCs but even those may be externally timed. Some ADC chips have serial outputs so the FPGA may need to provide a very high speed clock to run a deserializer.
- Clocks for real-time processing. Some processing in cameras must be done in synchronism with scanning to preserve real-time transmission of image data. The clocking needed could be for a high-speed ALU, for buffer or frame-storage memory or for clocking of an auxiliary processor with its own functions.
- Special waveforms to control data formatting and transmitting. Each external camera data interface has particular data formatting and timing requirements. Real-time interfaces like parallel LVDS and CameraLink require provision of low-skew data properly formatted for the transmission arrangement desired. Computer interfaces like Ethernet, USB and IEEE1394 require proper data preparation and transmission on request so data may have to be separately buffered in a FIFO controlled by the timing generator. Cameras with analogue outputs will need pulses tailored to insertion of sync and blanking.
- Waveforms to re-time external signals. Certain functions like external synchronization or triggering require retiming of the incoming signals to correspond with the camera timing. Rarely is it desirable or even possible to use external time bases to operate phase-locked loops to bring multiple cameras into synchronization. Retiming of image data from multiple sources is almost always better accomplished after data reception even if the exposures are closely synchronized by external pulses. The sole exception is the use of multiple sensors in a single camera as in prism assemblies or some other special configurations.

The microcontroller may have its own clock even if it is contained inside an FPGA that has other functions run by the timing generator.

10.6.4.3 Data Formatter and Interface

Before transmission, data must be put in the proper form to be compatible with the chosen data link. Most interfaces have special devices available to provide that last step in formatting. CameraLink has special parallel to serial converters and each of the standard computer interfaces has dedicated devices. Similar devices deconstruct the image data on the receiving end so that the receiving device can properly arrange the data for further use. Some links require addition of block or other data control information but these functions are performed by the dedicated chips.

10.6.4.4 External Controls

Every camera has a set of operations that can be externally controlled. In the simplest cameras, these may only be some mode-switching and on-off controls for a few automatic functions. Complex cameras can have literally hundreds of functions. The exact from of these functions will depend on the type of camera interface used and the actual commands used to communicate controls to the camera may never be seen by the user unless custom control software is needed. It is worth noting that if a camera is used with a framegrabber, the software path used to communicate with the camera is the framegrabber driver, not a separate camera driver. If the camera uses a standard computer interface, a special camera driver is likely required. In those cases, someone thoroughly familiar with drivers should be involved in camera selection to assure that the required functionality and compatibility with user software is achieved. Here are some typical controls arranged by category.

Setup

Commands are generally provided to allow control of the link between the camera and the computer. The nature of these depends heavily on the link chosen. In CameraLink, for instance, the mode (base, medium or full) may be selected. Baud rate and parity may be set for serial links. Commands may also be supplied for handling of error messages, verification of command receipt and query of the camera status. It is important in designing link control commands to assure that the link cannot be put in a mode that causes the camera to be unable to receive commands.

Commands to initiate a general reset to a known good state, to report camera hardware and firmware configuration, to report camera operating status and to set system monitor modes for upgrades are also often useful.

Power

External control of camera power is generally limited to putting the camera into and out of a standby mode. The actual effect internally in any camera will depend on the sensor and the electronics configuration. Power-down is useful to conserve power when the camera is not in use and to extend the life of parts that may be temperature sensitive. In practice, it is necessary to know how long a camera will take to stabilize electrically and thermally after the power is restored and what the starting state of the camera will be. Some cameras will accept configuration commands during power down and some will not. As a further complication, some cameras cannot respond to certain commands when in power down mode because access to sensor registers is blocked. It is recommended that a complete set of commands be sent on power up or that the camera be queried for all control settings to assure that the camera is in a known state before image acquisition commences.

Scan

While many CCD cameras permit some control over scan configuration, the advent of CMOS sensors has greatly expanded the possibility for control. The list of commands below is typical of a CMOS camera with a fairly broad control repertoire. Other commands could be unavailable or added depending on the sensor capabilities. Some cameras also have composite commands, which are not listed here. Typical of these are preset scan modes that could instruct the sensor to scan a particular matrix at a particular frame rate. Other, even more complex, preprogrammed modes may be available. It is worth asking any camera vendor if some special mode needed for a particular application can be made available by command.

- Size – to set the number of vertical and horizontal matrix locations to be read out
- Position – to set the starting points for the scan
- Pitch – to set the number of elements between each scanned point and the next
- Binning – to set the number of adjacent elements to be combined into one output sample
- Test – commands transmission of a synthetic test image

Acquisition

Acquisition of images can be repetitive or one-shot controlled by internal timing, software or external triggering. Acquisition will always be subject to the sensor timing rules, discussed above, and any additional constraints imposed by the camera or communications link.

- Trigger – to set the source of acquisition initiation; internal, external or software command
- Exposure – to set the exposure time or to enable external pulse control of exposure
- Mode – to select among the available exposure modes; rolling or global, for instance

Point Processing

In point processing operations, each sample is modified based only on its own contents and using no data from any other sample. Point processing operations are by nature monochrome, even in colour cameras. These are applied to each colour channel individually. The content of one colour channel does not affect the operation on another channel.

- Gain – sets the signal output level for a particular input relative to some reference level
- Offset – sets the shift in output for a particular input relative to some reference level
- Linearity – sets the curve of output vs. input; can be gamma, log or other function
- Clipping – sets the level above which a further increase in input causes no increase in output

Neighbourhood Processing

In neighbourhood processing, the output for each sample depends on the signal in nearby samples. Typically, the neighbourhoods are on the order of 3×3 or 5×5 but much larger neighbourhoods can be used for complex tasks. Bayer demosaicing, for instance can take data from up to 10 samples distant. Colour space transformation is a neighbourhood process because data from all three colour planes are used to modify all three colour planes. Many more processes are available than are listed here but most would not be implemented in a camera.

- Sharpen – sets parameters for any of a number of edge enhancement algorithms
- Blur – sets parameters for any of a number of smoothing algorithms
- Filter – sets parameters for nonlinear filtering such as with a median filter
- Colour space – sets the nine matrix parameters for a linear colour space transformation
- Demosaic – set the parameters for Bayer or other CFA demosaicing
- Encode – sets parameters for real-time image coding; run-length, wavelet or encryption, for instance

Temporal Processing

In temporal processing, samples are recomputed based on other samples taken at a different time. These previous samples may be from immediately preceding scans or from stored image data. Invoking temporal processing necessarily slows the acquisition process and may cause unwanted image data to persist from one scan to another.

- Integrate – sets parameters for accumulation of multiple scans so the sum may be read out
- Average – sets parameters for the averaging of multiple scans
- Smooth – sets parameters for computing of a weighted moving average of continuous scans
- Subtract – subtracts a stored image (usually dark) from all incoming scans
- Filter – sets parameters for non-linear inter-scan processing; limiting scan to scan changes, for instance

Accessories

In cameras with nearby accessories such as lighting, shutters, coolers, filter wheels, motorized lenses and similar items, including provisions for accessory control can save extra wiring and simplify computer interfacing. Such cameras will need some sort of accessory connector to pass on such commands. In some cases, the camera firmware may also need to reformat the commands for use by the accessories.

10.6.4.5 Analogue to Digital Conversion

Whether A/D conversion takes place in the sensor, in the camera or in the framegrabber, this interface must be properly utilized for maximum image quality. Complete discussions of A/D conversion can be found in several items in the recommended reading list. Here we include only a few important rules of thumb:

- Bit terminology – MSB is the bit that requires the largest change in input signal to change state. LSB sets the smallest change in signal that can be recognized digitally.
- Gain setting – to capture the full dynamic range of a sensor, allow about 10% headroom between the largest possible sensor signal and the maximum input signal.
- Dynamic range – DR of an ADC is 6.021 db (20 log 2) per bit. The ADC in a camera needs at least four more bits of dynamic range than the dynamic range of the sensor if images are going to be processed temporally in order to avoid generation of artefacts from ADC non-linearity during, summation, averaging or subtraction.
- SNR – The SNR of an ideal ADC when digitizing a sine wave is improved by 6.021 db for each additional bit. However, it should be assumed that this is never achieved in a real ADC.
- Offset – When the signal from a sensor is zero, the noise can go below zero so some offset must be provided at the input to the ADC to avoid noise clipping. The amount needed will depend on the relative levels of the various noise sources.
- Low-level signals – When low-level signals are to be digitized, add gain before the ADC process to preserve maximum ability to apply noise reduction algorithms. Adding gain after digitizing is simply shifting the bit position of the data leaving the lower bits empty. Information lost before digitization cannot later be reclaimed.
- Sampling – Make sure that the output signal from the sensor is clean during the interval that it is sampled by the ADC. Use the longest sample window possible.

10.6.4.6 Smart Cameras

Cameras must no longer be dumb transducers. The rapid increase in computing power available in small packages has led to moving some feature recognition and even decision-making functions to cameras. For systems using lower-speed connections between the camera and host, it is essential to minimize the amount of camera data carried over the link, especially if multiple cameras are to be assigned to a single computer port. Incorporating data-reduction is straightforward as long as the reduction ratios needed are small. Run-length encoding, for instance can provide lossless reductions around 2× as can discrete cosine transforms. If larger reductions are required, more complex coding can be applied but these are always lossy to some degree. Unfortunately in applications, the loss of data may make it difficult for the computer to make an accurate decision or measurement. In addition, high-ratio compression methods tend to involve block encoding that can introduce artefacts into the image that could be mistaken for edges in the object.

Smart cameras have substantial capabilities for detection and measurement as shown below but care must be taken to avoid running smart cameras at their limits of computation or giving them tasks that require frequent parameter adjustment, For example, a smart camera may be able to detect an measure two objects simultaneously but run out of power when presented with four. These limitations must be clearly understood before deployment and managed in case of failure by assuring that the camera can signal the host when it detects that it has failed its task. In situations where the product on a conveyor, for instance, changes often, changing the detection algorithms to match may be more effectively managed by keeping at least the highest-level software operations in the host rather than attempting to reprogram the smart camera for each different product.

Camera Structure

Smart cameras are similar in structure to the standard camera block diagram except that the processing block will include additional steps for feature extraction and measurement and the data formatter will not have to handle video-rate information. In addition, most smart cameras, except those preprogrammed for a specific function, require the microcontroller to run operating system software to provide programmability for the user. Such cameras generally operate in conjunction with a controller that can send and receive data from the camera, support programming and provide a conduit to a host computer for more complex coding using standard computer languages. To reduce the image data to features and, in some smart cameras, to provide decisions, requires that the camera take on some of the analysis capabilities formerly reserved for the host computer.

Feature Location

The simplest features to recognize are high-contrast edges. Sometime, simple thresholding can find them but more often, one of the two-dimensional edge-finding filters is used. Of course, the filter can only produce an image of the edge, not tell the camera where it is in the image so additional steps are needed to turn the edge into a real line and then to locate the line in the image. Alternatively, a grey-level edge-tracing algorithm might be implemented. These can provide location information directly but are more subject to upset from local variations than edge-finding filters. Other features such as holes, slots, notches and the like can be similarly detected and located. The location data can then be supplied to a host for analysis and action. This sort of scheme is applied often where the dimensional data must be combined from multiple locations that can't be viewed with a single camera or for special functions like stereo viewing or tracking in a volume.

Dimensional Measurement

From the location data, distances can be calculated for comparison with a standard to produce an accept/reject action or for transmission to a machine which might act by moving another part into alignment with a located feature. Depending on the capabilities of the programming tools supplied, the measurement capabilities of smart cameras can be quite sophisticated. A typically complex task might be checking the pitch and depth of a thread or verifying the spacing of a matrix of holes. It must be mentioned (even though this is not the optics section) that many precise dimensional measurement tasks require telecentric optics. Some smart cameras are designed to permit programming for a particular measurement task –perhaps measuring the diameter of a hole – and then retaining this program to act as if it were a dumb hole gauge.

Character Recognition

One common function performed by preprogrammed smart cameras is reading of alphanumeric characters or bar codes. Character reading is relative easy if the characters are well-formed and optimized for automatic reading like those on checks but reading characters stamped into metal is substantially more difficult. Nevertheless, this task is now routinely performed by smart cameras as are reading other types of characters on everything from warning signs to microchips. Barcode reading, too, is common. Smart cameras can read both one and two-dimensional codes, now including those with information coded in colour, and put out character strings representing the code content. Due to the variety of barcodes used, a typical camera designed for this task will have software controls to set the type of barcode to be read.

Object Recognition

Using blob analysis, in which a perimeter is drawn around an object in an image to provide dimensions for various ratios, individual cases of previously defined objects can be found. General sets of rules can be made to find cars, for instance, to permit managing of traffic flow. With the current power available in small processors, cameras can include these blob analysis and object detection capabilities. Programming these cameras requires the use of external tools but, once programmed, the cameras can run on their own. Often, this sort of camera will need to transmit to the host not only the detection information but a highly-compressed image with overlays to indicate what objects have been found in the image.

Higher-level functions may also be provided in the camera such as the ability to track identified objects, that is, identify objects that persist from frame to frame, even if they move. More detailed tasks may also be included. In the car application, locating and reading license plates might also be required. This is now within the capabilities of smart cameras. All of these functions depend on identifying actual objects in the scene.

Grey-Scale Analysis

In addition to geometric operations, smart cameras can measure intensities, calculate from these measurements and perform higher-level operations based on these measurements and geometric data. The available functions include classification of objects based on grey-scale properties. This operation could be used to sort objects or to determine surface damage. With proper calibration, smart cameras can make absolute measurements of parameters like reflectance and transmittance and quantize surfaces for texturing and other treatments. The limits here are associated with the number of layers of processing that are required. At some point, a smart camera will simply not have enough speed or memory. These limits continually shift so more capability is always coming.

Colour Analysis

Accuracy of absolute colour measurements is limited in any camera, not just smart cameras by the various factors discussed in the colour section. However, smart cameras are used for sorting on the basis of colour in agricultural applications and other manufacturing processes where acceptance is coded in colour. As long as high precision is not required, smart cameras can also measure colour uniformity and check for colour changes in a production stream. Also within the capabilities are slightly higher level functions like observing thin films and converting the colour of these to thickness using known colour maps. Colour-based blob analysis is likely beyond the capabilities of smart cameras, at least for a while.

10.6.5 Control and Data Interfaces

Interfacing to cameras offers a variety of options ranging from simple analogue and parallel digital data channels, which have been in use for decades, to the latest versions of general-purpose networking protocols. All of these have seen some modifications to handle the typically large data sets associated with images and, especially, with image streams. It is essential in selection of a camera to consider its capacity to provide images with the resolution, data depth and speed required for satisfactory application performance. In all links, some proportion of the time is used for signal or link overhead, more so with some links that others. Several other issues arise in link comparisons:

- Latency – The delay from acquisition of an image to receipt of data can be quite different for various links. Consider that if a strobe shot of an object is taken, the delay out of the camera for the last element is already more than one frame time. If some sort of temporal processing is used in the camera, this delay can be extended to two or three frames. Some links require data buffering that can further increase latency. If isolated imaged apart in time are suitable then none of this may be of concern but if the camera is in some sort of control loop, such delays can prevent successful system operation.
- Speed – Links based on direct wires from the camera to the host – called point-to-point connections – are generally only limited in speed by cable type and length. Protocol-based links can offer the same speed in the physical medium but much of the time is taken by overhead so the maximum camera data rates are reduced. For higher data rates, the properties of copper transmission lines limit cable length so in some cases fibre optic links are needed.
- Link support – Each camera requires support for its communication link from the host. For high-speed parallel links, this generally means that the data receiver must be a framegrabber. Link types that are commonly found on computers should not require additional hardware for support but in some cases the burden on the host CPU for the support of these links is excessive and additional hardware has to be added just to offload link service.

- Cabling and connectors – Parallel links tend to have larger, thicker, shorter and more expensive cables than protocol-based links. For some applications, the best compromise is a link in which the parallel camera data is reformatted for transmission on a smaller number of higher-speed serial data lines. Most of the computer links have fairly fragile connectors and low-strength connector retention to facilitate ease of insertion and removal. Using special versions of these connectors with some sort of retention lock or providing a separate retention device is recommended. In some cases, the connector entries may need to be sealed to keep foreign materials from entering the camera.

10.6.5.1 Analogue

Analogue signals actually convey a large amount of image data on a single wire but the susceptibility to signal degradation and the difficulty in providing sufficiently accurate inter-camera timing have nearly eliminated their use in industrial systems. However, some long-standing analogue interfaces based on television standards are still in use. EIA-170 defines the 525-line interlaced scanning use in NTSC video. It is still often implemented in cameras using chips design for NTSC resolution or VGA sensors. Similar chips are available for 625-line CCIR imaging. Camera tubes were operated at higher resolutions using the EIA-343A standard but this is rare in cameras with solid-state sensors.

In analogue cameras, the cabling is generally 75-ohm RG-59/U coaxial cable with BNC connectors. Runs to several hundred feet are feasible as long as electrical interference is minimal. Framegrabbers are used to digitize the video signal for computer use. Some cameras provide sync or horizontal and vertical drive signals and possibly a pixel clock to assure accurate detection of the time base by the framegrabber.

10.6.5.2 Digital

Digital interfaces offer various degrees of speed, ease of use, immunity to noise and link cost. In some cases, the tradeoffs are quite stark so understanding the specific limitations of each link is very important. For each of the links described, the salient issues are presented.

Parallel (AIA & Others)

Factor	Discussion
Architecture	One conductor for each bit of data transmitted plus additional conductors for timing signals
Speed	Up to 400 MHz per conductor using LVDS differential drivers and receivers
Support	A framegrabber is required for computer interface
Cabling	Multiconductor shielded twisted pair. Connectors of many types have been used
Concerns	Big, stiff cables. Distance limited to about 10 m. Potential skew errors
Documents	BSR/AIA A15.08/3-1993 (Automated Imaging Association)

CameraLink

Factor	Discussion
Architecture	A set of conductors, one for each serial stream of data transmitted plus additional conductors for timing signals. Optional power conductors. Three levels of implementation depending on number and width of data streams required
Speed	Up to 85 MHz pixel clock, up to 8 8-bit simultaneous data streams
Support	A framegrabber is required for computer interface
Cabling	1, 2 or 3 26-conductor shielded twisted pair. Connectors are MDR-26. Fibre optic extenders are available for links to 1 km
Concerns	Distance limited to 10 m
Documents	CameraLink® Specification Version 1.2 (AIA)

Ethernet

The particular version of Ethernet used for imaging is called GigE Vision™. The GigE Vision standard imposes certain constraints to assure availability of the data channel. Even so, about 10% of the channel capacity is taken by link management overhead. For cameras, Ethernet is almost always used as a point-to-point connection with each camera having its own port in the computer. This avoids camera data transmission request conflicts.

Factor	Discussion
Architecture	A four-conductor cable with the Ethernet protocol. Optional power
Speed	About 900 Mbps on a dedicated gigabit Ethernet link
Support	Can run on Ethernet computer port but an Ethernet card with its own protocol manager is recommended to free up the CPU. Communications may managed under the GenICam programming interface
Cabling	Cat5e or Cat6, up to 100 m. RJ-45 connectors
Concerns	No real-time triggering. Can have lost data
Documents	GigE Vision standard – AIA
	GenICam standards – European Machine Vision Association

USB 2.0

Factor	Discussion
Architecture	A four-conductor cable connected to a computer port. Provides 2.5 W power
Speed	Up to 300 Mbps on a 480 Mbps link (USB 3.0, under development – up to 4.5 Gbps available bandwidth)
Support	USB 2.0 port with custom drivers for each device

Cabling	Standard USB cables qualified for USB 2.0. Fibre optic bridges are available for links to 1 km. Standard USB A and B connectors
Concerns	Low data rate. Distance limited to 5 m. No real-time triggering
Documents	USB 2.0 Specification – USB Implementers Forum, Inc. USB 3.0 Specification – USBIF

IEEE 1394b

Factor	Discussion
Architecture	Nine-conductor cable connected to a computer port
Speed	About 500 Mbps on a 786 Mbps link. Faster implementations are allowed but uncommon
Support	FireWire 800 computer port. IIDC protocol is often used for communication
Cabling	Standard FireWire cable. FireWire beta connector. Fibre optic bridges are available for links to 1 km
Concerns	Distance limited to 4.5 m. Various speed levels of FireWire incompatible. No real-time triggering
Documents	IEEE 1394b-2002

Graphics Links

The HDMI graphics interface is very similar to CameraLink in that parallel data is multiplexed and serialized for transmission. Currently, HDMI ports are supplied only as outputs on computers but framegrabbers to accept camera data in this format are available. Since HDMI implements HDCP content control flags, it is important to assure that any camera made with an HDMI output does not assert these flags.

Factor	Discussion
Architecture	19-conductor cable connected to a computer port
Speed	Up to 8.16 Gbps or 340 Megapixels per second with 24 bits per pixel (colour). Triggering can be sent using audio channels
Support	Requires a framegrabber
Cabling	HDMI cable. HDMI connector
Concerns	Distance limited to 15 m
Documents	HDMI Specification 1.3 – HDMI Licensing, LLC

10.6.5.3 Industrial Nets

Smart cameras which are configured to accept simple setup and control commands and put out decision information are capable of being incorporated into industrial control networks.

This market is just beginning to develop as many industrial nets are abandoning proprietary architectures and switching ti Ethernet. To accommodate use in industrial environments, cameras have been built with isolated digital I/O ports for direct connection to programmable controllers, with RS-232 ports for instrument control and with 10 or 100 mbps Ethernet for network setup and monitoring. Cameras utilizing industrial protocols like MODBUS and others are also available. As smart cameras become more and more able to perform vision functions without attention, the industrial appliance models can be expected to increase.

11 Selecting Cameras for Machine Vision

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_11,

11.1 Types of Cameras

Machine Vision requires a systems approach; there are many subtle interactions that involve widget transportation, lighting, optics, cameras, video-capture hardware, computer system architecture, algorithms and software. When beginning a design, application requirements should always be considered first, in order to build a broad conceptual framework. It is most unwise to select any element of a Machine Vision system without considering all of the others as well.

In this chapter, we explore some of the practical issues that should be considered when choosing a camera. There are many different types of cameras and there are many subtleties associated with the way they work. In addition, the camera is a sensitive device that must often operate in a hostile environment. In this chapter, we shall therefore attempt to remove the mystery surrounding this, the central component of a Machine Vision system.

11.1.1 Area Cameras

An *area camera* is any camera designed to image a two-dimensional field-of-view. CCTV (closed-circuit television) cameras historically were extensively used in Machine Vision but they have become much less common in new system designs, due to the emergence of low-cost, high-resolution, digital area cameras.

Although rapidly disappearing, CCTV cameras can still be found in many legacy Machine Vision systems. The technologies of progressive scan and the LVDS (low-voltage differential signalling) interface facilitated the transition from analogue television to modern digital cameras. Other area cameras are also available, such as webcams and those used for electronic conferencing, but they are generally not suited for Machine Vision. Since CCTV cameras, analogue progressive scan cameras and digital cameras with LVDS interfaces can still be found in Machine Vision systems, they are briefly described below.

Generally, Machine Vision area cameras can be characterized by the basic image sensor technology, the image resolution and the interface technology. Cameras can also be classified into colour and monochrome categories. Each of these is discussed in the material that follows.

11.1.1.1 CCTV Cameras

CCTV cameras conform to existing well-established standards such as RS170, RS330, NTSC, CCIR and PAL. These standards dictate the image aspect ratio, signal amplitude, scanning pattern and timing.

Most of the common video standards use interlaced scanning in which the complete image (frame) consists of two partial images or fields. The first partial image (odd field) contains scan lines 1, 3, 5, ... The second partial image (even field) contains scan lines 2, 4, 6, ... (➲ *Fig. 11.1*). The RS330 specification is unique in allowing non-interlaced operation, in which there is one field with half as many scan lines as would be present in interlaced operation. Interlaced scanning was developed specifically to reduce the bandwidth required for standard (terrestrial) television broadcasting. It exploits a physiological property of the human visual system that makes it possible to obtain the benefits of good spatial resolution without actually sending all of the data simultaneously. This is achieved at the cost of allowing a barely perceptible degradation in rapidly changing scenes.

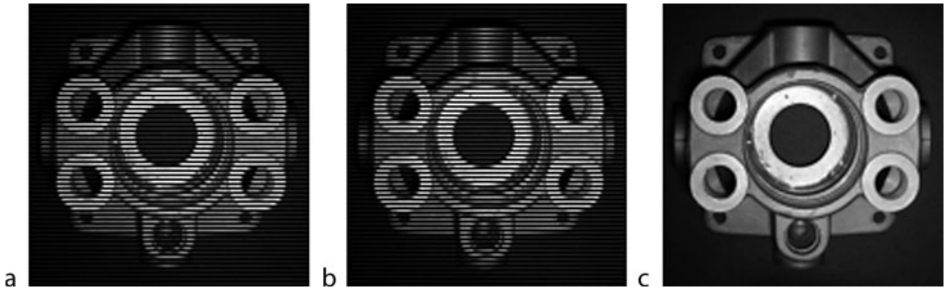

Fig. 11.1
Interlacing. (a) Field 1: odd-numbered lines. (b) Field 2: Even-numbered lines. (c) Full image

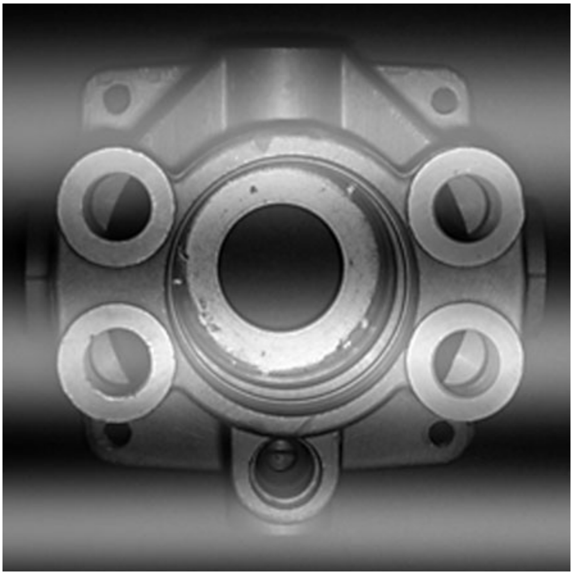

Fig. 11.2
Hum bars (simulated, to emphasize the effect)

Under the RS170 and NTSC standards, 30 frames/second (f/s) is used compared to 25 f/s for CCIR, and PAL. Note that these frame rates correspond to half the power-line frequency in the countries where they are most often used. Scan line timings are very similar for all of the standards. RS170 and NTSC standards provide about 480 active scan lines, while there are about 512 active scan lines for CCIR and PAL. Significant problems occur with traditional lighting, especially fluorescent or discharge-tube lighting, if the camera frame rate is not synchronous with the power-line supply. This can result in so-called hum bars in the camera video output (➋ *Fig. 11.2*).

For technical imaging applications including Machine Vision, interlacing caused problems when acquiring images of moving objects. Since the two fields are captured at different times, they will not be aligned properly resulting in a badly distorted image, called *image tear*, when objects are moving rapidly (➋ *Fig. 11.3*).

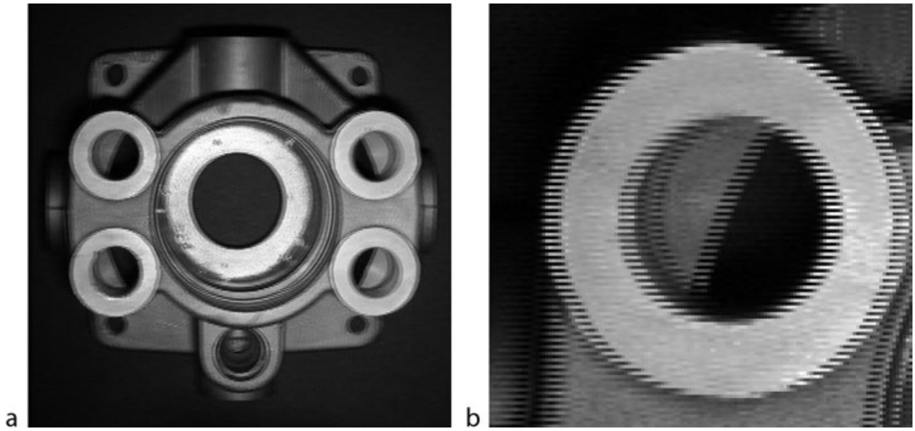

Fig. 11.3
Image tear (simulated, to enhance the effect). (a) Full image. (b) Detail

11.1.1.2 Progressive Scan Cameras

Manufacturers addressed the problem posed by interlaced scanning by developing progressive scan cameras where scan lines are read out sequentially. In some progressive scan cameras, the pixel data can only be read out sequentially in a non-interlaced format. Other cameras provide the option of either progressive or interlaced output. This gave the camera the ability to be compatible with legacy equipment while still retaining the benefits of progressive scan. With this type of camera, a standard TV monitor could be used for camera setup and then switched to progressive operation as required by a given application.

For applications using a strobe light for illumination and an interlaced CCTV camera, only a single field could be captured with a single flash, so the vertical resolution of the image was reduced by half. Even though the photo-sensors associated with the other interlace are exposed, the information is discarded when the first field was read out. With a progressive-scan camera, all scan lines acquire image data that can be read from the camera, and an image illuminated by a strobe had full resolution.

11.1.1.3 Aspect Ratio

At the dawn of television, the standard set the image aspect ratio, the ratio of image width to image height, to 4:3. This was a standard copied from the motion picture industry. This aspect ratio is still widely used today, but other aspect ratios are also common. The transition from analogue television to HDTV (high-definition television) started with an aspect ratio of 16:10 but eventually settled on the aspect ratio to 16:9. Photography had its own image aspect ratios, the most popular being that of 35 mm film; an aspect ratio of 3:2. There are non-standard image sensors that have aspect ratios ranging from 1:1 (square) to 25:1.

A given Machine Vision application will have a preferred aspect ratio based on the required field-of-view. Since custom image sensors are normally not practical, the application developer needs to choose the best aspect ratio available at reasonable cost.

Another consideration is the aspect ratio of pixels. This is determined by the centre-to-centre spacing of sensing elements on the image-sensing array in the camera. Most Machine Vision cameras have “square” pixels – the pixel spacing is the same horizontally and vertically. A few cameras do not have square pixels, and for those cameras, the image-processing software must be able to accept different calibration factors for the horizontal and vertical direction. Also, non-square pixels can make some image-processing algorithms more complex to implement.

11.1.1.4 Image Format

Back in the early days of CCTV, the most common image sensor was a vidicon image pickup tube. This was an enclosed cylindrical glass tube with a target on one end to sense the image, and pins for electrical contact on the other end. The image size was a function of the diameter of the glass tube, and the image format, a label for the image size was this diameter in inches and not the actual image size. This designation continues into the present for area cameras even though image pickup tubes have been replaced by solid-state image sensors.

Some of the common image format designations are:

Format (in.)	Image diagonal (mm)	Image width (mm)	Image height (mm)
1/4	4.50	3.60	2.70
1/3	6.00	4.80	3.60
1/2	8.00	6.40	4.80
1/1.8	8.93	7.18	5.32
2/3	11.00	8.80	6.60
1	16.00	12.80	9.60

For a camera's image sensor designation, the format is determined by the image diagonal and not by the height, width or aspect ratio.

11.1.1.5 Image Resolutions

As area cameras departed from the analogue CCTV standards, the image aspect ratio and the image resolution were no longer tightly constrained by specifications. Many different image resolutions and aspect ratios now exist; the most common ones are identified by their equivalent computer display resolutions. The table below lists some of the more common.

Image designation	Horizontal (pixels)	Vertical (pixels)	Aspect ratio
VGA	640	480	4:3
WVGA	752	480	16:10
SVGA	800	600	4:3
XGA	1,024	768	4:3
WXGA	1,280	720	16:9
HD_DVD			
UXGA	1,600	1,200	4:3
WUXGA	1,920	1,200	16:10

11.1.1.6 Monochrome Cameras

Monochrome cameras are sometimes called *black-and-white cameras,* which erroneously suggests that they are limited to sensing only black or white. In fact, this type of camera provides useful greyscale information as well. While the term *monochrome* implies a single colour, these cameras typically respond to the entire visible (VIS) spectrum and frequently beyond it as well. Silicon, the material from which most image sensors are made, is responsive over the spectral range of 300 (NUV) to 1,100 nm (NIR), with a peak sensitivity between 500 and 900 nm depending on the process used to fabricate the image sensor.

The spectral range of a camera can be further constrained by placing filters in front of the camera, or between the light source and object being viewed. In this way, certain features of an object are enhanced, while suppressing others (➋ *Fig. 11.4*). Similar advantages can be realized for wavelengths outside the visible spectrum. Many cameras employ an IR cut-off filter to limit the sensor's response to wavelengths shorter than about 750 nm (see ➋ Sect. 11.3.2).

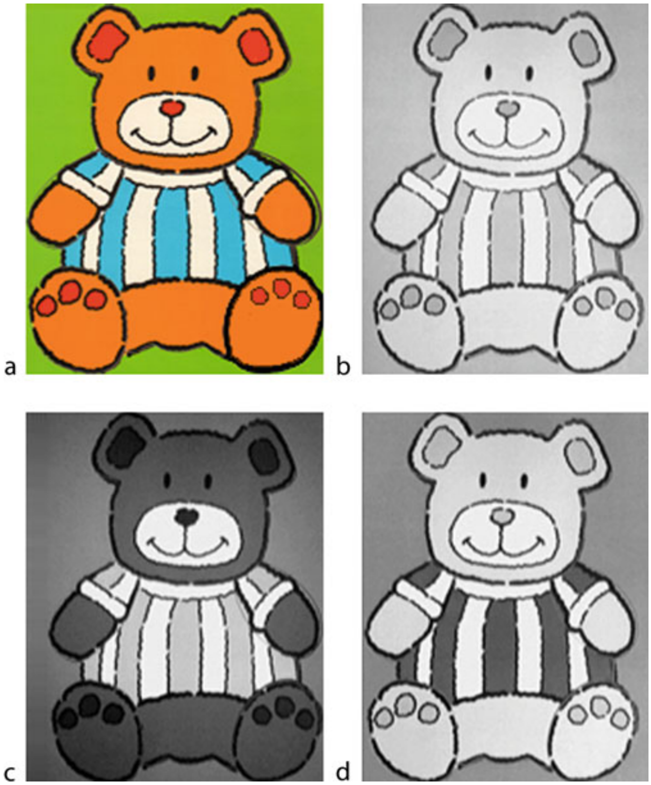

Fig. 11.4
Optical filters can greatly increase image contrast. (a) Original image. (This is a very simple printed jigsaw puzzle for young children.) (b) No filter, monochrome CCD sensor. (c) Short-pass filter (Cut-off: 550 nm). (d) Long-pass filter (Cut-off: 550 nm)

11.1.1.7 Colour Cameras

With colour cameras, there are two additional points to consider: what spatial resolution is provided, and how well the camera's colour response matches an established standard (➋ Chap. 4). Colour cameras measure light intensity in three different spectral bands at each pixel location. (These are commonly referred to as the *red, green* and *blue* colour channels. although this has been the source of considerable confusion. It is better to refer to them as the RGB channels.) The proportions of the three "primary colours" provide a measure of the colour and brightness of an object feature. When colour matching is important, both the camera and the illumination source must be carefully calibrated and checked regularly. Even with high-quality cameras, deficiencies in illumination can cause significant colour measurement errors. Some cameras provide compensation for different types of illumination (e.g., incandescent filament lamp, fluorescent tube, LED). This may help but resolving colour information at shorter wavelengths is difficult without wide-band illumination sources.

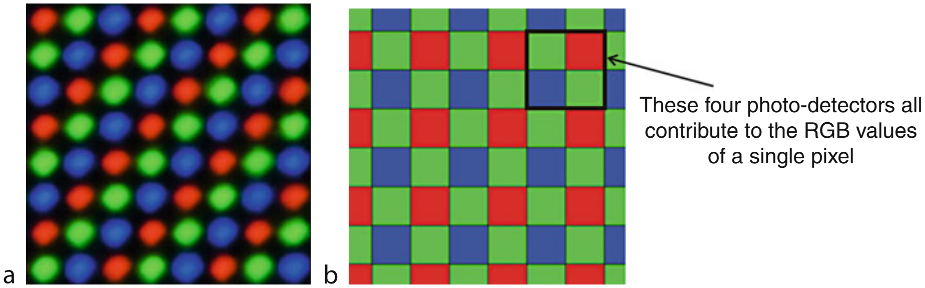
When colour television was under development (1950s and 1960s), advantage was taken of the relatively poor human visual perception in the red and blue portions compared to the central parts of the visible spectrum. Broadcast standards for encoding colour signals make use of the low spatial resolution at the ends of the visible spectrum to save bandwidth. This can, however, be detrimental to the performance of a Machine Vision system.

It is important to note that, given that RGB, sensing of colour is fundamental to nearly all colour cameras. Hence, there is no intrinsic advantage in converting to another format for representing colour, such as HSI (hue, saturation and intensity). For practical reasons, it may be convenient to do so, but information is not gained by calculating any other parameters. Although many physiologists and colour theorists complain that there are better ways of representing and describing colour, sensing based on spectral sampling cannot be avoided. RGB cameras provide the simplest, cheapest and most frequently used basis on which to base colour recognition and processing. Multispectral cameras exist but are expensive. The spectral response of a three-chip RGB camera can be modified, by the simple expedient of removing the standard RGB filters and then inserting different filters in the optical path.

11.1.1.8 Single-Chip Colour Cameras

Single-chip colour cameras are made by depositing colour filters over the sensing elements on an image sensor (➋ Chap. 10). The fidelity of colour reproduction depends to a large extent on how accurately these colour filters are applied in manufacturing. In general, the colour reproduction of these cameras is adequate for viewing scenes but is usually not sufficient for precise colour matching.

Since, at most, one out of three sensing elements will have a red filter over it, and more commonly only one out of four sensing elements has the red filter, the effective image resolution of the red-channel image will be substantially less than that of a monochrome camera with the same number of photo-detectors. The same is true for the blue channel. It is common practise to provide two green, one red and one blue photo-detector sites for each group of four sensory elements (➋ *Fig. 11.5*). Hence, the spatial resolutions of the red and blue sub-images typically are reduced by a factor of four, compared to an equivalent monochrome camera. Since the two green sub-images are normally merged, the resolution of this channel is



a
b
These four photo-detectors all contribute to the RGB values of a single pixel

Fig. 11.5
Bayer filter mask for a single-chip colour camera. (a) View through the mask. The unprocessed photo-detector outputs constitute a RAW image. (b) Converting the RAW image into RGB values. The outputs from two neighbouring green photo-detectors are averaged to form the G channel output, The R and B channels are derived directly from nearby red and green photo-detectors. Hence, there are twice as many photo-detectors contributing to the G channel as there are to the R and B channels. This reduces the appearance of noise effects. Moreover, the RGB photosensors, though very close together, are actually in different places

also reduced by a factor of four. Advantage is taken of the limited acuity of the human visual system in the red and blue portions of the spectrum by allocating fewer photo-detectors for the spectral extremities.

11.1.1.9 Three-Chip Colour Cameras

A three-chip colour camera uses three separate identical image sensors; an arrangement of dichroic beam splitters separates the optical image into three colour components, which are then projected onto the sensors (➔ *Fig. 11.6*). This type of camera produces three parallel video output channels corresponding to the red, green and blue portions of the spectrum. Each of these has the same full resolution as a monochrome camera using the sensor chip but is less sensitive than the monochrome sensor, since only a portion of the light energy reaches each sensor. This type of camera employs optical filters that are not integrated into the image sensor. As a result, more consistent and accurate colour measurements are possible compared to single-chip colour sensors. The response of each channel depends on that of the colour filter and the sensor chip, as well as the angle at which the light passes through the filter. Even with high-quality cameras, there is some unpredictability in its response, due to fabrication variations. Some sensors use the back of the sensor as the imaging surface, to avoid passivation layers and conductors that will alter the sensor's spectral response. This offers significant benefits for colour measurements.

The final consideration for accurate colour image acquisition is that the spectral band pass of an optical filter is specified for normally incident light rays. Because the optical path is longer for oblique rays, the filter response will be altered for these rays. This effect is most severe with wide-angle (short focal length) lenses since light at the edges of the image will be highly oblique. For most applications, it is not too significant. For maximum colour measurement accuracy, telecentric optics should be employed, since all rays are incident normally on the sensor.

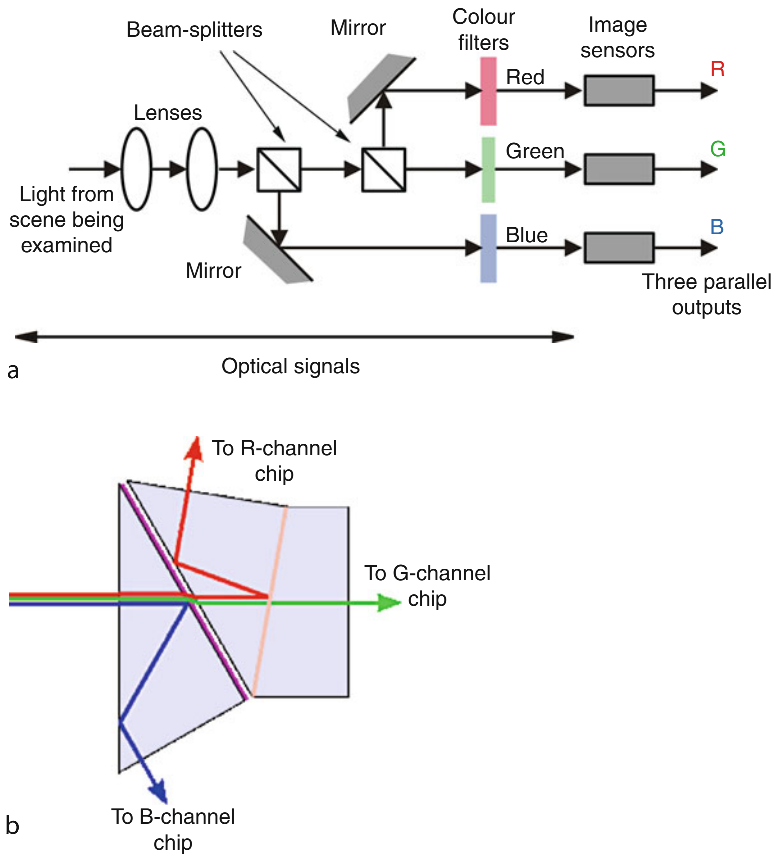


Fig. 11.6

Three-chip colour camera. (a) Using two beamsplitters. Notice that other colour discriminations can be achieved, by simply replacing the RGB filters. It is possible to perform fine colour separation, for example between different shades of "yellow," by using sharp cut-off (interference) filters. (b) Using a multi-element prism. This consists of three prisms with dichroic coatings cemented together

11.1.2 Line-Scan Cameras

The most commonly used line-scan camera consists of an image sensor with a single row of photo-detector elements. To acquire two-dimensional images, either the object under observation (the *widget*), or the camera/sensor must be moved. Through the acquisition of a series of scans, a two-dimensional image of the part is acquired (*Figs. 11.7* and *11.8*).

Many line-scan image sensors provide dual readout paths: one for odd-numbered pixels and one for even-numbered pixels. Some line-scan cameras merge the data from these two paths to form a single video output to facilitate ease of use. But, where speed is important, each of these paths is routed to its own video output. Even higher-speed line-scan cameras are available with multiple outputs.

Fig. 11.7

Using a line-scan camera to inspect objects on a continuously moving conveyor. The tachometer ensures that the camera clock and belt are synchronized. This is necessary, so that the image (and pixel) aspect ratio is known precisely. The image acquisition and processing are triggered when the object being examined breaks the IR beam of the part-present detector. (a) Area camera, (b) Line-scan camera

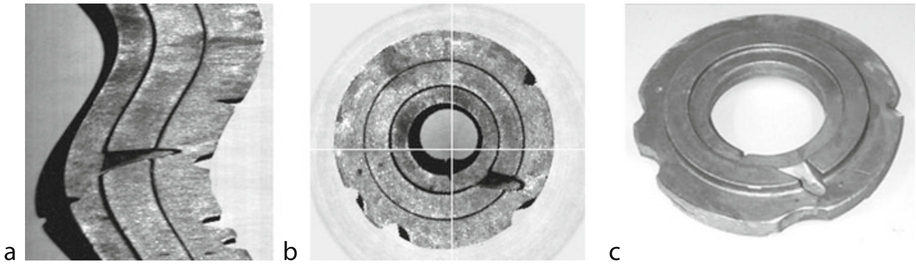

Fig. 11.8
Using a line-scan camera to inspect objects on a turntable, rather than a linear conveyor. (a) Image generated. (b) After Cartesian-to-polar coordinate mapping. (This "bends" the image so that it restores the geometry of the original object.) The crossed lines indicate the centre of rotation. (c) Photograph of the object

For high-speed image acquisition with line-scan cameras, very intense illumination is required due to the short integration ("exposure") time. An area camera's integration time is typically about 17 ms but a line-scan camera frequently may have a scan rate in the range of 0.1–1 ms/line. To compensate for this reduction, a wide lens aperture can be used but this may introduce undesirable optical aberrations. For some applications, illumination devices such as LED arrays, fibre optics or linear fluorescent tubes can be used to concentrate light around the very narrow strip that the sensor "sees"; there is no point in "wasting" light by illuminating a larger region when only a line of light is needed. Indeed, the unwanted and unused light may well reduce the image contrast.

Line-scan image sensors used in Machine Vision almost always have square sensing elements – the height of the sensing element is equal to their horizontal spacing. There are some line-scan arrays, like those made for spectroscopy, where higher sensitivity is needed. Their height is many times greater than their horizontal spacing. These image sensors are rarely used in Machine Vision.

The effective pixel size on the object in line-scan imaging depends on the spacing of the pixels along the line-of-view for one image axis and the speed of the part past the camera together with the line scan rate for the orthogonal axis. Therefore, the effective pixel aspect ratio is application dependent.

Line-scan cameras are available with a range of line lengths in pixels. Some of the common ones are: 512, 1024, 2048, 4096 and 8192. Simple calculations relating to the operation of a standard line-scan camera are presented in ❯ Sect. 11.5 of this chapter.

11.1.3 TDI Sensors

In order to mitigate the short exposure of line-scan cameras, the *time-delay integration* (*TDI*) architecture was developed. A TDI sensor incorporates a number of parallel rows of photo-detectors, typically 64–100, on a single chip. At the end of each scan, the accumulated charge in each row is transferred to the adjacent row, where further photo-generated charge accumulates. This process continues until the charge pattern reaches the final row where it is read out. The output of a TDI sensor is essentially the same as the output from a line-scan sensor, except that

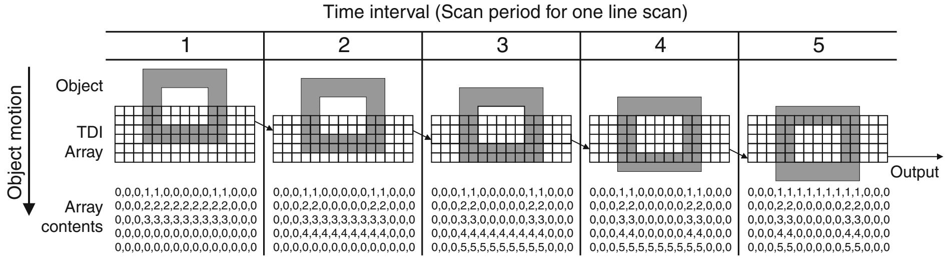

Fig. 11.9
Operation of a TDI camera

far less illumination is required. As for a conventional line-scan camera, the sensor chip or the widget must be moved at a constant, well-defined speed. For a TDI sensor, this motion must be carefully synchronized with the scan rate of the sensor, so that the same region of the widget is imaged on adjacent rows of the sensor at each scanning interval. Significant image blurring results, if the motion and scanning rate are not closely matched (➋ *Fig. 11.9*).

11.1.4 Camera Operation

A standard video (free-running) camera adhering to one of the legacy broadcast television standards, e.g., RS-170 (North America) or CCIR (much of Western Europe), is designed to acquire images continuously and generate video data in a defined format. While this type of camera works well for some vision applications, serious problems may occur when the widget is moving without proper synchronization. The widget-transport mechanism and the camera must be synchronized. Since the former is difficult to control precisely, a phase-lock loop receiving a signal from the mechanical system may be needed to derive the synchronization signals for the camera and its interface electronics.

Most cameras now being designed into Machine Vision systems are asynchronous. An *asynchronous camera* acquires images on command when a trigger pulse is received. Image acquisition and readout can be triggered at any moment, provided that the interval between trigger pulses is greater than the time taken for image acquisition and readout. Some asynchronous cameras are available with internal memory for storing a number of images. These cameras can accept a series of trigger pulses very close together. Image data is stored as it is acquired, and sent to the computer as fast as possible using the available transmission bandwidth.

Some asynchronous area cameras will not run at all without the appropriate control signals: external pixel clock, line-start and frame-start signals. A pixel clock synchronizes the scanning of photo-detectors in the camera with the collection of pixels within the digital image inside a computer. This is particularly useful for precision gauging applications, where sub-pixel interpolation is required. Line-scan cameras typically require only an external pixel clock and a scan initiating pulse.

In a free-running camera, the integration ("exposure") time is often the same as that needed to transmit one video frame (or field). However, many cameras allow shorter exposure times than this, to reduce blurring due to rapid movement. See ➋ Sect. 11.2.11 for more information on electronic shutters.

11.1.5 Image Sensor Architecture

A variety of camera types are available for Machine Vision applications, including:

- Interline transfer CCD
- Frame transfer CCD
- CMOS

Image sensors may be categorized in two principal ways, the type of sensor, and the structure of the readout electronics. Although it is not necessary to know the details of the architecture to choose a suitable camera, there are applications where some basic knowledge of image sensor architecture is useful.

The two basic types of solid-state photosensors, P–N junction (photodiode) and MOS capacitor (CCD) elements both employ a depletion region where photo-generated electron-hole pairs are separated and stored. A key property of a photosensor is its sensitivity at different wavelengths. Photons impinging on an image sensor penetrate into the sensor substrate some distance before being absorbed. The actual distance a given photon penetrates is dependent on its wavelength, and is expressed by a probability function. Shorter wavelength photons (e.g., blue and ultraviolet) tend to be absorbed nearer the surface while longer wavelengths (e.g., infrared) are more likely to penetrate deeper before absorption. Only those photons absorbed in the vicinity of the depletion region contribute significantly to the signal, so the depth of the depletion region influences the responsivity of the image sensor. Typically, shallow depletion regions are used to improve sensitivity in the blue region and reduce sensitivity at red and infrared wavelengths. Since longer wavelength photons are much more prevalent, this is often a desirable trade-off for cameras operating with visible light.

Another important factor affecting sensor responsivity is in the layers of materials placed over the photoreceptor. These layers have an optical effect similar to that of an interference filter. The responsivity of a photodiode sensing element, which is usually covered with only a passivation layer of SiO_2, is somewhat different from that of a MOS sensing element. The latter is usually covered with several layers of materials, including polycrystalline silicon. The photodiode spectral response is considerably smoother than that of an MOS device that has a series of peaks and valleys. To avoid these irregularities, some detectors using MOS sensing elements are back thinned, so that the image is projected on the back of the sensor where there is no passivation or conduction layers rather than its front. By etching the back very close to the depletion layer, the resulting spectral responsivity curve is much smoother.

For most Machine Vision applications, the details of the sensor construction are usually not very critical; other camera characteristics are more important. However, given that each sensor type has certain advantages and disadvantages, exceptionally challenging applications may be addressed more effectively by selecting the most appropriate sensor type.

11.1.5.1 Charge Coupled Device

Charge coupled device (CCD) sensors feature modest cost, low noise and high speed. They usually use a MOS capacitor as the sensing element, but there are some sensors that use a photodiode sensing element. CCD shift registers are used to read out the image information. There are two principal types of CCD image sensors, *interline transfer* and *frame transfer*, which differ in how data is read out.

Interline transfer CCDs have vertical CCD readout registers adjacent to their respective sensing elements. These sensing elements are typically photodiodes. The chip area is substantially less than for a frame transfer CCD, but the relatively low fill-factor (about 30%) reduces sensitivity and the ability to resolve small features (The fill-factor is the percentage of the area of the photo-detector array that is actually sensitive to light.)

As a result, interline transfer CCDs do not function optimally for applications requiring sub-pixel measurements. To mitigate these limitations, some interline CCD image sensors have arrays of plastic lenslets in which each photo-detector element is covered by a small lens to increase the amount of light reaching it. With lenslets, the effective fill factor increases to around 60–70%.

Frame-transfer CCD sensors use an array of MOS capacitors as the light-sensitive elements and have CCD readout registers in a separate area on the integrated circuit. Photo-generated charge is shifted through the array of sensing elements into the readout registers at the end of the exposure time and just prior to readout. Fill factors of 80–95% can be achieved, thereby enhancing sensitivity and resolution. However, this type of device requires a greater chip area and is therefore more expensive than interline transfer CCDs. Also, the transfer of charge from the sensing elements into the readout array uses the sensing elements themselves. Thus, there is the risk of some low level image smear from the light energy that falls on the sensing elements during this transfer.

11.1.5.2 CMOS (Complementary Metal Oxide Semiconductor)

Another class of image sensors is based on CMOS technology, which is in widespread use for integrated circuits, such as microprocessors. The sensing element can be either a photodiode, or MOS capacitor. Sensing elements can share an output circuit, or each photo-detector can have its own output circuit. In the first case, each sensor element is switched sequentially to an output circuit. In the second case, each output circuit is switched sequentially to the sensor’s output line.

Some CMOS sensors have no storage ability for photo-generated charge. The exposure time for a sensing element is the time between successive periods when data is read out. That means that the exposure interval for every sensing element is the same, but the time at which the interval occurs is different for each sensing element. This is called a *rolling shutter*. Rolling shutters are acceptable for imaging stationary objects, but they give a skewed image when imaging moving objects. (Vertical edges appear inclined in the digital image.)

Some CMOS sensors incorporate temporary storage of the photo-generated charge for each sensing element. The photo-generated charges for all sensing elements are transferred simultaneously into their corresponding storage. These storage elements are selected sequentially for readout. This is called a *global shutter*. All sensing elements are exposed at the same time, and no image skew results when imaging moving objects.

The major advantages of CMOS sensors are their low cost and their ability to incorporate other processing functions on the same chip as the image sensor.

11.2 Camera Characteristics

Solid-state image sensors are complex photo-electronic devices that have a variety of features that should be considered when choosing a camera for a given application. If these are ignored, grossly suboptimal performance will be achieved.

11.2.1 Resolution

Two types of resolutions are important when selecting cameras:

- *Sensor resolution.* The number of rows and columns of photo-detectors in the sensor array determines the maximum number of pixels that can be created in the digital image.
- *Optical resolution.* This refers to the ability of the optical system to resolve fine detail in a scene.

The overall resolution of a system is a function of a number of variables, including sensor resolution, focus and depth of focus. Imaging system resolution is frequently characterized by the *modulation transfer function* (*MTF*) and describes the ability of a system to discriminate patterns such as fine parallel lines or concentric circles (➲ *Fig. 11.10*).

11.2.1.1 Sensor Resolution

The sensor resolution is defined as the number of photo-detector elements in each row and column. Typical values were covered above in ➲ Sects. 11.1.1.5 and ➲ 11.1.2 on area and line-scan cameras.

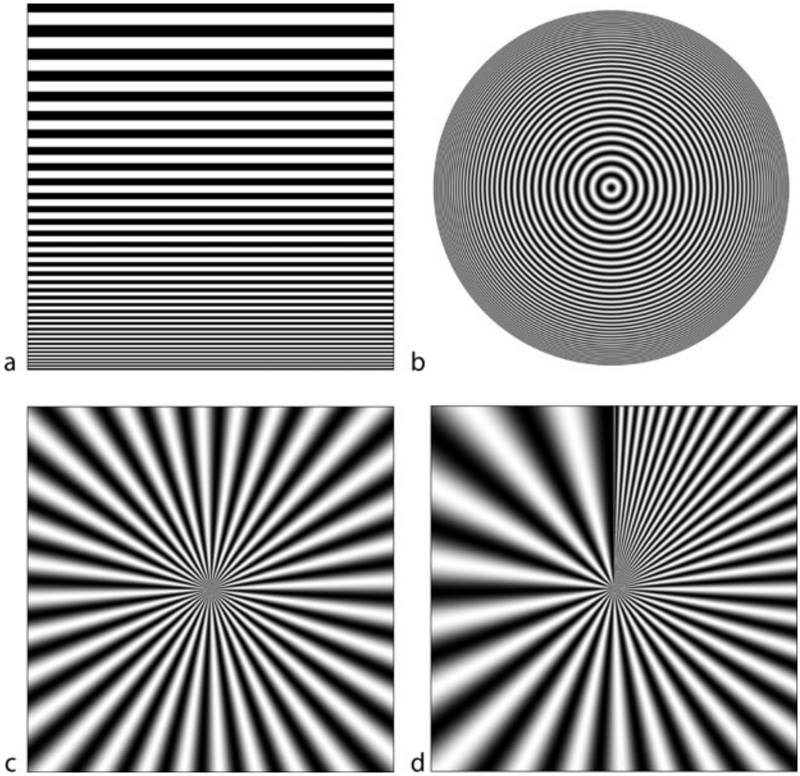

Fig. 11.10

Patterns for measuring acuity of a camera. (a) Variable frequency, linear. (b) Variable frequency, circular. (c) Fixed frequency, radial. (d) Variable frequency, radial

The cameras used most frequently in today's Machine Vision design all have digital outputs, in which case the image resolution exactly equals the sensor resolution. (This ignores situation in which the camera transmits only a portion of the sensed image. See ➔ Sect. 11.2.9.) In cameras with analogue outputs, the frame grabber samples the analogue signal to create the digitized picture. For solid-state analogue cameras, the image resolution is not necessarily equal to the sensor resolution.

11.2.1.2 Video Resolution

Video resolution indicates the size of the smallest feature that can be resolved by an image acquisition system. This includes the lens, image sensor, signal-conditioning electronics and digitiser. Video resolution indicates the number of vertical black and white lines across the field of view that can be resolved across the image. Both black and white stripes contribute to the count, whereas optical resolution is measured in terms of line-pairs. For this reason, the video resolution stated in lines may seem better than the optical resolution stated in line pairs. However, the reverse is always true; video resolution is never better than optical resolution. ➔ *Figure 11.10* illustrates how lines eventually blur together with decreasing pitch.

11.2.2 Sensitivity

Camera sensitivity is specified in two ways:

1. The light level necessary to provide a full-amplitude video output at the edge of saturation.
2. The light level necessary to give a "useful" image, as judged subjectively by a person.

Method [2], widely used in the surveillance field, has very obvious limitations for Machine Vision, while Method [1] is useful, as it is easy to measure and quantify. The factors that control a camera's sensitivity specification include:

- The presence or absence of an IR-blocking filter
- The illumination source used
- What lens, if any, is used and its aperture setting
- Whether or not AGC is enabled
- The gain setting of the camera electronics if AGC is disabled
- The exposure time

The image sensor's spectral responsivity is not equal to that of the human eye. Hence, radiometric (actual power density: watts/m^2) measurements are useful, since they allow accurate quantitative comparisons to be made. However, it is common practice for camera sensitivity to be expressed in photometric terms. This measures perceived brightness (lux or lumens/m^2) of light on either the target that is imaged by the camera or on the image sensors "retina."

Most camera sensitivity tests are performed with an incandescent light source (filament lamp), because its spectrum is very broad and follows a relatively smooth curve that is easy to characterize. Most of the energy radiated by such a source is in the infrared region, where a silicon-based image sensor has the most sensitivity (0.7–1.2 μm). To maintain a sharp image, an IR-blocking filter is very commonly used in practical systems. For this reason, some camera manufacturers specify camera sensitivity using an IR-cut filter. Since some companies do not, it is important to check how the sensitivity has been measured. By definition, non-visible illumination, in the UV and IR spectral bands, does not affect photometric measurements but it does affect the output of the camera, if not blocked by a filter. Therefore, camera sensitivity measured without an IR-blocking filter and with the illumination expressed in photometric terms is very misleading.

Some companies specify camera sensitivity with a given lens, at a given *f*-stop imaging a target with a certain level of illumination. Some others do so with no lens at all, specifying the illumination level incident on the image sensor. The comparison between them is relatively complex.

Ideally, all cameras would be measured at the same gain setting but this is not the current practise, since there is no standard, or convention. This is another reason why comparing cameras is difficult.

Saturation occurs when an increase in scene illumination does not result in an increase in the video signal level. There are three possible reasons for this:

1. The photo-detectors have collected their maximum charge.
2. The (analogue) video amplifier has reached its maximum output.
3. The analogue-to-digital converter is at its maximum output value.

Clearly, it is desirable that the camera be designed so these three situations occur at the same illumination level.

It is common practise in the surveillance field to operate a camera with its *automatic gain control* (*AGC*) enabled. On the other hand, AGC is rarely useful in Machine Vision, since the light levels are normally held within relatively closely defined limits. When a camera's sensitivity is measured with AGC enabled, the amplifier should be providing significant gain, with the sensor not in saturation.

Many older cameras, especially those used for CCTV applications, operate at a fixed clock rate, with a fixed exposure time. However, modern cameras have electronic shutters that provide an adjustable exposure time. Within the "active" period, the charge collected by a photo-detector is proportional to the integral over time of the light flux. Hence, if the illumination is constant, the integration time needed to generate a given output is inversely proportional to the light level. So, to minimize motion blur, high light levels and a short integration time should be used.

11.2.3 Noise

Noise is any component of the signal that does not contain useful information. For a camera, this is any component of the video output that is unrelated to the scene being captured. Video noise sources include:

- Random electrical noise
- Dark current
- Fixed pattern noise (FPN)
- Non-uniformity in sensitivity across the image sensor
- Blemishes (defective sensing elements)

Although it is camera noise that concerns us here, it is important to bear in mind that the digital representation of the scene being examined is also degraded in other ways:

- Fluctuations in the voltage applied to the lamps
- Lamp ageing and malfunction
- Dirty optical surfaces, due to dust, smoke and fumes in the atmosphere, and fingerprints!

11.2.3.1 Random Electrical Noise

Random electrical noise (temporal noise) is present in every electronic system. By careful design of the circuit and its layout, it can be reduced, often very significantly. The noise specification given on camera data sheets reflects only this random noise, which is affected by the temperature of the sensor chip and the clock rate. Cooling a camera is an effective way to reduce its random noise. For cameras that use an adjustable or external clock, the lowest practical clock rate should be used to minimize noise.

11.2.3.2 Dynamic Range

A camera's dynamic range (D_R) is the ratio of its saturation level (S) to its temporal noise level (N) expressed in db.

$$D_R = 20\ \log_{10}(S/N) \tag{11.1}$$

For a camera with 8-bit pixels, the minimum acceptable dynamic range is 48 dB (= 20.log(256)). For 10-bit pixels, this is 60 dB and for 12-bit pixels it is 72 dB. These values do not take into account any other factors contributing to the noise, so the system noise level is not the same as the camera manufacturer's quoted noise level.

11.2.3.3 Dark Current

Even when a camera is in complete darkness, the photo-detector array will provide an output, as if it were receiving a very small amount of light. This signal is called the *dark current* and is caused by the leakage of charge across a photosensor's depletion region. It is an inherent property of silicon-based image sensors. Dark current is proportional to the exposure time and is very temperature dependent; it doubles with every 7°C increase in chip temperature. It can be a significant factor when a camera is operated at elevated temperatures, or long integration times are used.

Most image sensors incorporate reference sensing elements at the beginning of each line. These are the same as normal sensing elements, except they are covered by metal and so are insensitive to light. The output of these elements is determined only by the dark current. At the beginning of each line, the camera electronics samples the signal from the reference sensing elements, and then subtracts that dark-current value from the output of the uncovered sensing elements in that scan line. This is effective in correcting for dark current changes. However, there is some variation in dark current from one photo-detector to another. This cannot be fully corrected in this way. These element-to-element variations in dark current will be exacerbated as the temperature increases.

11.2.3.4 Fixed Pattern Noise (FPN)

Capacitative coupling of control signals on the chip, or its surrounding circuitry, and variations in the readout circuitry produce some subtle unwanted variations in the signal level. Most often, this is a fixed offset to the pixel intensity data. It varies across the image sensor and does not change with exposure. For most cameras operating under normal conditions (i.e., moderate temperature and adequate exposure), this fixed pattern noise (FPN) is usually less than can be detected with 8-bit (256 grey level) digitization. If the voltages applied to the image sensor chip are misadjusted, the camera is operated in temperature extremes, or if the video signal is digitized to 10 or more bits, then fixed pattern noise may be observable. Fixed pattern noise can be corrected by subtracting an individual offset for each pixel.

11.2.3.5 Double Correlated Sampling

Double correlated sampling is a hardware technique used in many CCD image sensors to reduce both dark current noise and fixed pattern noise. Video information consists of a series of pulses in which the amplitude of each pulse is associated with the output of the value. The background level between pulses is a function of dark current plus fixed pattern noise. In double correlated sampling, the camera first samples the level between pulses, and then samples the level of the pulse representing the sensing element output. The main contribution to the difference between those two samples is a function of the amplitude of the light level at a given pixel, with much of the dark current and fixed pattern noise eliminated.

11.2.3.6 Photo Response Non-uniformity (PRNU)

Due to differences in sensing elements from the semiconductor process (e.g., exact size or doping level), not all sensing elements on an image sensor have the same sensitivity. Across the array, the sensitivity can vary by as much as 10%. In applications with high-contrast features, this variation is of little significance but in other cases this factor should be considered. Changes in exposure time can affect photo response non-uniformity (PRNU).

A technique for mitigating the effect of PRNU, called *uniformity correction* or *flat-field correction*, is to associate a stored gain value for each pixel in the image sensor array. This gain is calibrated by imaging a uniformly illuminated target. Thus, the correction not only compensates for PRNU but also for variations in the lens' light gathering capability (e.g., cosine^4 falloff and vignetting) as well as for any non-uniformity in illumination. While the correction can be applied digitally in a look-up table after the pixel's signal has been digitized, it is preferable for it to be applied to the pixel's analogue signal before digitization, to avoid any non-linearities or missed codes.

11.2.3.7 Blemishes

A blemish is one or more adjacent sensing elements whose response differs significantly from neighbouring pixels. Such pixels may be fully on or off all of the time, or just respond very differently. With improved manufacturing techniques, blemishes are much less of a problem now than in years past. However, for sensors with high resolutions, blemishes are still present. Usually, sensor manufacturers offer a range of grades of sensors where the grade is determined by the number and type of blemishes. Fewer blemishes give a higher grade sensor for a higher price.

11.2.4 Blooming

Every photon that is absorbed by a photo-detector element generates a hole-electron pair. The electric field in the detector's depletion region separates the electron from its corresponding hole.

The result is an accumulation of charge in the depletion layer, which in turn reduces the electric field, so that further charge carriers are held there less tightly. When the charge reaches a certain level, some of it "bleeds" into the depletion regions of nearby photo-detectors, or into other nearby circuitry. Hence, a very brightly illuminated spot on the sensor chip produces a much larger blurry region, or a streak in the digital image generated by the camera. Such an effect is called *blooming*. On an interline transfer CCD device, blooming usually appears as a bright vertical streak. Blooming is particularly likely to occur when the camera is pointed directly towards a lamp, or the highlights caused by glinting from a metal or smooth, polished surface.

While image sensor designs incorporate circuitry to remove the excess photo-generated charge, every solid-state image sensor suffers from blooming under intense lighting conditions. A good measure of blooming resistance is the ratio of exposure level at which blooming begins to the exposure level causing saturation of the image sensor.

11.2.5 Gamma (γ)

One way to express the transfer function of a device's output signal (S_{out}) is with the following equation:

$$S_{out} = S_0 . I_{in}\gamma$$

where S_0 is a positive constant, I_{in} is the input light level and γ is a positive parameter. For cameras using a vidicon tube, γ is 0.7. A similar equation relates the brightness of a display to its input signal; for a conventional monochrome CRT display, γ is about 1.3. The combination of the two gammas, gives a combined transfer function with an effective γ of 1. Photographers and users of Photoshop will also be familiar with the use of γ as a way of characterizing the non-linear response of a system.

Modern displays are designed with a γ of 2.2. Cameras designed for use with these displays incorporate circuitry to give them a γ of 0.45 so that again the pair together has a γ of 1.

Modern solid-state cameras are commonly available with γ in the range 0.45–1. In many cameras, γ can be changed by jumpers, switches or, in the case of digital cameras, by software. For Machine Vision a γ of 1 provides the best results. However, when greyscale information is important as, for example, inspecting textured surfaces, it may be preferable to use a different value. Small values of γ emphasize low intensity values and help to suppress highlights due to glinting. (The reader can experiment with this using the QT functions *dga* and *gma.*) Digitizing a camera's signal when it uses a gamma other than 1 will cause non-linearities in the video amplitude that are not anticipated by some image-processing functions. The designer of a Machine Vision system should use a γ of 1 unless it is clear that a different value is beneficial and compatible with the image-processing algorithm.

11.2.6 Electronic Shutter

A solid-state image sensor can emulate a mechanical or opto-electronic shutter, by adjusting the timing between control signals, so that the sensing elements do not accumulate any photo-generated charge. The exposure timing is set up by software.

11.2.7 Region-of-Interest Readout

In applications that do not require the use of all the pixels from the camera, significant improvements in speed can be achieved, by transferring only the data from those pixels needed for image processing. CCD image sensors typically provide for selective readout in which unwanted scan lines are discarded in the image sensor, and only the desired range of scan line information is output from the sensor and transmitted by the camera.

Its architecture limits a CMOS sensor to generating data from a rectangular region of interest (ROI).

11.2.8 Binning

Binning is a technique in which the video signal from two or more adjoining photo-detector elements are combined to define the intensity in a single pixel. Averaging four photo-detector outputs has the advantage of increasing the apparent sensitivity of the camera by a factor of 4 and reducing the noise level by 50% but at the cost of halving spatial resolution both horizontally and vertically. (The image will have only one-fourth as many pixels as it would if binning were not used.)

11.2.9 Camera Power

The majority of cameras require a single power supply, either an AC source or more commonly, a 12 V DC power module. A few speciality cameras, such as line-scan cameras, require two or even three, different power supply voltages. To avoid problems caused by ohmic voltage drop in the power supply cables, these cables should be as short as possible using as large a gauge wire as practical.

11.2.10 Size and Weight

A camera's size is usually specified by giving the height, width and depth of the box that will just contain it. This does not include the lens or other optics. Nor does it make any provision for the space required for cables/connectors. Furthermore, it may not include the necessary mounting hardware. Camera size is clearly important in many applications. Optical techniques such as folded optical paths or the use of coherent fibre optic bundles may save space at the point of imaging. Miniature cameras exist and are suitable for imaging in very constrained spaces such as inspecting the insides of very narrow pipes.

Cameras may be supplied as a one-piece device, or as a small remote sensing head along with a control unit containing the power supply, video amplifier, signal conditioning, timing and control circuitry. Two-piece cameras are more expensive than one-piece cameras with the same performance and are also available with superior performance. The distance between the camera head and its control box in a two-piece camera is normally limited to about 2 m.

The manufacturer's quoted weight for a camera is that of the camera body, and does not include the lens, power supply, connectors or cables. Generally, the weight of the camera is only a serious consideration when the camera is part of the payload on a robot arm; it is not usually important for inspection applications.

11.2.11 Cooling

The power dissipated by the camera can be computed from the product of the supply voltage and current. This, together with the protective housing, determines the temperature differential between the camera and its ambient environment. Cooling may be required for

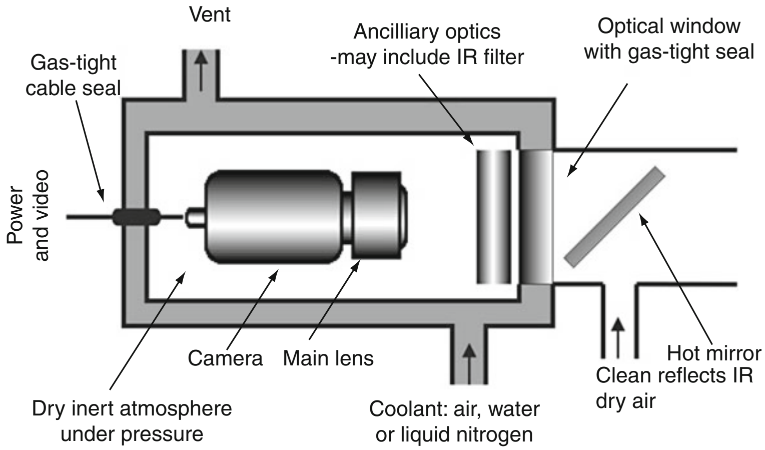

Fig. 11.11
Camera protection. In most applications, some but not all of these precautions are necessary

high-ambient-temperature conditions to ensure proper camera operation. In some cases where excess heat needs to be dissipated, a passive heat sink may be sufficient. At the other extreme in very hot environments, camera cooling may require a double-wall enclosure with circulating air, water or liquid nitrogen to cool the camera (*Fig. 11.11*). The choice of protective optical window for such an enclosure is discussed in Chap. 5.

11.2.12 Temperature

Cameras, like other electronic equipment are limited by the ambient temperature range over which they can be stored and operated. The storage temperature range is usually wider than the operating temperature range. Storage temperature is limited by the range over which thermal expansion will not cause irreversible damage. Operating temperature is limited by the temperature range over which the camera will meet is minimum specifications or, for some manufacturers, just continue to operate.

The performance of a camera is affected by temperature. Usually low temperature limits the upper speed (clock rate) of the camera. High temperature increases the dark current of the image sensor, and reduces the camera's lifetime. The lifetime of electronic components is halved by each 7°C rise in temperature.

11.2.13 Humidity

High humidity is not good for any electronic equipment. Cameras are especially prone to damage from condensation, which can degrade its performance and cause lens fogging. If a camera must be used in a high humidity environment, care must be taken to prevent condensation. This may be achieved by a protective housing, by a simple purging stream of dry, clean air or by slightly heating the camera a few degrees above ambient temperature.

11.2.14 Shock and Vibration

Cameras designed specifically for harsh environments will typically have specified shock and vibration limits. There are two concerns: one is the complete failure of the camera and the other is the loss of alignment between the lens, sensor and the camera's mount. The manufacture's specification usually defines limits to maintain good lens-sensor alignment. Vibration can cause image blurring, particularly when using a telephoto lens. As a general principle, shock and vibration should be minimized to avoid these problems. Since some lenses weigh considerably more than the camera, it may be necessary to support the lens separately. It should also be remembered that vibration can be transmitted to the camera via its cabling.

11.2.15 Radiation

Specialized x-ray sensors have been built by the simple expedient of placing a suitable phosphor on a line-scan camera. These can operate for many months without serious degradation of performance. These are suitable for direct sensing of soft x-rays (i.e., beam energy less than 50,000 keV). However, at high energies, the crystal lattice becomes damaged. Irreparable damage is also caused by high-energy particle beams. The particle stream emanating from a strong radioactive source, such as that found inside a reactor will effectively destroy an image-sensing chip within a few minutes. It will even damage standard glass optical components, rendering them opaque and will make insulating sleeving brittle. Specialized tube cameras are needed for applications where there is a strong particle flux. For less hostile situations, it may be possible to provide sufficient protection for the camera using an optical relay system, such as a periscope, that allows the sensor chip to be placed out of harm's way behind a shielding wall.

11.3 Camera Interface Standards

As discussed earlier, Machine Vision started out using CCTV cameras with analogue outputs meeting one of a number of television standards. Analogue cameras are no longer common in the design of modern Machine Vision systems. Leading the transition into digital camera interfaces, many camera companies offered LVDS (low-voltage differential signalling) interfaces where the signal levels met the RS422 standard. The LVDS interface was never a standard. Typically, there was one line pair for each bit of a pixel's output (e.g., eight pairs for 8 bit digitization) and some number of pairs of signals for camera control. There was no standard for the number, naming or timing of control signals, nor was there a standard for the connector or its pin assignments. With the emergence of standardized digital interfaces, the availability and use of LVDS cameras in new designs has vanished.

There are currently four commonly used interface standards for digital cameras: universal serial bus (popularly known as USB), IEEE 1394 (also known as FireWire), gigabit Ethernet known as GigE, and CameraLink. ➲ *Table 11.1* gives a comparison of the different standards.

The specified bandwidth is the maximum data transmission rate. Except for CameraLink, the data includes header and other information in addition to pixel data. In these three cases, the maximum pixel rate for 8-bit pixels is 90%, or less, of the rated bandwidth.

Table 11.1
Camera interface standards

Feature	Interface type			
	USB 2.0	IEEE 1394b	GigE	CameraLink
Bandwidth (Mbytes/s)	50	80	100	≤ 680
Topology	Client/host network	Peer-to-peer network	Peer-to-peer network	Point to point
Interface protocol	None	IIDC (formerly DCAM)	GenICam	CameraLink
Guaranteed delivery	Yes	No	Yes	No
Guaranteed bandwidth	No	Yes	No	Yes
Cable length (m)	≤5	≤10	≤100	≤10

Except for CameraLink, the protocols are all for networked connections. The topology of a network indicates how it is managed. A client/host network is managed by the host, with all data transmissions being between the client to, or from, the host; clients cannot interface directly with each other. A peer-to-peer network allows any device connected to the network to communication with any other one. If the image capture rate is low and the real-time demands on the system are very relaxed, cameras can share the network with other devices. However, when the Machine Vision system requires the use of much of the available bandwidth, or the system has real-time requirements, then the camera or cameras must be on a dedicated network that is not shared with other devices.

An *interface protocol* allows developers to design software to work with cameras from different manufacturers who conform to the same standards. This allows a camera to be exchanged without needing to change its interface.

Asynchronous protocols guarantee data delivery, by facilitating handshaking and acknowledgement between the sender and receiver. If the transmitted data is not received, or if it is received corrupted, then the data is retransmitted. Thus, delivery is guaranteed, but the retransmission uses up some of the allocated bandwidth and real-time operation cannot be guaranteed.

I*sochronous protocols*, guarantee bandwidth even when other devices are connected to the network. IEEE 1394b provides this capability. When a device is connected to the network, it is given the ability to send a packet of data every 125 μs; the size of the packet is fixed to grant the device the bandwidth it requests. The isochronous protocol does not facilitate handshaking, so there is no guarantee of delivery.

Each protocol has a maximum cable length. In every case, hubs and repeaters that can extend that distance. There are, however, limits on the number of hubs that can be chained together between any two devices on the network. There are interfaces to optical fibres that can extend the data transmission lengths to much greater distances.

It should be noted that each of these standards is under continuing development with higher performance versions expected in the near future. In most cases, the future versions will increase the available bandwidth along with other changes that may, or may not, be useful for interfacing cameras.

11.3.1 USB

The universal serial bus (USB) is a ubiquitous interface facilitated on virtually all PCs. As such, it is a natural choice for a camera interface. Earlier versions of USB, versions 1 and 1.1, were too slow to facilitate a camera interface for all but the slowest Machine Vision systems. USB version 2.0 has sufficient bandwidth to be a viable interface. However, note that the speed of the network is determined by the slowest device connected to the network.

No industry software standard currently exists for interfacing USB cameras to a computer; each manufacturer defines a different standard. Therefore, to switch between cameras usually requires the implementation of a different software interface.

Although the USB specification provides for isochronous operation, most camera manufacturers elect to use the more common asynchronous operation. Delivery is guaranteed but bandwidth is not.

11.3.2 IEEE 1394b

IEEE 1394 is popularly known as *FireWire*. The current version, IEEE 1394b, is a popular camera interface because it offers good bandwidth for most Machine Vision applications, guarantees bandwidth with virtually no image data delivery problems and is a standardized software interface. The earlier version, IEEE 1394a, provides half the bandwidth of IEEE 1494b, but is nevertheless adequate for many Machine Vision applications.

IEEE 1394 supports both asynchronous and isochronous data transmission modes. The IIDC camera standard specifies the use of the isochronous mode. The camera, if accepted onto the network is guaranteed bandwidth independently of what other devices are connected to the network and whether or not they are actively transferring data.

11.3.3 Gigabit Ethernet

Gigabit Ethernet, also known as *1000 base T* or *GigE*, is the latest widely adopted Ethernet standard for copper wire interconnection. It is strictly an asynchronous networking protocol, because it allows any device to transmit data any time it detects the network is not being used. This means that it is possible for two devices to try to transmit data at the same time. The network protocol facilitates detection and recovery from these collisions through both senders detecting the collision and retrying their transmission after a random delay. Handshaking between the transmitter and receiver of the data ensures delivery of the data. GigE is the highest speed network connection currently available, but higher-speed versions are in development.

The *GenICam* specification defines the interface for a Machine Vision camera over the GigE network.

In most computers, the native GigE ports are managed by the CPU. High data rates can consume up to 30% of a CPU's resources. Separate interface boards that contain onboard processing to manage the data transmission are available. These boards reduce the CPU load to a negligible level.

11.3.4 CameraLink

CameraLink is a standard developed specifically for very high-speed Machine Vision camera interfacing. It is not a network protocol, but provides the highest bandwidth standard currently available. Camera data is sent directly from the camera to a dedicated port in the CameraLink frame grabber in the processor. The CameraLink specification dictates the control signals, the data signals and an RS232 serial link between the camera and the interface. There are three versions of CameraLink that differ in the number of parallel data signals: Base, Medium and Full. The differences are in the maximum bandwidth, 227, 453 or 680 Mb/s, and the number of connectors: 1 for the Base version, 2 for the Medium and Full versions. The RS232 serial link is used to program camera parameters, such as exposure time.

11.4 Practical Issues

In this section, two important points are considered that if ignored, will lead to grossly suboptimal performance.

11.4.1 Lens Mount

The lens mount should provide a secure and vibration-proof fixture, and determines:

- The focal distance, measured from the lenses seating flange. (This is called the flange focal distance.)
- The maximum diameter of the optical path.
- The maximum size of the image sensor.

Camera lenses used in Machine Vision often use the C-mount, CS-mount or one of the 35 mm camera lens standards. Mechanical mounts can be classified as either screw or bayonet type. The predominant screw-mount type used for Machine Vision is the C-mount format originally developed for 16 mm movie cameras. The thread diameter is nominally 1 in., with 32 threads/in. In the ANSI B1.1 standard for unified screw threads, it is designated as *1–32 UN 2A*. The flange focal distance is 0.69 in. (17.526 mm) for a C-mount, and 0.5 in. (12.52 mm) for CS-mount, which is otherwise identical.

Bayonet mounts were originally developed for single-lens reflex 35 mm cameras to facilitate rapid lens changes. They are used for Machine Vision applications that require large image-sensing arrays, such as long line-scan arrays. Considering their price and image quality, 35 mm camera lenses can be very cost effective. (Since they are made in very large quantities for the photographic market, manufacturing costs can be kept low.) C-mount lenses are smaller and lighter than 35 mm camera lenses. It is also possible to adapt C-mount cameras to use 35 mm camera lenses, usually with excellent results. More generally, it is possible to adapt a lens with one type of mount to fit a camera with another mount, provided the flange focal distance of the former is greater than that of the camera's mount. In other words, the lens can be moved further away from the camera but not closer. Thus, a C-mount lens can be fitted to a CS-mount camera by using a 5 mm spacer ring.

Some lenses, particularly wide-angle lenses, protrude into the camera body, behind the front flange plate. For monochrome and single-chip colour cameras, this is not normally important. However, three-chip colour cameras require an optical beam splitter in front of the image sensors, so it is not possible to operate a camera of this type with a wide-angle lens.

Bayonet-mount lenses have two drawbacks:

- The springs in the mount have a limited ability to support large heavy (e.g., telephoto) lenses properly. In some attitudes (e.g., viewing horizontally, or vertically downwards), the mounting springs may not provide sufficient tension to keep the lens seated against the mounting flange. This problem can be mitigated by ensuring that the lens mount has sufficiently strong retaining springs for the given lens. The situation is, of course, made worse if there is any significant level of vibration.
- The lens-centring tolerance is relatively loose, to facilitate the rapid changing of lenses. This clearance provides the opportunity for the lens to shift on the camera and can degrade calibration. (On a photographic camera, the ability to change lenses quickly and easily is important. On a fixed-lens Machine Vision camera, it is not!) Modification of bayonet mounts, using set-screws or a similar mechanical approach, is effective but must be done on a bespoke basis.

11.4.2 IR-Blocking Filters

Silicon image sensors respond to light with wavelengths in the range 300–1,100 nm. The glass cover normally placed over the sensor effectively eliminates NUV (i.e., wavelengths shorter than 400 nm). In the NIR region, 700–1,100 nm, the image sensor is very sensitive, but typical lenses are only colour-corrected in the visible region (400–700 nm). So, a good deal of spherical and chromatic aberration occurs at NIR wavelengths and the resulting images will be blurred. Hence, many cameras are provided with IR cut-off filters, either as standard or as an option. With these IR-blocking filters, the image quality is improved dramatically, but at the cost of significantly reduced sensitivity.

For monochrome cameras, with the IR-blocking filter in place, the camera's spectral response roughly approximates that of the human eye. This is, of course, important when the vision system is expected to evaluate the cosmetic appearance of a product.

For colour-imaging applications, the IR-blocking filter is essential, since colour filters often pass IR radiation with little attenuation. Removing NIR radiation also avoids the poor focusing that occurs because *achromatic lenses* do not provide appropriate correction outside the visible wavelengths. Since most silicon-based sensors are very sensitive to NIR wavelengths, this can be important in ensuring good image quality.

11.4.3 NIR Imaging

Since a silicon-based sensor is able to detect near NIR radiation, it is possible to extend the working spectral range of a camera outside, simply by removing its IR-blocking filter. The result is a camera with a wide spectral response (300–1,100 nm). This may be useful in certain applications. By inserting a filter that eliminates all visible light, we produce a camera that is sensitive only to NIR (700–1,100 nm). This is a simple and inexpensive way to produce a camera that has applications in areas where natural products are inspected and will often suffice for preliminary feasibility studies (➲ *Fig. 11.12*).

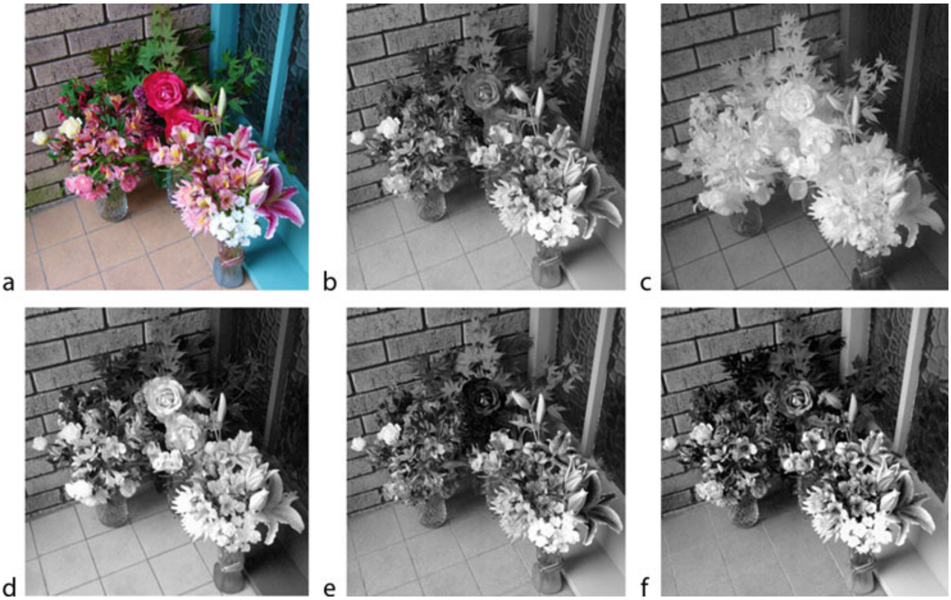

Fig. 11.12
Visible and NIR images. (a) Natural colour. Image obtained using a Sony DSC-H9 digital camera. The NIR-blocking filter is in situ. (b) Intensity channel. At each pixel, the intensity here is equal to the sum of the RGB values. (c) The NIR blocking filter was removed and a VIS-blocking filter inserted. The spectrum detected here is approximately 850–1,100 nm. (d) R-channel. (e) G-channel. (f) B-channel

11.5 Operation of a Line-Scan Camera on a Linear Conveyor

11.5.1 Notation

f – Clock pulse frequency (Hz)
N_a – No. of *active* photo-detectors in the line-scan array. (Defines no. of pixels across the image.)
N$_d$ – No. of *dead* photo-detectors. (This is a fiction, introduced to simplify the calculations.)
V – Conveyor speed (m s^{-1})
T_i – Integration time for the photo-detectors to accumulate charge. Note: $T_i \leq N_a/f$
M – Optical magnification
W – Width of the line visible to the line-scan camera

- Scan time

$$T_s = (N_d + N_a)/f \text{ s}$$

- Active scan interval

$$T_a = N_a/f \text{ s}$$

- "Dead" interval

$$T_d = N_d/f \text{ s}$$

- During the scan interval (T_s) the conveyor moves

$$V(N_d + N_a)/f \text{ m}$$

- Conveyor movement between consecutive clock pulses (1/f s)

$$D_1 = V/f \text{ m}$$

- Conveyor movement during the active scan period (T_a)

$$D_a = N_a V/f \text{ m}$$

- Conveyor movement during the “dead” period (T_d)

$$D_d = N_d V/f \text{ m}$$

- Conveyor movement during the complete scan period ($T_d + T_a$). This is the effective height of pixels.

$$D_t = (N_d + N_a)V/f \text{ m}$$

- Effective pixel width (across conveyor)

$$W/N_a \text{ m}$$

- Effective angular offset of the line-scan array due to scanning it in finite time

$$\theta = \tan^{-1}(N_a V/fW)$$

(This can be corrected by rotating the camera by an amount $-\theta$.)

12 X-Ray Inspection

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_12,

Abstract: Automated X-ray Inspection (AXI) is useful for two types of application: detecting foreign bodies, particularly in food, and examining the internal detail of safety-critical products. At first sight, AXI merely seems to be a straightforward extension to Machine Vision but there are several complications. There is only a limited scope for adjusting the spectrum of an x-ray beam. It is not easy to build x-ray mirrors and lenses, so we cannot effectively focus, or collimate, an x-ray beam. Since an x-ray ray tube generates a conical beam, the images it forms are complicated. The diverging beam introduces parallax errors. Furthermore, objects near the x-ray source appear to be bigger than those further away. Features along the beam are superimposed, creating a jumble of detail that is difficult to analyse. AXI has its own set of special features that distinguishes it from other areas of Machine Vision. One particular point emphasises this. X-rays present a clear danger to health, so there is a need for good radiation screening and a variety of other safety measures. Mathematical and software modelling of AXI systems can often help in devising effective image analysis algorithms. These are simple and effective when inspecting close-tolerance accurately aligned artifacts. In this case, a point-by-point comparison of the test image and a reference image may be effective. As the image variability increases, more complex inspection algorithms may be required, often involving the use of sophisticated AI methods. The chapter concludes with a discussion of twin-beam x-ray systems that can improve the detection of defects and foreign bodies.

12.1 Introduction

The term *X-ray* is used to refer to electromagnetic radiation with wavelengths between those of ultraviolet and gamma rays (➔ *Fig. 12.1*). While the exact boundaries are blurred, we shall take it that *X-ray* refers to radiation within to the following approximate limits:

Frequency: 3×10^{16} Hz to 3×10^{19} Hz
Wavelength: 10^{-8} to 10^{-11} m
Energy: 120 eV to 120 keV

In fact, many of the remarks below are also relevant to gamma rays, which have higher energies than X-rays.

We shall take it that X-rays are generated by a cathode ray tube, while gamma rays are emitted from radioactive materials, such as radium and uranium. Again, this boundary is blurred. Both X-rays and gamma rays are forms of *penetrating ionizing radiation* and are capable of travelling through many common materials, including human tissue. Of course, X-rays are familiar to everyone through their use in medicine but it is industrial applications that interest us here. In a naive way, we might study Automated X-ray Inspection (AXI) by

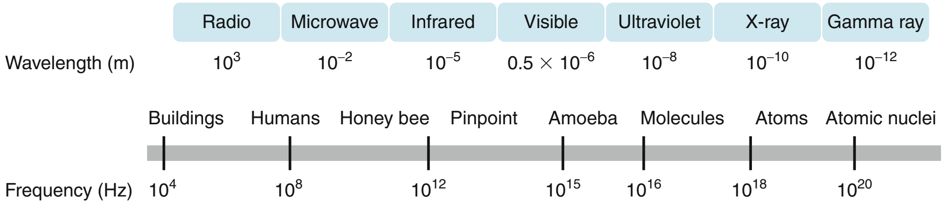

Fig. 12.1
The electromagnetic spectrum (EMS)

merely applying established image processing techniques to the pictures obtained by taking a few samples to the Radiography Department of the local hospital. That is the Computer Science approach! However, it does not give us the complete picture of the potential and complexities of AXI. Firstly, there are many different types of X-ray generator. We can use X-rays covering a wide range of spectral forms. We can use either area-scan or line-scan sensors and specialised image processing algorithms are often needed. AXI is a rather specialised area of Machine Vision but it is, nevertheless, part of the broader subject of this book as it is concerned with all aspects of system design, including the very important health and safety issues that must be addressed when using X-rays. The engineering of X-ray image-forming systems requires specialist skills and knowledge. By claiming that AXI is an area of Machine Vision we are simply reflecting the fact that it is engineering, not merely science. This chapter should not be seen as giving a complete coverage of AXI; we are only able to point to some of the highlights and problems. This is a fascinating and, as yet, largely under-used area of Machine Vision. We hope to show the potential for the future, as well.

Automated X-ray Inspection has two principal areas of application:

(a) Examining the *internal* structure of engineering products and assemblies. Checking the integrity of high-value, safety-critical items is particularly important.
(b) Detecting embedded foreign bodies, particularly in food materials, food products, and pharmaceutical products.

For tasks like these, X-rays provide an obvious sensing mechanism, since they provide hygienic, non-contact sensing that does not damage even delicate and fragile structures. (At the low X-ray doses involved, there is no significant damage, even to protein and other large organic molecules.) There is a popular misconception that X-rays make materials radioactive. *This is not so!* As soon as the X-ray beam is switched off, there is no significant residual radiation. There is no danger to health from a sample that has been inspected using X-rays. Of course, special care must be taken to protect people from exposure to the X-ray beam. *This is a legal requirement!* With good equipment design, routine maintenance, regular independent testing and diligent monitoring of worker exposure dose, there should be no reason to fear the presence of X-rays in the factory.

In the past, X-rays have been used in a wide variety of inspection applications. ➲ *Table 12.1* lists a representative sample of these.

12.2 Elements of an X-Ray System

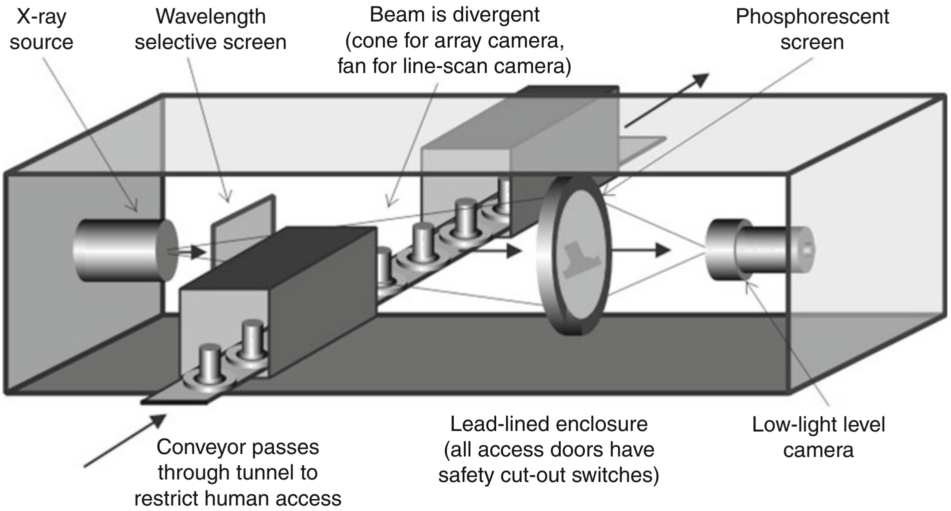
An AXI device has the same basic features as any other Machine Vision system (➲ *Fig. 12.2*). However, the former presents some special requirements and challenges, due to the shorter wavelengths involved. In an AXI system, the standard modules can readily be identified, albeit in a disguised form:

1. Mechanical handling of the widget/material to be inspected. This presents very special requirements for hygiene when working in the food and pharmaceutical industries. (These are two of the subject's most popular areas of application.) In view of the danger associated with ionising radiation, the mechanical handling system must be designed with worker safety in mind.
2. Radiation source (X-ray tube)

Table 12.1

Applications of AXI

Application	Detecting/inspecting/checking
Aluminium castings	Inclusions, voids
Baby Food	Foreign bodies
Baked Products (e.g. cakes, pies)	Amount of filling
Ball grid arrays	Integrity of solder joint
Blister packs	Existence of contents, foreign bodies
Bread	Texture analysis
Cans	Structural integrity
Cartons and boxes (pharmaceuticals)	Presence of medication and leaflet
Ceramic packaging (microelectronics)	Structural integrity
Ceramics	Structural integrity
Chicken, fish and meat	Bones
Cultural/archeological artifacts	Statues, pots, paintings, mummies, etc.
Eggs	Developing embryo
Electronic/electrical assemblies	Loose wires, correctness of assembly
Fish	Bones, weighing
Food materials (milk, soup, etc.)	Foreign bodies
Gems	Inclusions, air bubbles
Glass jars and bottles	Birdswings, spikes, malformation
Leather	Thin spots due to earlier animal injury
Meat	Weighing
Multi-packs (filled jars on tray)	Foreign bodies
Pipes	Structural integrity of seams
Plastic Bottles	Dimensions, inclusions,
Plastic jars and bottles	Dimensions, inclusions, wall thickness
Printed circuit boards	Conductor alignment and integrity
Product counting	Various
Ready meals	Foreign bodies, Filling levels
Rice (plant stems)	Infestation by insects
Seals	Structural integrity
Timber	Knots, splits, fungal attack
Turbine/compressor blades	Integrity, clearance of cooling channels
Tyres (automobile and aircraft)	Structural integrity
Vegetables	Infestation by insects
Welding	Structural integrity



X-ray source
Wavelength selective screen
Beam is divergent (cone for array camera, fan for line-scan camera)
Phosphorescent screen
Conveyor passes through tunnel to restrict human access
Lead-lined enclosure (all access doors have safety cut-out switches)
Low-light level camera

Fig. 12.2

Imaging formation system for AXI. The parts handling system is designed to prevent workers from putting their hands in the X-ray beam

3. Device to modify the radiation properties (X-ray filter)
4. Image sensor and capture module. This may be a standard monochrome visible light camera, or a camera that has been modified to detect X-rays directly. It may be an area-scan or line-scan device.
5. Image processing. X-ray images require both standard techniques and a degree of innovation in algorithm design, in view of the special nature of X-ray images.

Of these, 2–5 are discussed below, in view of their rather special nature in AXI. One additional feature is essential: *radiation protection*. This involves

(a) Shielding using lead sheeting to line the walls of the inspection chamber
(b) Masking to block X-rays except when they are needed
(c) Automated parts delivery and removal (e.g. a conveyor belt running through the inspection chamber)
(d) Tunnels at the entrance and exit ports, so that hands cannot reach inside the inspection chamber
(e) Safety cut-off switches on all access doors
(f) Detectors (e.g. infra-red) to sense hands being placed close to the beam
(g) Anti-tamper fixings; locks on access doors
(h) Regular checking for radiation leakage
(i) Monitoring of staff exposure to X-rays
(j) Automatically switching off the X-ray beam when no part is present for inspection

Additional, features required by certain X-ray systems include:

(k) Cooling water or air
(l) Stabilised power supply
(m) Air conditioning, for certain types of sensitive X-ray detectors

12.2.1 Generating X-Rays

The construction of an X-ray generator is roughly similar to that of a cathode ray tube; a beam of electrons is accelerated by an electric field to high energy (➋ *Fig. 12.2*). The energy of electrons in the beam is proportional to the accelerating voltage (e.g. cathode–anode potential difference) The beam is focussed onto a metal target, such as copper, tungsten, molybdenum or silver. X-rays are generated through the interaction of the energetic electrons in the beam to those bound to the metal atoms. Much of the beam energy is absorbed by the anode, causing intense local heating. The remainder of the beam energy actually generates X-rays, through the *Bremsstrahlung effect.*

Continuum Spectrum A broad spectrum of X-ray energies is generated by a beam of high-speed electrons falling on a metal surface and can be modelled approximately using *Kramer's equation* [1]

$$\mathrm{I(E)} = \mathrm{I_B Z((E_0 - E)/E)} \tag{12.1}$$

where

- I_B is the anode current in the tube. (This is proportional to the number of electrons forming the beam.)
- Z is the atomic number of the tube target material (Tungsten is often used for this purpose, in which case Z =74. Copper is also used sometimes. Z=29).
- E_0 is the cathode–anode potential difference. (The velocity of electrons in the beam is proportional to the accelerating voltage.)
- *I(E)* is the intensity of the X-ray beam. (*I(.)* is proportional to the number of X-ray photons created.)
- *E* is the X-ray energy (measured in keV).

Energy is related to frequency (*f*) using the following equation:

$$E = hf \tag{12.2}$$

where h is Planck's Constant ($4.13566733 \times 10^{-15}$ eVs) Since

$$f = c/\lambda \tag{12.3}$$

where c is the speed of light (c=299,792,458 ms^{-1}) and λ is the wavelength (m), we also have

$$E = hc/\lambda \tag{12.4}$$

➋ Equation 12.1 generates an hyperbolic curve with $I(E_0)=0$ and which increases to infinity at E=0. It describes the *Bremsstrahlung effect* (German. In English, *Braking Radiation*) but does not give a complete picture. The observed output spectrum drops off at very low energies (long wavelengths), because very soft X-rays are easily re-absorbed within the target material. Increasing either the atomic number (*Z*) of the sample, or the beam current (I_B) produces a higher continuum, that is a more intense X-ray beam but does not alter its spectrum.

Refinements Two other factors modify the spectrum (➋ *Fig. 12.3*):

- The exit window of the x-ray tube. This absorbs some of the energy emitted from the anode.
- The anode material. Some elements generates additional X-ray energy within narrowly defined energy bands, superimposing characteristic spikes on the continuum spectrum.

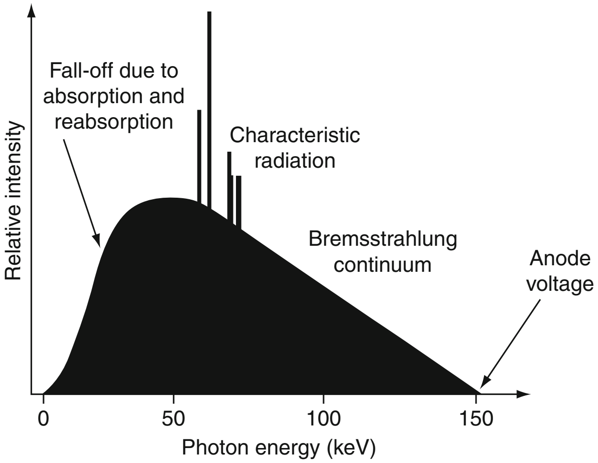


Fig. 12.3
In practice, the X-ray spectrum is determined by four major factors: Bremsstrahlung effect (continuum, Eq. 12.1), narrow-band characteristic of the anode material, reabsorption within the anode, absorption within the exit window

These spikes are caused by quantum energy level changes in the electrons surrounding atoms within the anode material. Although these peaks are relatively large compared to the continuum spectrum, the total amount of emitted energy they contribute is small compared to that from the *Bremsstrahlung* effect.

Beam Power Only a very small fraction of the incident energy from the electron beam is emitted as X-rays within the continuum spectrum. The proportion of the beam energy converted to X-rays is approximately

$$1.1 \times 10^{-8} ZE_o \tag{12.5}$$

Hence, if the anode voltage is 25 KeV and $Z=74$ (tungsten target), only about 2% of the beam energy is converted to X-rays. The remainder is converted to heat in the anode. Since the beam current is I_B, the (continuum) beam power is about

$$1.1 \times 10^{-8} ZI_B E_o{}^2 \tag{12.6}$$

The power dissipation in the tube is almost equal to $I_B E_o$. (This ignores the filament power.) A fundamental difficulty with this method of generating X-rays is that this power is concentrated over a very small spot on the anode. It can be high enough to cause evaporation from a static anode, even from tungsten (Melting point 3,695 K; boiling point 5,828 K), leaving the surface pitted. As we shall see, special precautions are sometimes needed to avoid this.

12.2.1.1 Types of X-Ray Tube

There are several types of X-ray tube (*Fig. 12.4*):

- *Oil Coiled*: The whole tube is immersed in oil to remove excess heat.
- *Gas Cooled*: The tube is surrounded by gas. Heat transfer in gas is much lower than oil, so this type is suitable for lower power levels.

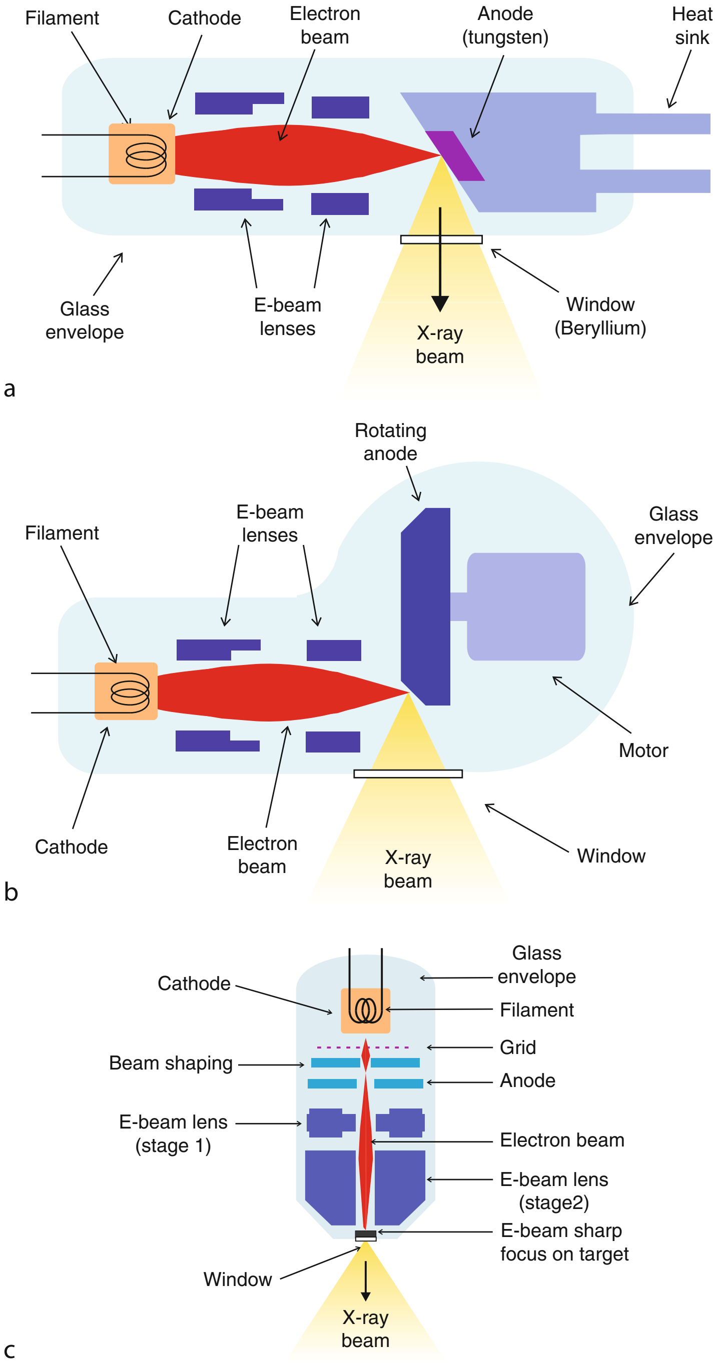

Fig. 12.4 (Continued)

- *Rotating Anode*: The target is a thick metal disc (e.g. tungsten, copper or silver) that is rotated rapidly so that the heat generated by the electron beam does not cause pitting as metal is evaporated from its surface. To increase the power levels further, the whole assembly can be immersed in oil.
- *Micro-focus*: The target is a thin film. Electrons strike it on one side and X-rays emerge from the other. The spot formed by the electron beam on the cathode has a small diameter (a few in microns). The electron beam can be diverted to different parts of the target by a magnetic deflection unit. This allows the life of the tube to be extended, by allowing different parts of the target to be used.

Intense high-energy (i.e., short wavelength) X-rays are produced in a particle accelerator (cyclotron and synchrotron) generating Bremsstrahlung radiation. They been used for high-value, specialist applications, such as examining aircraft and automobile engines.

Beam Switching: Just as in thermionic valves, a grid can be used to control the anode current. This allows the beam to be switched on only for the very short interval when it is needed. This makes the system safer and increases the life of the tube, by reducing anode heat dissipation.

Alternative Sources: Radioactive sources can also be used to produce X-rays. One important advantage of nuclear sources of penetrating radiation is the fact that they can be formed into a variety of shapes: plate, wire, rod, disc, sphere, torus, etc. They are also available in liquid form. Unlike an X-ray tube, radioactive materials cannot be "switched off", so they have to handled with extreme care. In addition, there are strict legal controls about their use, storage and disposal. For these reasons, nuclear sources are unpopular but they do offer three very important benefits: versatility, low running costs and the fact that they do not require any power at all. They do have a finite life but this can be predicted accurately, as can the spectrum. ➋ *Figure 12.5* shows how a nuclear source can be used to generate a crudely collimated beam of X-rays.

12.2.2 Beam Divergence

An important feature of an X-ray tube is that all rays are generated within a very small area on the target. The rays then spread out to form a conical beam (➋ *Fig. 12.4*). Beam divergence is an

◘ Fig. 12.4

Physical construction of three different types of X-ray tube. (a) Standard low-power device. The filament is heated by an electric current to generate a cloud of electrons. To facilitate electron emission, the filament may be coated with a material such as caesium. These thermal electrons are then accelerated by the high potential difference applied between the cathode (filament) and anode. This accelerates the electrons to high speed (energy). The electron beam is focussed to a small spot on the anode, which consists of a block of metal (e.g. copper or tungsten) X-rays are generated as these electrons are suddenly decelerated. Notice the diverging (conical) X-ray beam, which is a feature of the Bremsstrahlung effect (b) High-power X-ray tube [2]. In this case, the target is a thick disc of copper or tungsten that rotates rapidly, to avoid local over-heating. To improve cooling, the whole tube may be immersed in oil. (c) Micro-focus X-ray tube [3]. The electron beam is focussed by an electromagnetic lens onto the target. As a result, the focal spot may be only a few microns in diameter. The target is formed by a thin layer of tungsten on a plate of other metal. The latter also acts as the exit window for the X-rays

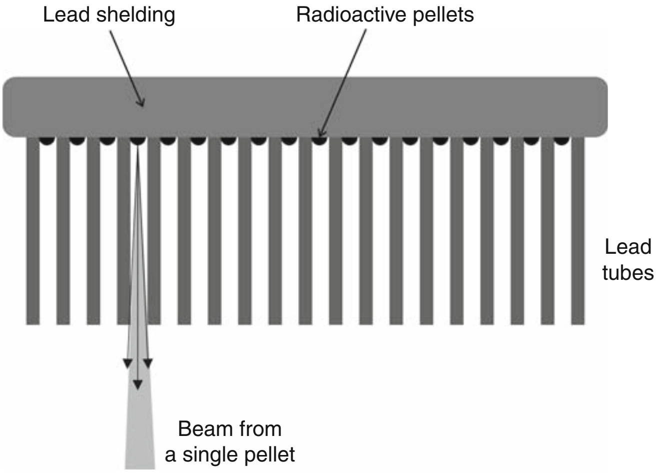

Fig. 12.5

Collimator for a nuclear radiation source. When a line-scan sensor is used, the collimator is a comb-like structure. For an area-scan sensor, the collimator consists of a series of parallel, deep, narrow wells, set on a 2-dimensional array

important feature of many AXI systems that use an area scan image sensor. It complicates the structure of the images produced and consequently has major implications for the design of AXI image processing algorithms. It is difficult to produce a lens, or mirror, that can effectively deflect X-rays and correct beam divergence. So, it is left to the image processing software to accommodate the images produced by a radiation source that is in many ways far from what would be ideal. More will be said later about the consequences of beam divergence.

Beam divergence is important along only one image axis in a line-scan AXI system (➔ *Figs. 12.21–12.24*). It can effectively be overcome by using a nuclear radiation source and a collimator. (➔ *Fig. 12.5*)

Beam divergence can be used to good effect to build an X-ray microscope. Placing the sample close to micro-focus tube and the scintillator screen much further away can provide high magnification. If the target-sample distance is D_1 and the target-scintillator distance is D_2, the X-ray magnification is D_2/D_1. The resolving power is, of course, limited by the spot size.

12.2.3 Scintillators (Phosphors)

Neither a conventional video camera, nor the human eye can sense X-rays directly. (It would be dangerous to try to view them!) So, a scintillator is used. This consists of a thin screen coated with a phosphorescent material that converts X-rays to VIS light (VIS). A variety of materials, many quite exotic, has been used. For example, *yttrium oxysulphide* will glow when it is irradiated with low-energy X-rays, while *gadolinium oxysulphide* can be used for sensing high-energies.

An ideal scintillator would absorb all the X-rays it receives and generate a bright VIS image. However, thick film of phosphorescent material would trap a lot of the visible light it generates, thereby reducing the sensitivity of the detector.

Three important factors when choosing a phosphor are:

(a) The spectrum of X-rays that it absorbs. Clearly, this must be compatible with the spectrum of the X-ray source (i.e., the tube and filter sub-system). Doping the phosphor material affects the light emitted. Gadolinium oxysulphide doped with europium emits light with wavelengths close to the peak in the spectral response of a silicon photodetector. This allows efficient conversion of X-rays to electrical signal.
(b) The spectrum of VIS light that it emits. (This should match the spectral response of the photo-detector array.)
(c) The decay of visible light after the X-ray beam has been switched off. If the time constant of this decay is too long, a blurred image will usually result. If it is too short, the final (i.e., digital) image will be noisy. Some temporal smoothing can be deliberately introduced by using a slow-decay phosphor. The decay process consists of two parts. The first is an exponential decay to a low level of light emission, known as *afterglow*. The second is a slower arithmetic dimming of the afterglow. (The decrease in intensity is approximately linear over time.)

In ❯ *Fig. 12.1*, the camera is shown on the opposite side of the scintillator screen from the sample. Of course, this requires the transmission of radiation through the screen. It is possible to place the camera and sample on the same side, thereby avoiding this and improving the sensitivity for a given X-ray intensity. Although the camera is then off-set, the resulting image warping is slight and can easily be corrected optically.

The sensor geometry may be 2-dimensional (array-scan), or 1-dimensional (line-scan). In the latter case, a 2-dimensional image is formed by repeatedly scanning the photo-detector array, while the object being examined moves past, at a constant and known speed. In most systems, particularly those involving large inspection samples, it is necessary to use a separate scintillator screen, together with a standard (i.e., monochrome, area-scan) camera. Notice that it may be necessary to make the scintillator screen considerably larger than the object being examined. There are two reasons for this:

- The beam continues to expand after passing the inspection sample.
- Different inspection samples may not always be located in exactly the same position.

Another option is to use a VIS line-scan camera, with a strip of phosphor material placed in front of its lens. The conical beam will probably be masked off, close to the generator tube, to produce a fan-shaped beam. (This reduces the radiation hazard.) Proprietary line-scan sensors for X-rays are also available. These use several phosphor-coated, line-scan array chips. These can be butted end-to-end, to produce a very long line-scan device.(There are inevitably small gaps between the chips.) Twin line-scan sensors, overlaid with different phosphors, have been used in dual-wavelength X-ray systems (❯ *Fig. 12.6*).

A summary of the characteristics of commonly used phosphors is given in ❯ *Table 12.2* [4, 5, 11].

12.2.4 X-Ray Filters

Just as in conventional optics, it is possible to adjust the spectrum of an X-ray beam using a filter. It is possible to enhance image contrast using a flat plate composed of some suitable material. This is particularly important for detecting foreign bodies in food and pharmaceutical

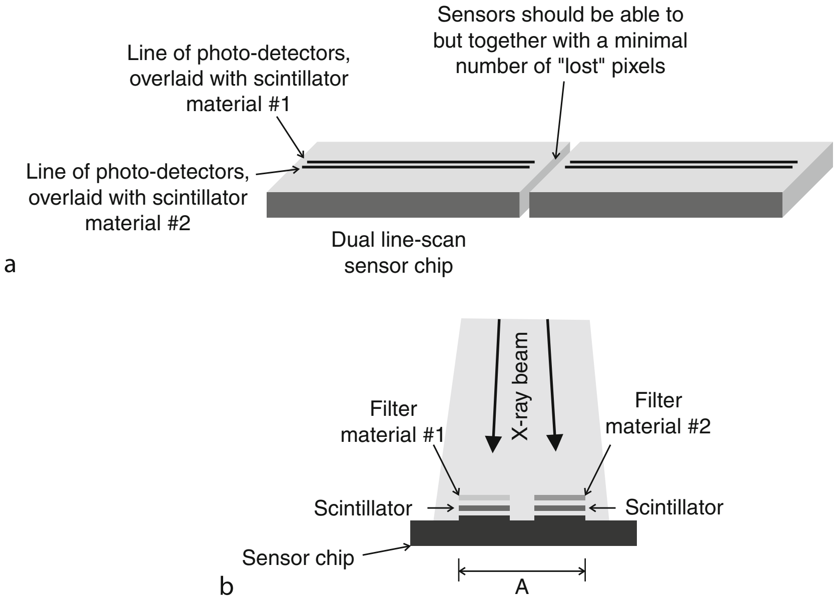

Fig. 12.6

Sensor for dual energy sensing of X-rays. (a) Two line-scan arrays on a single chip. These are conventional VIS sensors but are overlaid with a phosphor and different filter materials. Protective layers are not shown. (b) End view (schematic; the fan-shaped X-ray beam is viewed from the side). For this arrangement to be effective, features in the inspection sample should be several times larger than distance A

Table 12.2

Phosphors commonly used in X-ray scintillators

Phosphor (Key – main material: doping material)	Wavelength at peak emission (nm)	Time constant (decay to 10% intensity)	Afterglow
Gd_2O_2S:Tb	545	1.5 ms	Low
Gd_2O_2S:Eu	627	850 µs	Yes
Gd_2O_2S:Pr	513	7 µs	None
Gd_2O_2S:Pr Ce	513	4 µs	None
Y_2O_2S:Tb	545	1.5 ms	
Y_2O_2S:Eu	627	850 µs	Yes
Y_2O_2S:Pr	513	7 µs	None
Zn(0.5)Cd(0.4)S:Ag	560	80 µs	Yes
Zn(0.4)Cd(0.6)S:Ag	630	80 µs	Yes
$CdWO_4$	475	28 µs	None
$CaWO_4$	Blue (410 nm)	20 µs	None
ZnS:Cu (GS)	Green (520 nm)	minutes	Long

materials/products. However, the options are rather limited; we cannot, for example, build “high-Q” X-ray filters with arbitrary waveband limits. Typical materials used in X-ray filters are:

- To pass high energy X-rays: platinum, gold and lead
- To pass low energy X-rays: molybdenum, silver or tin

Copper, aluminium, zinc and more exotic materials, such as the rare earth elements, are also used [6, 7]. Figure 12.15 sketches the absorption spectra for various materials.

Dual-band systems can be built, using two photo-detector arrays. These are fitted with different filters. ➲ *Figure 12.6* shows the physical layout of such a sensor based on two line-scan photo-detector arrays. The principle of operation is explained in ➲ *Fig. 12.7*. Cobalt, Chromium, Magnesium and Silicon all have very similar spectral characteristics, differing only in the wavelength of a single “step” change in absorption. Graphite has a similar characteristic but does not have a “step” and can therefore be used as an attenuator to match the gains in the two video channels.

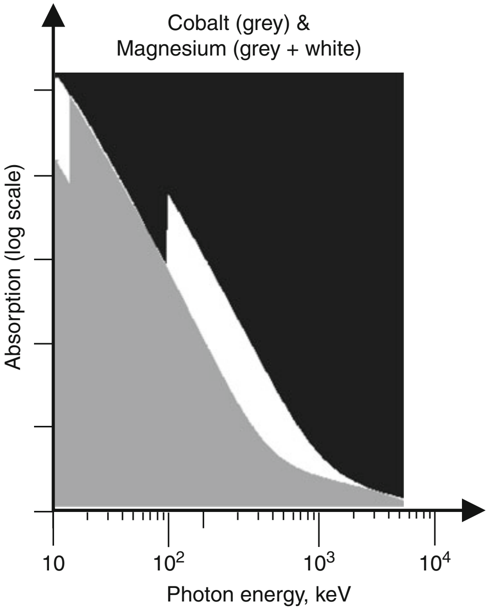

Fig. 12.7

Creating an X-ray band-pass filter by comparing two sensor channels coated with different materials. The absorption spectra for Cobalt (*grey*, Co) and Magnesium (Mg, *grey plus white*) are very similar in the range 30–70 keV. Co is used as a filter in one channel and Mg for the other. The gains in these two channels are carefully adjusted, so that within this energy band, the two cameras produce identical outputs. These two outputs are then subtracted electronically or in software. The combined output is therefore sensitive only to energies in the band 100 keV to about 1,000 keV. Within this waveband, the Co channel has a gain about 4.5 times that of the Mg channel. Thus, the gain of the dual-channel system is very nearly constant over the band 100–140 keV with a sharp cut-off to near zero at about 100 keV. Since Cobalt, Chromium, Magnesium, Silicon and Graphite all have similar absorption spectra, any two of them may be combined in this way. Other pairs of filter materials are possible; the Co:Mg pair is simple to explain

12.2.5 Digitising the Signal

The video signal from the sensor must be digitised before it can be processed by computer. This is achieved in the same way as in any other Machine Vision system and hence will not be discussed further in this chapter.

12.3 Understanding and Analysing the Images

In some applications, standard image processing techniques will suffice to complete the inspection function (➲ *Fig. 12.8*). Hence, for example, a simple processing sequence should suffice to measure the filling level in a tube of tooth-paste, or count the tablets in a blister-pack strip. Although conventional image processing has a role to play, analysing X-ray images sometimes requires special methods, in view of their particular characteristics. As in other areas of Machine Vision, automating the interpretation of AXI images is easier and more effective if we know exactly what to expect when "good" product appears at the point of inspection. Simple existential inspection (i.e., determining whether a part is present/absent) of rigid close-tolerance engineering products/assemblies is straightforward. The task is made even easier if parts are always presented in the same position and orientation, relative to the X-ray source and sensor. ➲ *Figure 12.9* shows an example: an aerosol spray valve. This consists of a number of accurately made plastic and metal components. (Although these are not high-precision parts in the normal engineering sense, they are very much less variable than natural products.) Verifying that such a product is complete and correctly assembled can be achieved very easily, simply by checking the intensity profile along a series of pre-defined scan lines. If there is some small variation in the position/orientation of the assembly, it may be necessary to

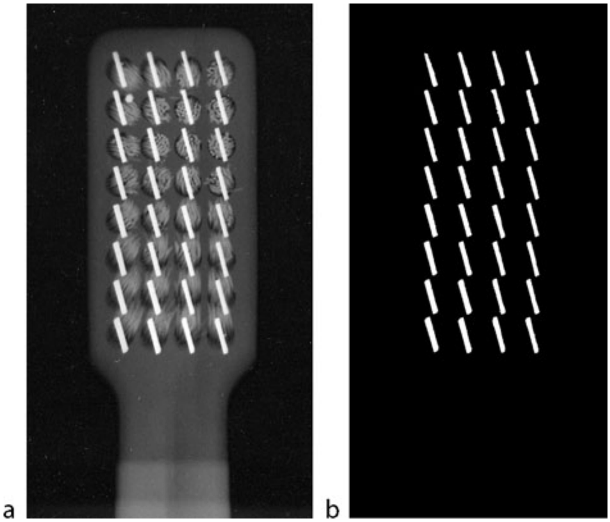

Fig. 12.8

Checking completeness of assembly of a tooth brush. (a) Original image. The bright bars are metal clips needed to retain the bristles. (b) Metal clips detected by simple thresholding

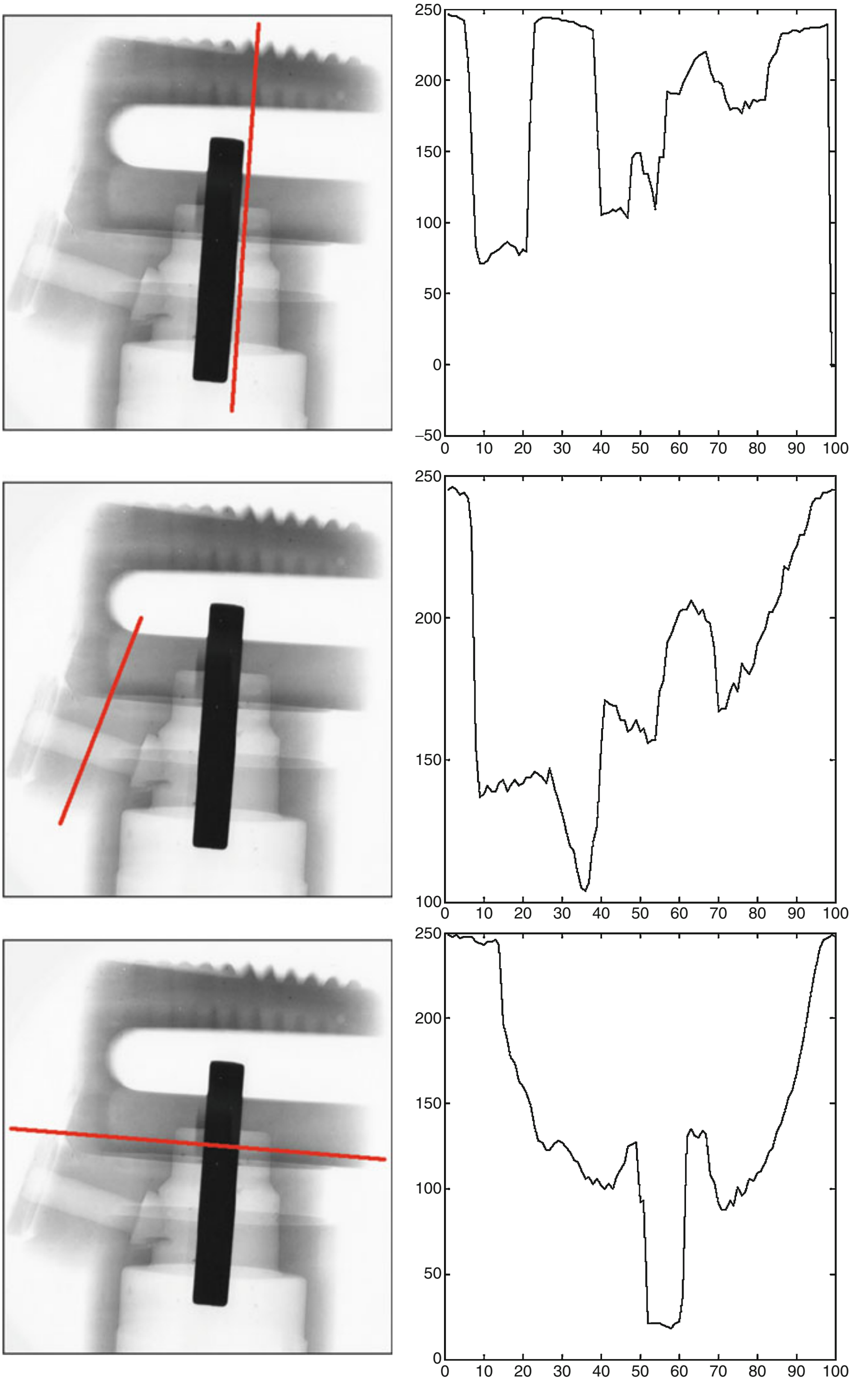

Fig. 12.9
Aerosol spray assembly. Scan lines (*red*) and intensity profiles (*right*)

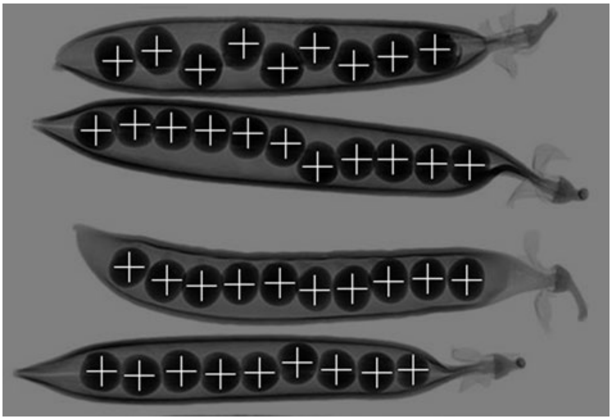

Fig. 12.10

Locating and counting peas in their pods. The algorithm can be adjusted to detect peas within a given range of sizes. [QT: wri, enc, thr, neg, ero(10,0), shk, crs(10), rei, swi,adi, mxi]

adjust the position of these scan lines relative to easily discernable edges, or other features. Binary and grey-scale morphology can also be used to perform fairly crude existential inspection (➋ *Fig. 12.10*). Further applications are illustrated in ➋ *Figs. 12.11–12.13*.

12.3.1 Modelling X-Ray Absorption

In simple situations, such as that illustrated in ➋ *Fig. 12.9*, there is little difficulty in understanding the structure of the X-ray image; each step change in intensity can be attributed to an easily identifiable component edge within the assembly. However, this is not always the case; the image structure may be very complicated indeed. (The reasons for this are listed later.) In this event, it may be helpful to generate a synthesized image that predicts what the X-ray image will look like. Understanding and analysing X-ray images automatically can both be helped considerably by the judicious use of computer graphics. In some cases, synthesising a low-resolution image is sufficient, to help an engineer to understand why the X-ray image appears as it does (➋ *Fig. 12.16*). In some applications, it may be necessary to use a very detailed synthesised image as a "golden sample" that is then compared to the real X-ray images. In this short section, we can only indicate the broad nature of the physical model underlying image synthesis.

Consider a single monochromatic X-ray, of initial intensity I_0, travelling normally through a slab of homogenous material of thickness X and with X-ray *absorption coefficient* μ. The intensity of the emergent ray is given by the *Beer equation*:

$$I_0\exp(-\mu X) \tag{12.7}$$

Notice that, when the ray is travelling through the block at an oblique angle, the path length is bigger, so the attenuation is larger (➋ *Fig. 12.14*). If the angle of incidence is θ, the path length is equal to X/cos(θ). In this case, the intensity of the emergent beam is reduced to

$$I_0\exp(-\mu X/\cos(\theta)) \tag{12.8}$$

In what follows, we shall consider normal incidence, unless otherwise stated.

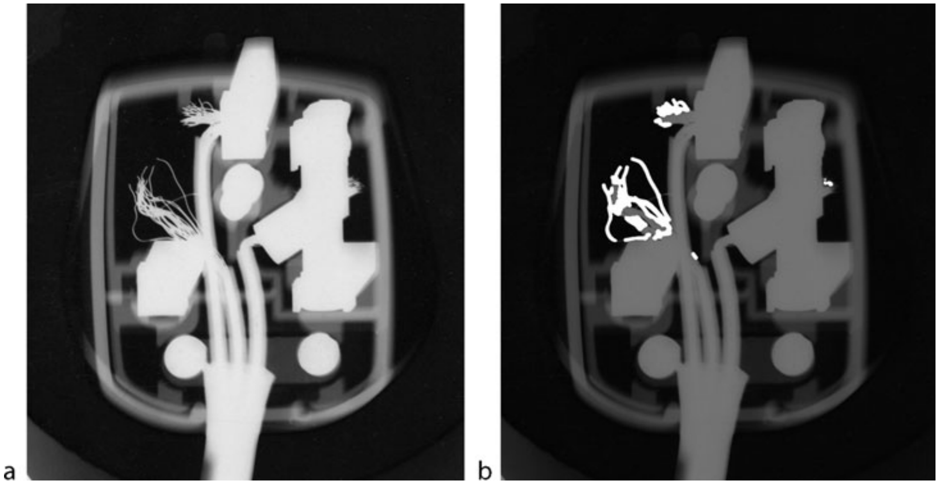

Fig. 12.11
Electrical power plug with faulty wiring. (**a**) Original image. (**b**) Thin bright streaks (strands of bare copper wire) detected using the QT crack detector, *crk* (Chaps. 19 and 21)

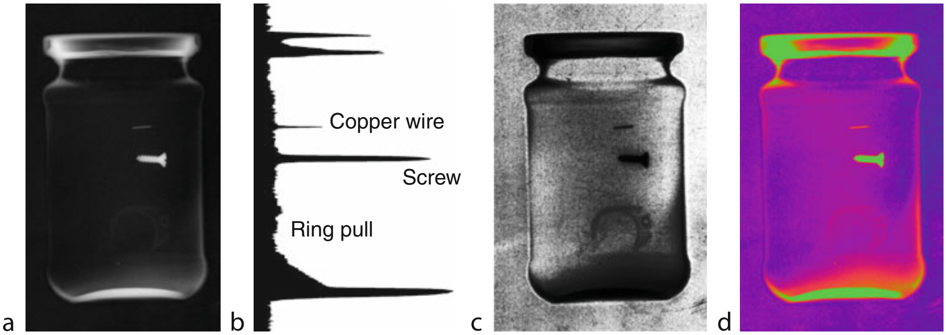

Fig. 12.12
Jar of baby food. (**a**) Original image, negated for clarity. Three foreign bodies have been introduced for testing: short length of copper wire, steel screw and an aluminium ring-pull (almost invisible). (**b**) Intensity profile along the vertical scan line. Notice the high contrast of the copper wire, despite its small diameter. However, the ring-pull does not produce an obvious change in intensity. Notice that this graph also indicates the thickness of the side-wall and, in particular, the distribution of glass around the base and neck-shoulder regions. (**c**) Contrast enhanced to demonstrate that the ring pull really is there! (**d**) Pseudo colour often helps to improve visibility

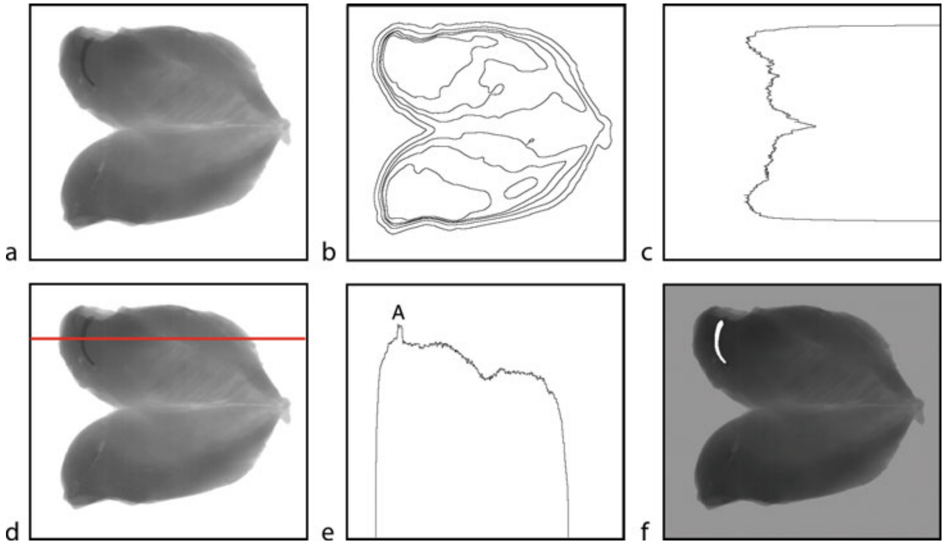

Fig. 12.13

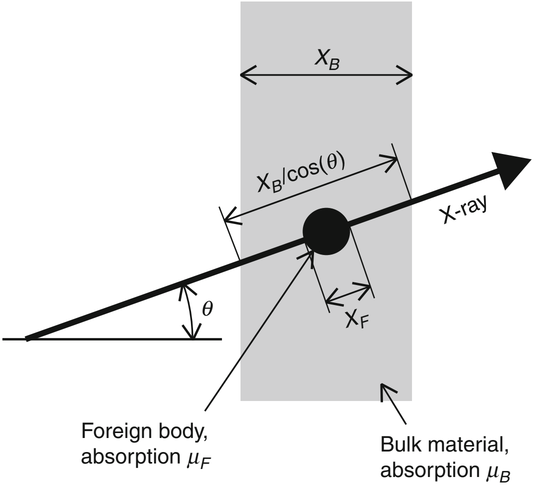
Analysing chicken breast meat. (''Butterfly'') (a) Original image. Source: Spectral Fusion Technologies Ltd. (Birmingham, B46 1JT, UK) (b) Isopohotes. (c) Intensity profile through the centre of the image. (d) Scan line through the crescent-shaped bone. (e) Intensity profile along the red scan line. Notice the low contrast between the bone (A) and the meat. (f) Bone detected using morphology. Although it is effective in this instance, the algorithm used here is not robust enough for practical use



X_B
$X_B/\cos(\theta)$
X-ray
θ
X_F
Foreign body, absorption μ_F
Bulk material, absorption μ_B

Fig. 12.14

An X-ray travelling at an oblique angle through a block of absorbing material containing a spherical foreign body of diameter X_F encounters a path of length ($X_B/\cos\theta$) and will therefore be attenuated more as θ increases. However, the contrast, as defined by Eq. 12.13, depends upon ($\mu_F - \mu_B$) and X_F but is independent of θ

Now, consider a ray travelling through a multi-layer structure, in which the individual layers are of thickness X_i (i=[1,...,N]) and have absorption coefficients μ_i (i = [1,...,N]). The emerging X-ray intensity is given by the following product:

$$I_0 \prod_{i=1}^{N} \exp(-\mu_i X_i) \tag{12.9}$$

or in another form

$$I_0 \exp\left(\sum_{i=1}^{N}(-\mu_i X_i)\right) \tag{12.10}$$

This analysis can, of course, be extended to describe the absorption of a ray travelling through continuously varying medium. However, for our present purposes, ➲ Eqs. 12.9 and ➲ 12.10 will suffice.

Let us now consider a special case: a small piece of material (i.e., a foreign body) of thickness X_F and with absorption coefficient μ_F, is embedded within an homogenous block of overall thickness $X_B(X_B>>X_F)$ and absorption coefficient μ_B. (This is illustrated in ➲ *Fig. 12.14* with the angle θ equal to zero.) The intensity of the emergent beam is

$$I_F = I_0\exp(-\mu_B(X_B - X_F))\exp(-\mu_F X_F) \tag{12.11}$$

If no foreign body is present, the emergent beam intensity is clearly

$$I_B = I_0\exp\left(-\mu_B X_B\right) \tag{12.12}$$

Using ➲ Eqs. 12.11 and ➲ 12.12, we can define a measure of the local contrast (C), caused by the presence of a foreign body. We define C as

$$C = |I_B - I_F| \div I_B \tag{12.13}$$

which reduces to

$$C = |(1 - \exp(\mu_\mathrm{B} - \mu_\mathrm{F})\mathrm{X}_\mathrm{F})| \tag{12.14}$$

The contrast ratio defined in this way is independent of the initial intensity, I_0 and the block thickness (X_B) but varies with the difference in the absorption coefficients of the bulk material and the foreign body ($\mu_B - \mu_F$).➲ Equation 12.14 also shows that larger foreign bodies produce an increased contrast compared to small ones with the same material composition (i.e., same value of μ_F.) The corollary of this is that a wedge-shaped foreign body may not be detectable in its entirety, since the contrast is low at the "thin end". For the same reason, the diameter of a spherical foreign body may be underestimated.

This assumes that the foreign body and the bulk material have the same spectral response. So far, we have assumed that both μ_B and μ_F are both dependent upon the X-ray wavelength, λ. ➲ Equation 12.14 describes the worst-case situation, in which the spectral variation of μ_B and μ_F are exactly the same. To obtain a more precise estimate of the contrast ratio, we should include the following:

- Spectral emission characteristic of the X-ray source, G(λ)
- Spectral absorption characteristic of the bulk material, $\mu_B\left(\dot{\lambda}\right)$
- Spectral absorption characteristic for the foreign body, $\mu_F\left(\dot{\lambda}\right)$
- X-ray-to-VIS conversion efficiency of the scintillator, S(λ,Λ). This is a 2-dimensional function, since there is a different VIS emission spectrum for each incident wavelength λ. Λ is the VIS wavelength.)
- Spectral sensitivity function of the camera (i.e., the VIS image sensor), $C(\Lambda)$

The camera output is then given by

$$\int_{\Lambda}\int_{\lambda} G(\lambda).R(\lambda).S(\lambda,\Lambda).C(\Lambda).d\lambda.d\Lambda \tag{12.15}$$

R(λ) is a generalised version of ➋ Eq. 12.9, viz:

$$\mathrm{R}(\lambda) = \mathrm{I}_0.\exp(-\mu_B(\lambda).(X_B - X_F)).\exp(-\mu_F(\lambda).X_F) \tag{12.16}$$

For most practical purposes, we can estimate the absorption coefficient ($\mu_Z(\lambda)$) for an element of atomic number *Z*, at wavelength λ, using the *Bragg and Beer Equation*:

$$\mu_Z(\lambda) = \mathrm{K}\lambda^3\mathrm{Z}^3 \tag{12.17}$$

K is a constant depending on the element's specific weight. A mixture, or compound, containing elements with absorption coefficients σ_1, σ_2, σ_3,... in proportions P_1: P_2: P_3: ... has an overall absorption coefficient equal to:

$$\sum_i P_i\sigma_i \tag{12.18}$$

Details of X-ray absorption spectra are given for elements 1–92 in [7]. Sample spectral absorption curves are given in ➋ *Fig. 12.15*.

These formulae are, of course, just part of the computation needed to simulate a real X-ray system. Additional calculations are needed to derive the path lengths, X_B and X_F, for rays covering the whole cone occupied by the X-ray beam. These are standard geometric calculations but it must be remembered that the beam intensity diminishes according to the inverse square law.

Examples of synthetic X-ray images are given in ➋ *Figs. 12.16* and ➋ *12.22*. In the former case, they can be compared to the images from an experimental X-ray system. In the second instance, the synthetic X-ray images actually showed that it would not be worthwhile building a system with the particular layout in question because the images are too complicated to analyse.

12.3.2 Why X-Ray Images Are Complicated

Divergence of the X-ray beam causes one of the major complicating features in X-ray systems. This and other factors causing further difficulties are listed below.

- *Non-homogenous beam* The intensity varies across an X-ray beam, is normally greatest in the central region and becomes smaller towards its edge. There are two contributary factors. First, the energy transmitted by the X-ray tube is greatest towards the centre of the beam and decreases towards its periphery. Secondly, the beam divergence spreads the available energy unevenly across the cone (➋ *Fig. 12.17*).
- *Variable magnification* When two identical objects, are placed at different points along the X-ray path, the one closer to the source appears to be larger (➋ *Figs. 12.18*, ➋ *12.23* and ➋ *12.24*).
- *Parallax errors* Parallax distortion occurs as a result of beam spreading (➋ *Fig. 12.19*). For example, two component-lead connecting pads, on opposite sides of a printed circuit board, sometimes create an 8-shaped X-ray shadow. A parallel beam would form a simple

X-ray absorption spectra (two previous pages)

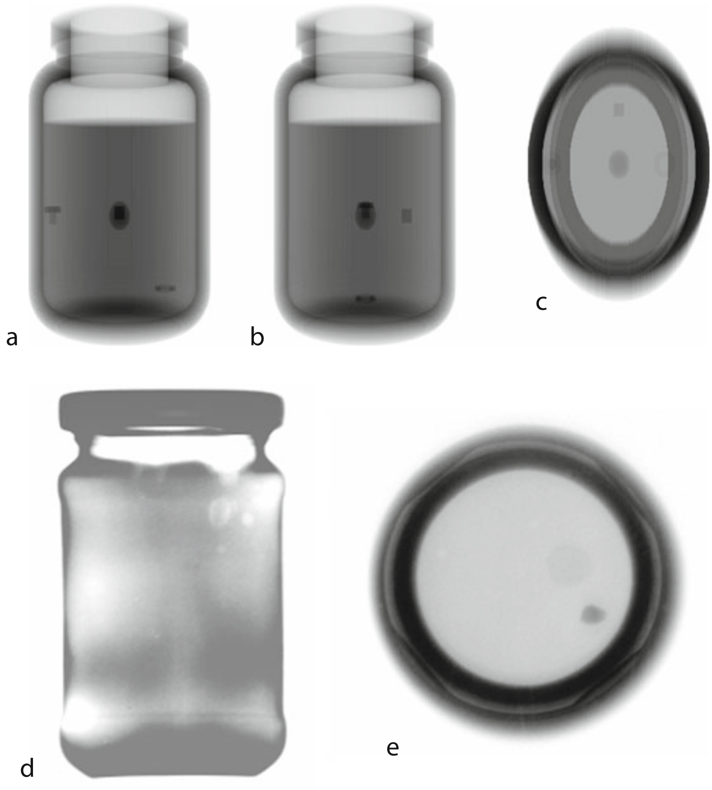

Fig. 12.16

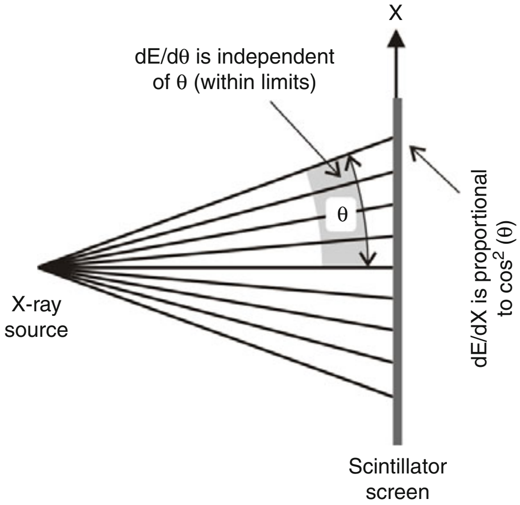
Synthetic X-ray images of a glass jar containing a liquid and four foreign bodies. (a) Side view. (b) Front view. (c) Plan view. The washer, near the base of the jar, cannot be seen easily in the front view. The screw cannot be seen properly in the plan view and is totally obscured in the front view by the sphere. Similarly, the cube is obscured in the side view. (d) and (e) Real jar for comparison. There three foreign bodies. One of them is invisible in the plan view. Variations in the thickness of the glass wall complicate the picture. This jar is fitted with a metal cap

circular ring. Furthermore, conductor tracks that are aligned but on opposite sides of the board become separated, if they close to the edge of the beam.

- *Warping across the image* Consider a grid, or regular array of spots, inclined to the central axis of the beam (➲ *Fig. 12.20*). A distorted grid is projected onto the scintillator screen, since the diverging beam magnifies features close to its edge more than those near the centre. As a result, it may be difficult to register an X-ray image to that from a "golden sample". In addition, it is difficult to measure point-to-point distances precisely.
- *Blurring* Since the X-ray source is not a true mathematical point, images are always blurred to some extent; the larger the spot on the anode targeted by the electron beam, the greater is the blurring effect. So-called *micro-focus* X-ray sources are designed specifically to minimise blurring. Provided the spot size is known and constant, deconvolution software can be used to compensate for blurring but this would not normally be the preferred solution,



X

Fig. 12.17
The diverging beam produces an uneven energy density on the scintillator

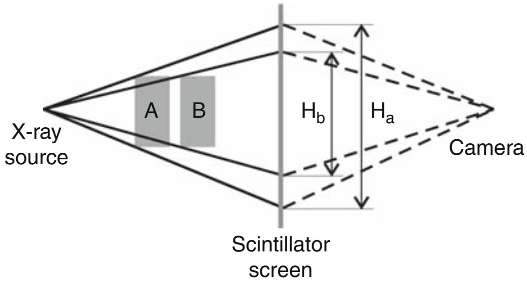

Fig. 12.18
Variable magnification due to beam spreading. H_a is the height of the shadow of object A, while H_b is the apparent height of B. Since A is closer to the point source of X-rays, $H_a > H_b$

since it is computationally expensive and rarely achieves the precision needed for automated analysis.

- *Superimposition of feature shadows* Information about all of the features lying along the path of a given ray is reduced to a single number. This is the implication of Eqs. 12.9 and 12.10. The 3-dimensional structure of the sample is effectively compressed into a single planar image. For example, in the case of the aerosol spray assembly (*Fig. 12.9*), there are several plastic components and a metal pin contributing to the image. Their shadows are superimposed. Notice that any features lying behind the metal pin, which is effectively opaque to X-rays, are lost.
- *Back-scatter* X-rays do not behave exactly in the simple manner described so far. A small proportion of the X-ray energy is scattered, rather than being transmitted or absorbed. This process is akin to the scattering of VIS radiation within a transparent medium such as glass. Scattering of X-rays can lead to degradation of the image quality.
- *Noise* Camera and photon noise both contribute to degradation of image quality.

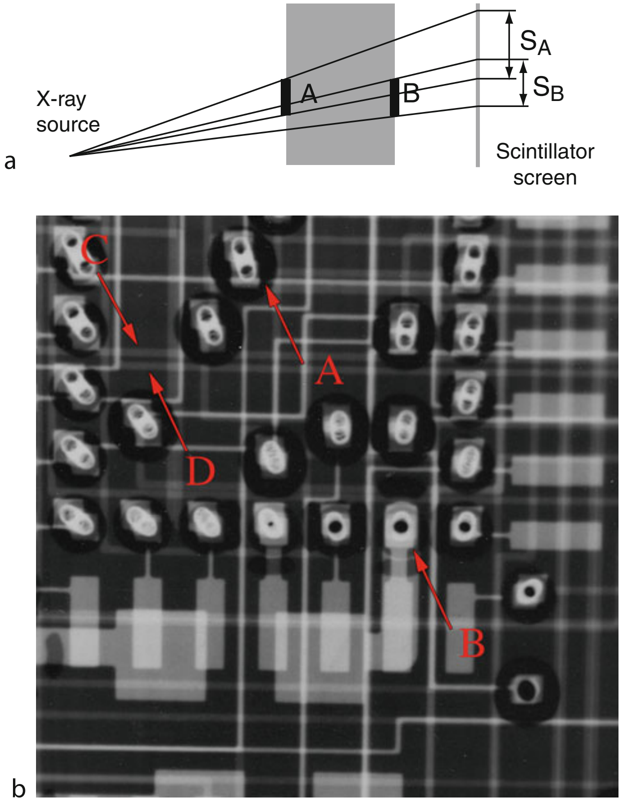

Fig. 12.19

Misalignment of X-ray shadows as a result of parallax. (a) Objects A and B are aligned but are separated along the central axis. S_A is the shadow of A. Similarly, S_B is the shadow of B. S_A and S_B do not coincide exactly and possibly not at all. (b) Printed circuit board showing marked parallax effects: the shadows of two ring-like pads are not aligned near the edge of the image and produce a combined shadow in the form of an 8 (A) However, near the centre the pads overlap to resemble an O. (B). In the same way, overlapping conductor tracks do not appear to be aligned near the edge (C and D)

12.4 Dual Axis X-Ray System

In this section, we describe a *Twin Orthogonal Fan-beam* (TOF) x-ray system for detecting foreign bodies in multi-package food products. The geometric organisation of one such system is explained in *Fig. 12.21*. Other physical arrangements were considered but were quickly discounted, as they were not found to confer any significant advantages. (See for example *Fig. 12.22*.) The work reported in this section was conducted as part of an experimental project funded by the European Union [8]. The objective was to advance AXI system technology across a broad front: from sensors to algorithms. We shall limit our discussion here on the overall concept development and how image processing algorithms were developed specially for the particular type of data that a TOF system generates. This is, once more, an

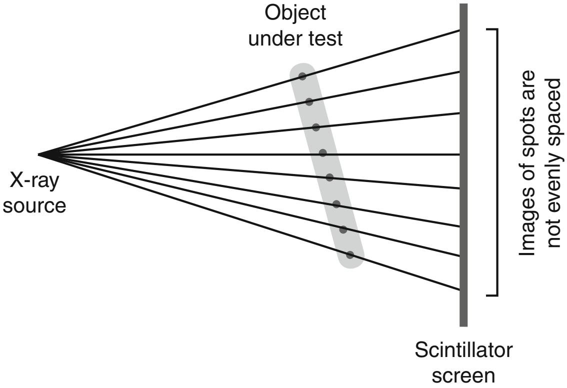

Fig. 12.20
Distortion due to beam divergence

exercise in systems thinking; the physical layout of the image acquisition sub-system creates distinctive data types that require special algorithms to extract the maximum amount of information.

12.4.1 Image Acquisition

In a certain food-processing plant, six empty glass jars are delivered simultaneously, on a cardboard tray, to a multi-nozzle filling station. At no time are the jars ever available separately for filling, capping, or inspection; they must be examined in situ, alongside the other jars on the tray. In the TOF system, two images are digitised simultaneously from line-scan sensors and are then pre-processed separately. These line-scan sensors are aligned precisely, the significance of which will be explained later. The image pair is then processed to locate foreign bodies and operate an *accept/reject* mechanism that diverts the whole tray appropriately. Information about the location (in 3D space) of any foreign bodies is also calculated.

In the side view (*Figs. 12.23* and *12.24*), approximately 90% of the volume of the product is clearly visible, unobscured by the rim and shoulders of the jars. These regions of the side-view image are characterised by having a smoothly varying intensity profile. That part of the product that overlaps the heavy shadows caused by the jar is much more difficult to analyse and therefore requires quite sophisticated image processing techniques. The plan view generates an even more complex image and only 60% of the product volume remains unobscured. The cardboard tray is effectively transparent to the x-rays and, hence, can safely be ignored during the inspection process.

Understanding the Images When we obtained the first TOF image pairs, we were puzzled by their complex form. To gain a greater understanding of their structure, several pairs of x-ray images were synthesised, using a ray-tracing program based on the idea implicit in Sect. 12.3.1. This exercise provided some valuable insight, enabling us to:

- Advise our collaborators who were building a TOF x-ray system.
- Predict how various alternative TOF systems would behave, without ever building them (*Fig. 12.22*).

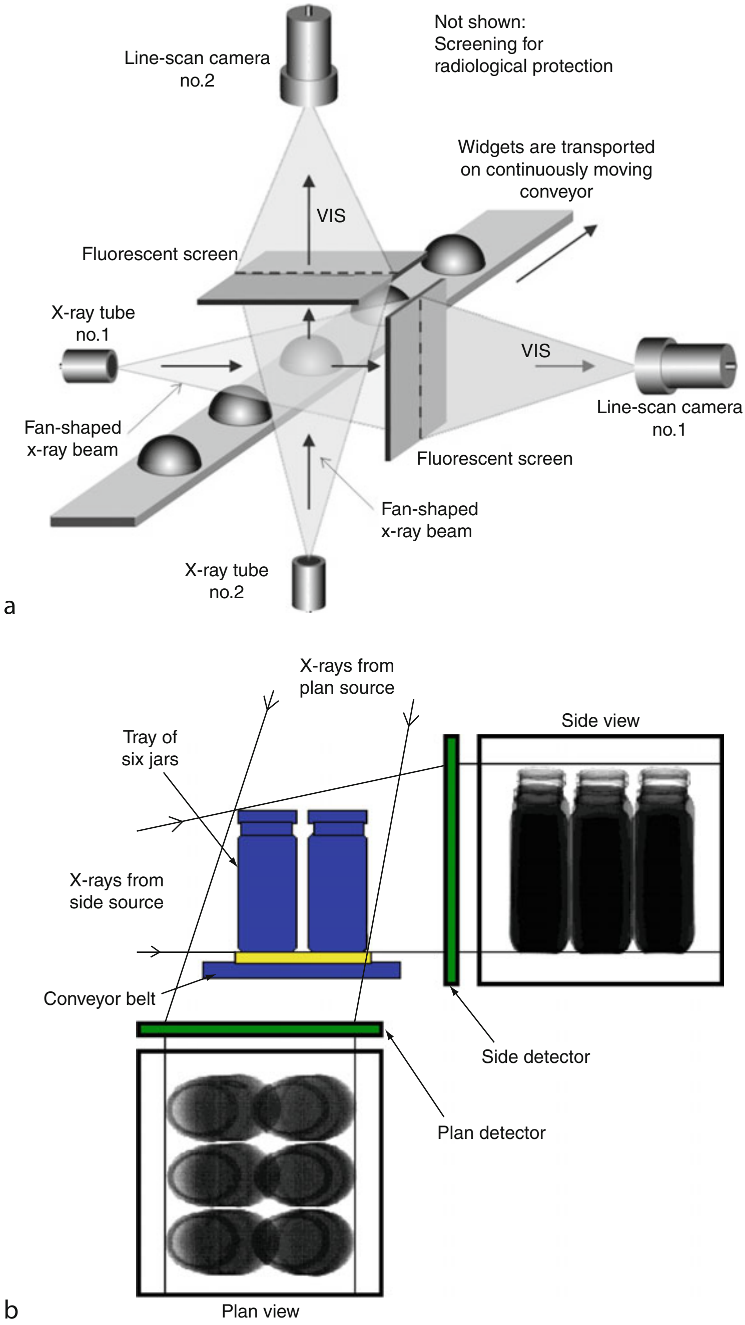

Fig. 12.21

Twin orthogonal fan-beam x-ray inspection system. (a) Layout. (b) Image formation. The system was designed to inspect six glass jars simultaneously. These are held on a cardboard tray. The jars contain tomato sauce. Sample image pairs generate by such a system are presented in *Figs. 12.16* and *12.23*

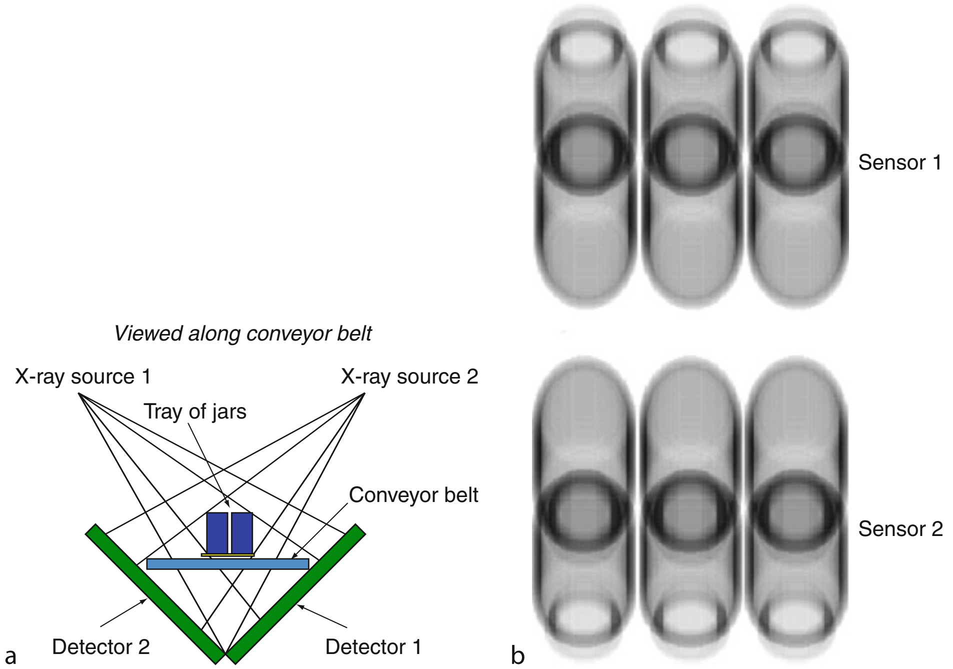

Fig. 12.22
Alternative design for a TOF x-ray inspection system. (a) Layout. (b) Sample image pair (synthesised images). As a result of seeing these images, the idea of building an x-ray system like this was abandoned

- Identify that part of the product that is clearly visible to just one, or neither, of the x-ray sensors.
- Devise procedures for analysing "real" images (i.e., those derived from the TOF x-ray rig).
- Assist in the debugging the x-ray rig.

Since this is a line-scan system, beam divergence affects only one axis. (Vertical axis in the plan view: across the conveyor. Vertical axis in the side view: normal to the conveyor.) In the side view, superposition and beam divergence cause particular problems in the neck/shoulder region. This complicates the image analysis, so that new techniques had to be devised [9]. The plan view shows a composite shadow of three pairs of jars. In this case, beam divergence makes the mouth of each jar appear ovoid.

Interpreting Image Pairs An essential feature of the TOF x-ray systems illustrated in *Figs. 12.21* and *12.22* is that the side- and plan-images are aligned precisely along the X-axis. This makes their joint interpretation much easier. (*Fig. 12.23*) Hence, the presence of a foreign body at position (X, Z) in the side view image suggests that there should be a foreign body evident at a point (X,Y), for some value of Y, in the plan view, and vice versa. However, certain regions of both images are problematical, notably the neck-shoulder regions in both images and the base regions in the side view. Standard image filtering methods, such as convolution and morphology, can be used to look for intensity anomalies due to foreign bodies but the results must be interpreted in an intelligent way. Making inferences about one

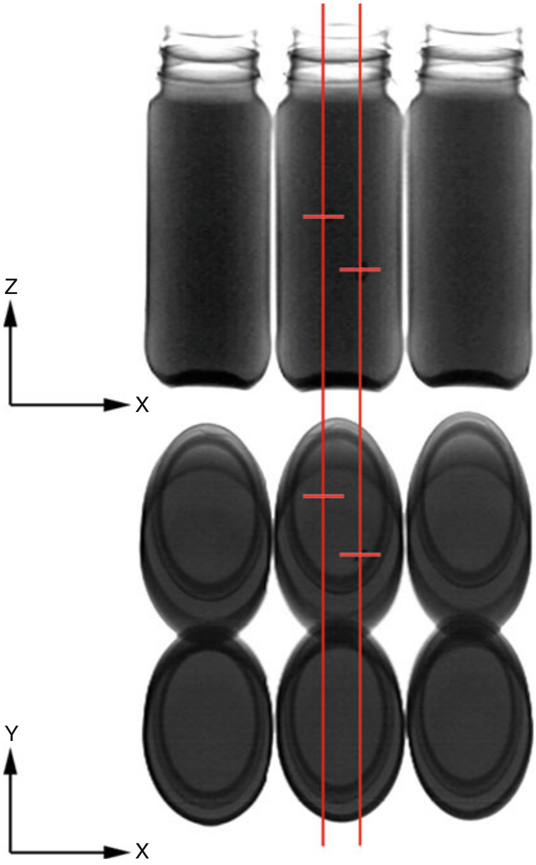

Fig. 12.23
The plan and side view images of a TOF pair are aligned exactly. Hence, a suspected foreign body at position (X, Z) in the side view indicates that there should be a foreign body at (X,Y) in the plan view, for some value of Y. This allows suspicions gained from one image to be confirmed/refuted with reference to the other. The jars move along the X-axis, so beam divergence has no effect in this direction

picture based on what has been found in another image requires a level of intelligence that cannot be represented easily in an image processing package such as QT (Chap. 21) or NeatVision (Chap. 22). This type of task is well suited to a language that combines image processing and Prolog-style reasoning (Chap. 23)

In view of the complexity of the TOF images and the low contrast of many foreign bodies, the author and his colleagues decided to investigate the use of template matching. This technique is usually derided because it is sensitive to position, orientation and scale changes. *Figure 12.24* shows the result of simply subtracting a reference image, obtained by shifting the test image, from the test image before shifting. Provided the difficulties just mentioned can be overcome, image subtraction can provide a useful way to improve the visibility of foreign bodies. It is effective even when processing images of a complex container, provided it is of fixed

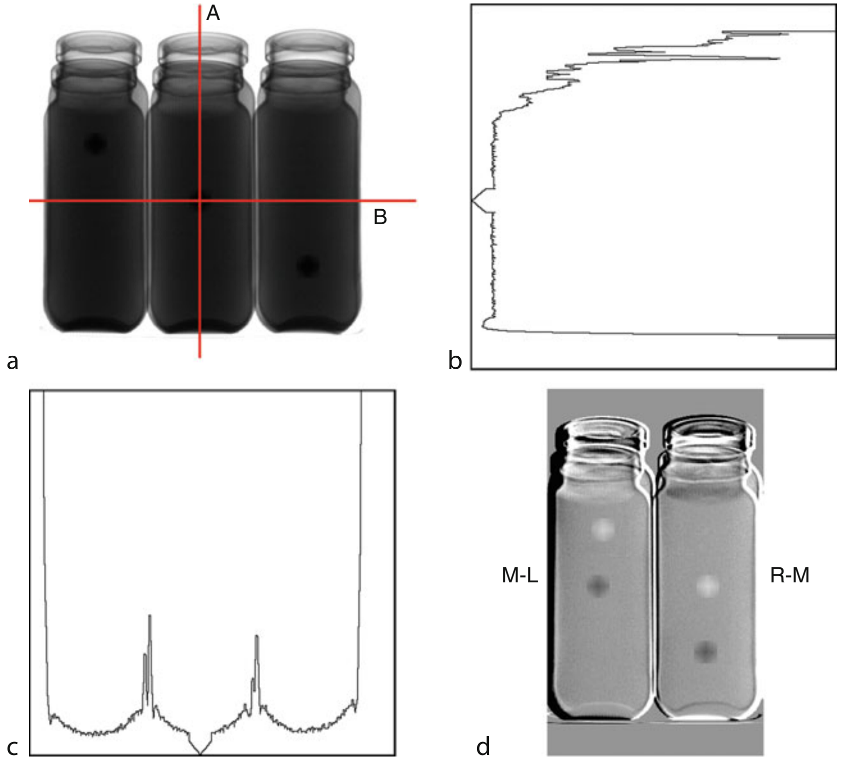

Fig. 12.24

Improving the visibility of foreign bodies by subtracting a reference image. (a) Original image. Six jars are arranged in three pairs, each pair aligned with the system's central axis. Three low-contrast foreign bodies have been simulated, one for each pair of jars. (b) Intensity profile, along the red vertical line (A) through the simulated foreign body in the middle pair M. (c) Intensity profile, along the red horizontal line B. (d) For the purposes of illustration, the middle pair (M) provides the reference image. The original image was shifted to the left by a distance equal to the width of one jar. This result and the original image were then subtracted and the contrast increased by histogram equalisation. M–L: the image of the left-hand pair (L) subtracted from that of M. R–L: the image of M subtracted from that of the right-hand pair (R)

material composition, and has known shape, size, position and orientation. Image registration might involve some complicated processing. It may even be necessary to perform local feature matching repeatedly, to accommodate image variability. In their research, the author and his colleagues used a deformable reference image, which was subtracted from the test image. The warping process was guided by contours extracted by following edges with a high intensity gradient. A degree of intelligence is needed to do this, because edge contours cross one another, due to superposition. The deformable model was required to accommodate the fact that the images may be warped, because the jars are examined in a different part of the diverging beam. By subtracting the carefully deformed reference image, it is possible to increase the contrast of foreign bodies and hence make their detection more reliable. However, the computational process is complicated and slow. This was a research study and resulted in new ideas but, so far, has not lead to a factory installation.

12.5 Practical Issues and Future Trends

So far, we have concentrated on the fundamental technical and conceptual features of an x-ray inspection system. In addition, there are many other systems issues that must be taken into account; no machine would be truly successful if these were neglected. An x-ray system that is designed with only theoretical performance in mind would almost certainly be unreliable, unsafe, and unhygienic. The fact that theory, or laboratory-based experimentation, predicts that it is possible to detect a specific foreign body, does not necessarily mean that a practical x-ray inspection system can be built that is able to do so reliably in a food processing factory. A wide range of factors affect the technical feasibility and commercial viability of building and operating an x-ray system see ➲ Sect. 12.6.

12.5.1 Redirecting X-Rays

It would be a great advantage if x-rays could be focussed and reflected like visible light, to avoid beam divergence. This would make image processing in AXI systems very much simpler. Building large detectors would also be very useful but depends on our ability to construct large lenses or mirrors for x-rays.

A highly polished metal surface will reflect an x-ray beam if the angle of incidence is above about 89.7°. A very smooth, very narrow gently-curved groove in a block of copper will act as an x-ray wave-guide. Lenses and collimators can be built on this principle to redirect an x-ray beam but they require very precise machining and alignment. Also see Ref. [10].

Diffraction focussing of x-rays is possible but will only work properly for narrow-band sources. A third method, is to use a very pure curved crystal as an x-ray lens. Recent work has shown that it possible is to build a refracting lens using an array of extremely small lenses. These might be hollows in a block of aluminium [11]. Using ideas like these it may, one day, be possible to generate parallel, or even convergent, beams. However, at the moment, it is too difficult/expensive to incorporate them in a practical shop-floor AXI system.

12.5.2 X-Ray Lasers

Designing an AXI system would be very much easier if we could build x-ray lasers cheaply. A monochromatic x-ray laser with a very narrow "pencil" beam would be very useful, as it could be incorporated into a flying-spot scanner (see ➲ Chap. 9) A laser source would be a great advantage for another reason, it would have a well-defined and possibly controllable wavelength capable of discriminating between different materials very much more easily than a broad-spectrum source can. If the beam intensity is high enough, there are two additional possibilities for creating images: using x-ray back-scatter and x-ray fluorescence. If it were possible to build an array of tiny x-ray lasers, AXI would truly be revolutionised.

12.5.3 Improving Image Processing

The ability to analyse x-ray images is not as well developed as we would like. A high level of intelligence is needed to detect foreign bodies because x-ray images are inherently complicated. Moreover, they are often unpredictable, particularly when inspecting natural products/materials. As we have seen in the case of the TOF images, new algorithms had to be invented. This is also the case for applications where image subtraction is appropriate, since image registration algorithms are problem specific. The development of image processing algorithms that are guided by a CAD model would also be beneficial, particularly for applications in high-precision manufacturing. This may involve image synthesis, as we have illustrated, or automatically generating "driving instructions" for an image proccessor.

12.5.4 Reducing Costs

The high cost of present-day x-ray inspection system is due, in large part, to the engineering effort needed to design a special system for every individual application. The cost could, of course, be reduced significantly, if large numbers of identical machines could be built. Unfortunately, the market has not yet reached the critical point at which repeat orders make mass-production of x-ray systems a commercial reality. The high cost inhibits investment in the technology, which limits the savings that can be made by copying existing designs. The principal equipment costs are incurred for mechanical handling, environmental protection, x-ray beam generation, x-ray shielding, x-ray sensing and image processing. It is difficult to envisage major reductions in cost for any of these. However, if x-ray lasers became a practical option, it might be possible to reduce the cost of shielding and the physical size of a system considerably, since the beam would be better controlled.

12.5.5 Final Remarks

Industry has not really exploited AXI to its potential. While it is somewhat limited by existing technology, many more applications could benefit from its use. Lack of understanding and confidence in AXI technology are probably two of the most important reasons for this. There is a need for better education about the capability, achievements and potential of AXI. There is also a need to reassure managers and shop-floor personnel about the safety of properly engineered x-rays systems.

12.6 Supplement

12.6.1 Factors Affecting Performance and User Acceptance

The following list indicates just some of the major factors that influence the success of an x-ray inspection system. There are many subtle interactions between the various parts of a system and neglecting these may mean that it will fail to satisfy the customer.

Speed: An automated x-ray system must be fast enough to match the product throughput rate. This is normally dictated by the food-processing machinery and cannot be reduced merely to accommodate the needs of the inspection system. Speed is defined using two parameters: latency (i.e., the time between capturing an image and calculating a decision about it.) and throughput rate (measured by the number of objects inspected in unit time, i.e., seconds or minutes). In addition, the speed that the product is moved past the x-ray source and sensor is determined by that of the conveyor belt, which is, in turn, fixed by the production process.

X-ray beam intensity: It may be necessary to increase the system sensitivity, to improve its operating speed. This can be achieved by increasing the beam intensity but this reduces the tube life and may generate an unacceptable and dangerously high level of radiation. (This parameter is controlled by the tube beam current.)

Beam energy: This parameter is measured by the accelerating voltage (i.e., anode-cathode voltage) applied to the tube. It effectively defines the peak x-ray wave-length.

Mechanical sub-system: Must be robust and easy to maintain and clean. This is, of course, particularly important in the food and pharmaceutical industries. "Strip-down" times of less than one minute are needed in some industries, to meet stringent hygiene standards, without causing undue disturbance to the production process.

Robustness: Care must be taken to design a rugged machine, as a food factory can be a very hostile environment for electronic and mechanical equipment.

Human factors: Workers who will be required to operate the x-ray equipment must be considered to be an integral part of the inspection process. If a machine is too complicated to operate, or it requires continuous adjustment or supervision, it will not be effective and won't be used for long. Equipment operating in a food-handling environment must be easily cleaned. There is no point in eliminating a foreign body problem, only to create a microbiological hazard.

Foreign body: Material (determines the x-ray density), size, shape, location within the inspected product, type (often varies in a predictable way within the product), orientation.

Product: Size, shape, orientation, materials (Determines the x-ray density. Moisture or fat content may vary), internal structure, relative positions of internal features (may vary from one sample to another, e.g., bones within a carcass).

Maintenance: The system should be easy to maintain and repair, with comprehensive self-diagnosis software.

Calibration: There should be a well-defined calibration procedure. Any calibration targets must be easy to keep clean and be stable over a prolonged period of time. Moreover, they must thoroughly test those functions of the machine that are critical to its proper operation.

Hygiene: It should be possible to strip down and clean all parts of the inspection machine that are likely to come into contact with food materials/products, within a few seconds. It should be completely waterproof, so that it can withstand regular hosing down. Antibacterial sprays and washing agents should not damage the machine.

Safety: X-rays are dangerous. Legal safe-guards exist to protect workers from exposure to penetrating radiation. This imposes certain constraints on the design, such as fail safe operation, restrictions on access when the system is generating x-rays, as well as operator training and health checks.

Environmental: The system should be able to withstand the hostile environment found in a factory environment, which may be hot, cold, damp, or dusty. It should be able to withstand wide variations in temperature, as well as electrical noise generated within the factory.

Packaging: Product packaging can have a significant effect on detection performance. For example, a small splinter of glass that is easily detectable in a loosely packed product may be much more difficult to identify inside a glass container. There are two reasons for this: (a) Image contrast is reduced because the container absorbs x-rays. (b) The complex geometry of the container makes the analysis of x-ray images more difficult.

Process requirements: A system must be designed for a specific purpose, taking into account all of the requirements imposed by the customer company's working practices, existing equipment, legislation, etc.

Commercial/economic: The perceived pay-back period for any capital outlay is critical in deciding the success of a project.

Work practices: The system should complement, not radically change existing inspection and manufacturing protocols.

Resolution: The smallest object that can be resolved is, in practice about 3–5 times larger than a pixel. For a system using a line-scan camera and a conveyor belt, the resolution along the web is controlled by the camera clock speed and the belt speed. The resolution across the belt is dictated by the physical spacing of the photo-detector elements. The resolution along the direction of travel is dictated by the sampling speed of the array read-out electronics. The resolution in these two directions should be the same, to avoid changes in the apparent size of an object as it is rotated.

Conveyor belt speed: The speed of the conveyor belt should be regulated, to avoid altering the image resolution.

Performance: See *Balancing rejection rates.*

Production run: This affects the economics of the building and operating an x-ray inspection system.

Wash-down procedure: For reasons of hygiene, many x-ray systems are designed to withstand washing with a high-pressure water jet, as well as cleaning chemicals. Hence, both mechanical and electrical elements must be enclosed in fully water-proof housings.

Temperature variations: The x-ray power supply generates considerable heat. Large temperature variations can occur inside the cabinet, especially if the equipment is sealed inside a water-proof cabinet. This can lead to drift in the x-ray detector output. To stabilise the internal temperature inside the cabinet, it may be necessary to provide air conditioning.

Balancing rejection rates: In any inspection process, there is a trade-off between false-acceptance and false-rejection levels. For some products, such as finished packaged goods, the false-rejection rate must be limited (perhaps less than 1%), to avoid discarding high-value product that is perfectly acceptable to the end customer. In these circumstances, it may be worthwhile manually inspecting all product that the x-ray system has rejected. The x-ray system can then be tuned in favour of rejecting more "suspicious" product; much higher false-rejection levels (perhaps 3–5%) might then be acceptable.

Reliability of the rejection mechanism: Mechanical accept/reject devices have a limited reliability, particularly when they are used to move products that are sticky, fibrous, gritty, dusty, or for some other reason, likely to cause jamming. Accept/reject actuators are exposed to an uncontrolled, dirty environment, so they must be designed with great care and serviced regularly. It is foolish to spend a great deal of effort to improve the performance of an inspection algorithm only to neglect the mechanical handling sub-system.

Acknowledgements

Much of the material in this chapter was supplied by Dr. Mark Gravess, previously of Spectral Fusion Technologies, Birmingham, B46 1JT, UK, and was included in our joint book [13].

Much of the work on Twin Orthogonal Fan-beam (TOF) x-ray inspection systems was conducted by Stephen C. Palmer, working with the author on the project entitled "*Automated 3D X-ray Inspection System for On-line Foreign Body Detection in Food Products*". This was funded under the Agro Industries Research (AIR) programme of the Commission of the European Communities – Directorate General XII. Reference number AIR2-CT93-1054.

13 Illumination-Invariant Image Processing

John W. V. Miller · Malayappan Shridhar
The University of Michigan-Dearborn, Dearborn, MI, USA

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_13,

Abstract: Illumination-invariant image processing is an extension of the classical technique of homomorphic filtering using a logarithmic point transformation. In this chapter, traditional approaches to illumination-invariant processing are briefly reviewed and then extended using newer image processing techniques. Relevant hardware considerations are also discussed including the number of bits per pixel required for digitization, minimizing the dynamic range of the data for image processing, and camera requirements. Three applications using illumination-invariant processing techniques are also provided.

13.1 Introduction

Scene illumination is one of the most important factors that determine success or failure for many imaging and machine vision applications. With appropriate lighting, irrelevant information can be eliminated, contrast of significant image features enhanced, and the sensor signal-to-noise ratio improved. Stringent requirements, however, may be placed on the lighting with regard to the need for very uniform and temporally constant levels of illumination unless suitable low-level processing is performed. Frequent lighting adjustments, tightly regulated power supplies or special feedback circuitry for controlling light level may be needed in these cases which can increase system cost and complexity significantly.

Even with ideal illumination, deficiencies in the optics and imaging hardware can introduce apparent variations in scene illumination that reduce the robustness and reliability of vision systems. Optical losses increase significantly from the centre of the field to the edge due to the $\cos^4$ law and vignetting [12]. Imagers often exhibit sensitivity variations (shading) as a function of spatial position. While higher-quality system components reduce these problems, the added cost can be excessive.

Real-time gray-scale image processing hardware which is generally available in newer vision systems can alleviate the effects of these imperfections economically. Traditionally, linear high-pass filtering prior to thresholding has often been used to reduce the effects of these variations since they are most significant at low spatial frequencies. Because image features of interest such as edges predominate at high spatial frequencies, the effects of illumination variations can be reduced prior to further processing [8, 21].

Morphological processing also has been used to correct for illumination variations [4, 22]. In some applications, a closing operation will generate an image that is a good estimate of background illumination by suppressing dark features at higher spatial frequencies. Calculating the difference between the background image and the original image generates a high-pass-filtered image.

High-pass filtering alone, however, does not completely eliminate these effects because most images are approximately a function of the product of the illumination and reflectance properties of a given scene [23]. An image feature in a dim area of an image will have poorer contrast than the same feature in a bright area as a result of this modulation-like property. A number of techniques have been used to remove the gray-level distortion introduced by this effect including shading correction and homomorphic filtering.

The term “illumination invariance” will be used to describe these techniques since they attempt to generate an image in which gray-scale errors associated with illumination, optics and the imager have been eliminated. Errors associated with illumination and optics are presumed to be purely multiplicative while the imager may require both an additive and a multiplicative correction factor [5]. Compensation for the multiplicative effects from all three sources can be provided simultaneously after imager offset errors have been removed.

Shading correction can directly compensate for these error sources if an “empty” scene is available, that is, a scene that is only a function of the illumination, optics and imager. For purposes of this chapter, such a scene is designated as the background. Scene elements of interest, such as objects or image features, comprise the foreground. Hence, if an image of the background can be acquired directly and stored, it can be divided into the foreground image data to compensate for existing nonuniformities [5, 12]. If imager offset errors are significant, a completely dark scene can be captured and subtracted from the imager data prior to multiplicative correction. Shading correction has been used in a variety of applications including thin-film disk inspection and the evaluation of lumber [3, 20].

Homomorphic filtering represents another approach to illumination-invariant processing [17, 23]. Here, gray-scale values of a given image are nonlinearly transformed, the resulting image is linearly filtered, and the inverse of the original nonlinear transformation is performed on the filtered image. Homomorphic filtering using a logarithmic transformation to linearize the multiplicative effect of illumination is a classical and well established image and signal processing technique [17]. Typical applications include enhancement of photographs containing scenes with wide illumination variations and edge detection [19, 21]. Homomorphic Wiener filtering has also been used for restoration [8].

In this chapter, classical techniques for illumination-invariant processing are reviewed and a number of enhancements are proposed. Homomorphic filtering, for example, has very advantageous properties. However, obtaining linear filters that remove or pass specific scene elements in a given image can be very difficult to implement. Nonlinear filtering operations such as morphological closings can often be generated with the desired characteristics. By logarithmically transforming a given image prior to morphological filtering, illumination-invariance may also be achieved.

Implementation issues are also examined here. A detailed discussion regarding the minimization of quantization errors with applications that require large dynamic range is presented. The use of an analog logarithmic amplifier prior to digitization is shown to provide significant benefits. Additional techniques to minimize A/D resolution requirements are discussed here also.

A discussion of various aspects of illumination-invariant processing has been divided into four sections in this chapter. In the next section, a basic approach to illumination-invariant processing based on background estimation with very general assumptions is developed along with a brief discussion of classical illumination-invariant processing approaches. A presentation of new techniques is given in ➋ Sect. 13.3 and hardware considerations for minimizing quantization errors are given in ➋ Sect. 13.4. In the last section of the chapter, three applications using illumination-invariant processing techniques are discussed.

13.2 Classical Illumination-Invariant Processing Techniques

The basic concept for illumination invariance follows from the image formation model in which light reflected from an object is approximately the product of the incident light and surface properties [12, 17]. If the background illumination is known, it can be used to normalize the light reflected from the object and minimize errors caused by illumination variations.

The same approach also can be applied to back-illuminated translucent objects or with an image created by passing X-rays through an object. In either case, the observed radiation is the product of the physical properties of the objects and the incident radiation. In this chapter, a simple one-dimensional model will be presented that is suitable for both reflectance and transmittance. If desired, this model can be generalized to two dimensions easily.

13.2.1 A Simple Image Formation Model

Consider the expression for the incident light $I[n]$ at the nth pixel of a sensor,

$$I[n] = I_0[n]s[n] \tag{13.1}$$

where $I_0[n]$ is the illumination for an empty scene and $s[n]$ is the value of the transmission or reflectance for the object in the scene at that point. The value of $s[n]$ can range from zero when no light is reflected or transmitted to one for total light reflectance or transmittance. Note that $s[n]$ is rarely smaller than 1% for the reflectance case [23].

This simple model does not take into consideration the complex manner in which objects with both specular and diffuse components reflect light. Other considerations such as the angle of incident light upon the observed surface, light polarisation, spectral properties and angle of the camera to the observed surface can also affect the detected light pattern markedly [12]. However, for purely transmissive cases and many machine vision applications employing reflected light, this model is appropriate.

If the assumption is made that the sensor linearly converts the illumination it receives into a voltage $v[n]$, then

$$v[n] = b[n]s[n] \tag{13.2}$$

where $b[n]$ is proportional to $I_0[n]$.

The maximum illumination signal possible at the nth pixel, $b[n]$, is a function of both the light source and the optics. Typically, this function is slowly varying such that

$$b[n] \approx b[n+k], 0 < k < d \tag{13.3}$$

in which d represents the number of sensor pixels with relatively little change in illumination. If the background illumination has significant high-frequency components, then d is correspondingly small.

To illustrate this concept further, consider one scan line of data from a simulated sensor plotted in ➋ *Fig. 13.1*. Here, small dark objects cause sharp drops in light level against the slowly varying background illumination. These objects have a transmission or reflectance value of 0.5 so that $s[n]$ is unity everywhere except in the presence of these objects. The background illumination level falls to zero at the edges of the scan. While this rarely happens in actual applications, similar but less severe illumination patterns are observed in typical applications due to optical and illumination properties [11, 12]. Note that no linear threshold exists that can differentiate between the background and all of the dark objects simultaneously.

13.2.2 High-Pass Filtering

As mentioned in the introduction, high-pass filtering is often used to reduce the effects of such nonuniformities. The high-pass filter will remove DC and low-frequency components while

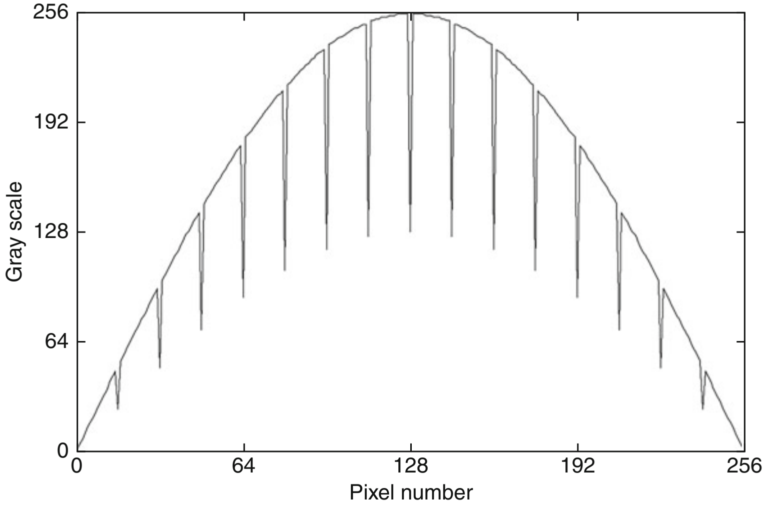

Fig. 13.1
Simulated scene containing small objects with *s*[*n*] = against a slowly varying background

retaining the high-frequency features of interest. In essence, the high-pass filter "subtracts" the low-frequency background from the image. Consider a high-pass filter which is implemented as the difference between a given signal and its filtered output obtained with a low-pass filter. Under the assumption that the low-pass filter will recover $b[n]$ (as shown in the upper trace of ➜ *Fig. 13.2*) from the expression $b[n]s[n]$ exactly for all n, the high-pass filter $y_{hp}[n]$ is defined as

$$y_{hp}[n] = b[n]s[n] - b[n] = b[n](s[n] - 1). \qquad (13.4)$$

Since $s[n]$ is unity everywhere except in the presence of the dark objects, $y_{hp}[n]$ is nonzero only for pixels covered by these objects. The output of the filter will be zero except in the presence of the dark objects where its output will be positive. Negative output values imply that the foreground image is brighter than the background illumination which is impossible for backlit objects. Specular reflections with front illumination can be brighter than the background estimate if it was obtained with a diffuse reflector. Note that the assumption for the existence of a filter $f(\cdot)$ such that

$$b[n] = f(b[n]s[n]) \qquad (13.5)$$

may prove to be very difficult to obtain in practice. If $f(\cdot)$ is to be a linear filter, serious implementation problems arise unless the power spectrums of the background and foreground are widely separated. Certain types of nonlinear filters, however, are likely to be much more suitable for estimating $b[n]$ accurately which are presented in ➜ Sect. 13.3.2.

Using the filter given in (➜ Eq. 13.4) to process the data of ➜ *Fig. 13.1* provides the results shown in the lower trace of ➜ *Fig. 13.2*. Although low threshold values exist that will detect the features of interest, the amplitudes of the dark objects vary significantly in proportion to the background light level. Low threshold values, however, will be very susceptible to noise and irrelevant features when $b[n]$ is large [11].

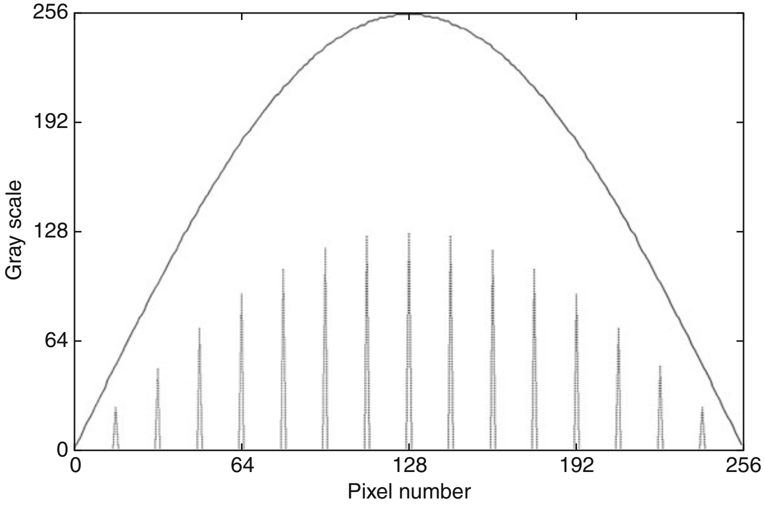

Fig. 13.2

By applying an ideal low-pass filter to the data of *Fig. 13.1*, the background illumination can be obtained as shown in the top trace. Subtracting the unfiltered data from it generates the lower trace

13.2.3 Illumination-Invariant Processing

Consider modifying (Eq. 13.4) so that the low-pass filtered signal is divided into the original signal.

$$y_{ii}[n] = \frac{b[n]s[n]}{b[n]} = s[n] \qquad (13.6)$$

Here, $y_{\mathrm{ii}}[n]$ is unaffected by illumination variations and thus is illumination invariant. This technique is often referred to as *shading correction* and may include correcting for sensor offset errors prior to the division operation [5, 20]. From this simple model, it would appear that any value of illumination is satisfactory. However, because of sensor characteristics, random noise, and quantization effects, the acceptable range of light variations will always be limited. Typically, illumination variations of up to 16 to 1 can be tolerated for many vision applications with 8-bit uniform quantization since at least 4 bits are still available in the darkest portion of the scene to represent $s[n]$ digitally. Further quantization considerations are discussed in Sect. 13.4.1.

13.2.4 Processing Using a Logarithmic Gray-Scale Transformation

Illumination-invariant processing can also be obtained by logarithmically transforming the gray-scale data from the sensor prior to high-pass filtering. The basic approach here is to replace the division operation in (Eq. 13.6) by the subtraction of two logarithmically transformed values. While the results are theoretically identical for the two methods, the logarithmic implementation has significant advantages with low-noise cameras which are considered in Sect. 13.4.2.

A linearly-digitized image is represented by a matrix of numbers which correspond to the light intensity of an image. Calculating the logarithm of each pixel results in a new image that is proportional to the density of a photograph of the same scene [23]. As will be seen, there are significant advantages to working with a density representation for achieving illumination-invariant processing.

To begin, consider a modification of (Eq. 13.4)

$$y_{\log hp}\,[n] = log(b[n][s[n]) - log(b[n]) = log(s[n]) \tag{13.7}$$

If desired, exponentiation can be performed so that results identical to equation (Eq. 13.5) are obtained. However, since the output of the filter is often only used for thresholding purposes, this additional operation is not required for many vision applications.

Applying (Eq. 13.7) to the simulation data plotted in *Fig. 13.1* gives the results plotted in *Fig. 13.3*. Here, the top trace is the logarithmically-transformed data from *Fig. 13.1* and the bottom trace is the result of background subtraction after logarithmic transformation. Note that all amplitudes are equal regardless of the illumination level.

If the low-pass filter used to estimate $\log(b[n])$ is linear with a spatial (not temporal) impulse response $h_1[n]$, the resulting high-pass filtering operation will be homomorphic after its output is exponentiated. This can be demonstrated by convolving $h_1[n]$ with the density image to obtain the low-pass-filtered output signal $y_1[n]$,

$$\begin{aligned} y_1[n] &= h_1[n] * \log(b[n]s[n]) \qquad (13.8)\\ &= h_1[n] * \log(b[n]) + h_1[n] * \log(s[n]) = \log(b[n]). \qquad (13.9)\end{aligned}$$

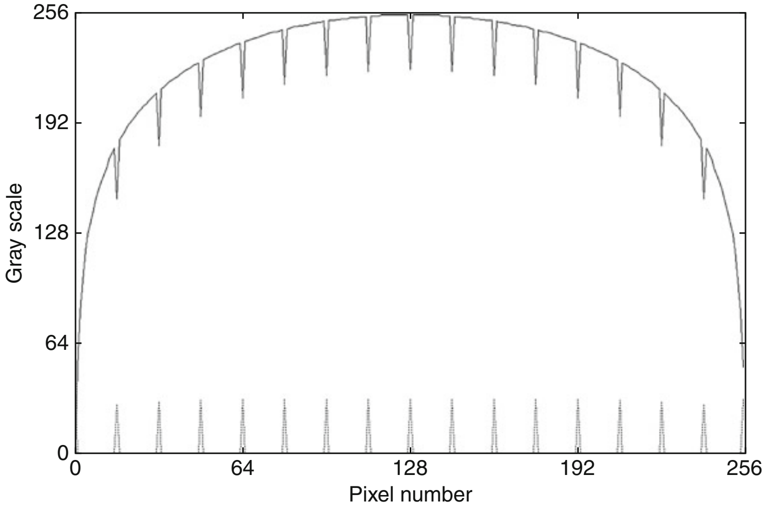

Fig. 13.3
The top trace has been generated by performing a logarithmic transformation of the data in *Fig. 13.1*. Low-pass filtering this trace and subtracting the top trace from it creates the bottom trace

A new impulse response can be defined as

$$h_2[n] = \delta[n] - h_1[n] \tag{13.10}$$

Convolving $h_2[n]$ with $\log(b[n]s[n])$ generates the high-pass filtered output $y_2[n]$,

$$\mathrm{y}_2[n] = h_2[n] * \log(b[n]s[n]) \tag{13.11}$$

$$= \log(b[n]s[n]) - h_1[n] * \log(b[n]s[n]) = \log(s[n]) \tag{13.12}$$

which is the desired information. As previously stated, $y_2[n]$ can be exponentiated to obtain a homomorphic filter.

13.2.5 Illumination-Invariant Filtering Using an FIR Filter

Values for $s[n]$ can be recovered very well from a scene if a good estimate of the background illumination $b[n]$ is available. The ability to generate this estimate is very application dependent and is essential if $s[n]$ is to be recovered accurately. For other applications, however, it is only necessary that the filter remove the DC component in a local region of the image. The gradient operator is one example of a commonly used *finite-impulse response* (FIR) filter in which $s[n]$ cannot be recovered although useful information is extracted from it.

Consider a high-pass FIR filter that removes the DC component over the extent of the filter and assume that it is small relative to the variation of the background illumination. If a density image is filtered by it, the resulting image will be illumination invariant. To show this, consider the basic FIR convolution operation

$$y[n] = \sum_{k=-K/2}^{K/2} C_k \log\left(x[n-k]\right) \tag{13.13}$$

in which C_k is the kth filter coefficient, $x[n]$ is the data to be filtered, and K is the kernel size. Since the output of the filter must be zero when the input signal does not vary over the extent of the filter, we will use the constant α to represent $x[n]$ over the extent of the filter.

$$y[n] = \sum_{k=-K/2}^{K/2} C_k \log\left(\alpha\right) = log(\alpha) \sum_{k=-K/2}^{K/2} C_k = 0 \tag{13.14}$$

From this, it can be inferred that

$$\sum_{k=-K/2}^{K/2} C_k = 0. \tag{13.15}$$

This condition can now be used to illustrate that the output of the filter is independent of the background illumination. Since $v[n] = s[n]b[n]$,

$$y[n] = \sum_{k=-K/2}^{K/2} C_k \log\left(s[n-k]b[n-k]\right) \tag{13.16}$$

$$= \sum_{k=-K/2}^{K/2} C_k \log\left(s[n-k]\right) + \sum_{k=-K/2}^{K/2} C_k \log\left(b[n-k]\right) \tag{13.17}$$

Using the requirement for a DC removing filter from (Eq. 13.14) and letting $\alpha = b[n]$ over the extent of the filter (recall that $b[n] \cong b[n \pm k]$ for k small),

$$y[n] = \sum_{k=-K/2}^{K/2} C_k \log\left(s[n-k]\right) \tag{13.18}$$

Clearly, $y[n]$ is independent of the background illumination. Note that in general $y[n] \neq \log(s[n])$.

13.2.6 Shading Correction

Shading correction is another technique that may be used if background illumination levels can be obtained directly. The inspection of transparent or translucent objects which are backlit is a typical class of applications that can be addressed with this approach. Often, an object will not be in the field of view continuously so that an image of the empty scene is available. In some applications, this will provide a direct measurement of the effective scene illumination. If the illumination is temporally invariant (Eq. 13.6) can be used to obtain illumination invariance.

Alternatively, background subtraction can be performed between the background density image and a density image containing both background and foreground information as in (Eq. 13.7). This approach is appropriate for both linear and matrix cameras. Implementation is usually easier with linear-camera systems since data from only one scan of the empty scene is required. For matrix cameras, a frame buffer can be used to store the background scene.

Note that no special assumptions about the spatial properties of the background relative to features of interest are required since spatial filtering is not used either to estimate the background illumination as in (Eq. 13.5) or to remove its effects as in (Eq. 13.12). If (Eq. 13.7) is used for shading correction, a time-domain filtering operation is being performed by the subtraction of two sample images acquired at different times.

However, sampling the background only once, and subtracting that image from more recent images results in a time-varying filter. As time progresses, the temporal frequency response of the filter changes because the effective sampling interval increases. In general, there is no loss of effectiveness provided that the background illumination level does not change significantly. It can be shown that adjusting for illumination changes is relatively straightforward if spatial and temporal illumination functions vary independently. A suitable approach for exploiting this is presented in the next section.

13.3 New Approaches for Illumination-Invariant Processing

While traditional approaches to illumination invariance are quite effective in many applications, significant enhancements can still be realized. In this section, extensions and improvements for realizing a more effective illumination invariance are described. To begin, a method for increasing the robustness of the direct background measurement approach is presented based on the assumption that spatial and temporal illumination variations are independent. The basic objective here is to correct for short-term lighting variations without having to capture a new background image. The basic assumption is made that illumination variations occur proportionally and simultaneously over the entire scene.

13.3.1 Compensating for Short-Term Temporal Illumination Variations

While both long- and short-term illumination variations can occur, long-term variations due to darkening and similar ageing effects can be ameliorated with relatively infrequent (daily or weekly) periodic sampling. However, short-term illumination variations associated with power-line fluctuations require a different solution. These variations can occur over periods on the order of 10 ms. which makes background resampling impractical in most applications. Incandescent sources exhibit a pronounced 100 or 120 Hz ripple when powered by 50 or 60 Hz. sinusoidal power sources. This ripple is caused by lamp filament cooling during zero crossings. With DC voltage sources, even modest voltage changes cause significant light output variations due to the great sensitivity of black-body radiators to temperature changes [15].

A variety of techniques can be used to deal with short-term deviations. Regulated DC sources can provide power for the illumination sources although this solution can be quite expensive if power requirements are substantial. In some applications, cameras can be scanned synchronously with the power line although AC power regulation may still be required. Television-type cameras are often synchronized with the 50 or 60 Hz power source using phase-locked loop circuitry to minimize light-source ripple. This approach, however, is unsuitable for high-speed matrix and line-scan camera applications.

More robust compensation can be provided using an extension of concepts previously discussed here. To begin, consider modifying (➋ Eq. 13.1) so that the effective illumination reaching the sensor is a function of both time and spatial position,

$$I[j,n] = I_0[j,n]s[j,n] \tag{13.19}$$

where $I[j, n]$ is the effective radiation for the jth time sample impinging on the nth camera pixel. Since illumination sources are usually driven from a common power source, the light output of each illumination source will vary temporally in exactly the same manner.

For this reason, $I_0[j, n]$ can be decomposed into the product

$$I_0[j,n] = I_t[j]I_s[n] \tag{13.20}$$

where $I_t[j]$ is the relative illumination level for the jth sample and $I_s[n]$ is the value of the illumination for the nth pixel at a specific time sample, such as $j = 0$. Under the same assumptions as (➋ Eq. 13.2), the voltage output of the sensor becomes

$$v[j,n] = I_t[j]b[n]s[j,n] \tag{13.21}$$

The density representation for (➋ Eq. 13.21) is

$$d[j,n] = \log(I_t[j]b[n]s[j,n]) = \log(I_t[j]) + \log(b[n]s[j,n]) \tag{13.22}$$

Assume that some reference region R exists in the image that is temporally invariant except for variations due to $I_t[j]$. This region can be a fixed painted white strip that is always present in the field of view of the camera. The light reflected into the camera from this region will vary directly as a function of the illumination. Let $a[j]$ be the average value of the N density-image pixels in this region for the jth sample,

$$a[j] = \frac{1}{N}\sum_{n\varepsilon R}\Big(log(I_t[j]) + log(b[n]s[j,n]\Big) \tag{13.23}$$

$$= \frac{1}{N}\Big(\sum_{n\varepsilon R} log(I_t[j]) + \sum_{n\varepsilon R} log(b[n]s[j,n]\Big) \tag{13.24}$$

Note that $\log I_t[j]$ is constant for all pixels in region R since it only varies as a function of the sample number. Similarly, a constant k_R can be defined as

$$k_R = \frac{1}{N}\sum_{n\varepsilon R} log(b[n]s[j,n]) \tag{13.25}$$

since region R is temporally invariant by definition except for $I_t[j]$. The average of region R becomes

$$a[j] = \log(I_t[j]) + k_R \tag{13.26}$$

This value can be used to generate a normalized version of the jth image, $d_n[j, n]$

$$d_n[j,n] = \log I_t[j] + \log(b[n]s[j,n]) - a[j] \tag{13.27}$$

$$= \log I_t[j] + \log(b[n]s[j,n]) - log(I_t[j]) - k_R \tag{13.28}$$

$$= \log(b[n]s[j,n]) - k_R \tag{13.29}$$

Notice that the amount of processing required is relatively small. The region R need only be large enough to minimize errors due to camera signal noise. The image normalization operation simply requires that a constant value be added to each pixel which could be done easily with a lookup table.

There are a number of ways in which this approach can be applied. Consider a simple case in which spatial uniformity of the illumination source is relatively good and image features have sufficiently high contrast. Assume simple thresholding is sufficient for segmentation or identifying features of interest with a temporally constant light source. Given some initial image, the average gray-scale value of the reference region can be found and used to normalize the image as given in (➲ Eq. 13.29). A threshold value can be found using a suitable technique and used on all succeeding images after they are normalized. Alternatively, the threshold T_0 could be found for the initial image and a new threshold value T_j calculated for the jth succeeding image as

$$T_j = T_0 - a[0] + a[j]. \tag{13.30}$$

Depending on the hardware available, this operation may be faster than normalizing each image and using a constant threshold.

Illumination-invariant template matching can be performed using this approach also. Assuming that the 0th image is the reference image, the difference image $\mathrm{d}[j, n]$ is calculated as

$$d[j,n] = d_n[j,n] - d_n[0,n] \tag{13.31}$$

$$= \log(b[n]s[j,n]) - k_R - (\log(b[n]s[0,n] - k_R) \tag{13.32}$$

$$= \log(s[j,n]) - \log(s[0,n]) \tag{13.33}$$

Background subtraction results if the 0th image is empty, that is $s[0, n] = 1$ for all n. Substituting this into (➲ Eq. 13.33) gives

$$\mathrm{d}[j,n] = \log(s[j,n]) \tag{13.34}$$

which is only a function of the foreground image.

13.3.2 Morphological Illumination-Invariant Processing

When the background cannot be measured directly, some means of background estimation by spatial filtering is very desirable. One effective technique for accomplishing this in many applications is gray-scale morphology. Given an image in which features of interest have limited spatial extent relative to a bright background, gray-scale morphology can provide an excellent estimate of the background.

Traditionally, the estimate of the background image obtained by morphological filtering is linearly subtracted from the original image prior to thresholding or some other segmentation operation. As discussed in Sect. 13.2, the result will not be illumination invariant since the modulating effects of the background illumination will still be present. However, using the background estimate with either (Eq. 13.6) or (Eq. 13.7) will provide illumination-invariant processing.

The basic approach advocated here is to use the closing operation on a density image. The closing operation consists of the sequential application of dilation and erosion using the same structuring element [4, 22]. The dilation operation fills in darker regions of an image as the brighter regions enlarge. If a given structuring element spans a dark region such as the narrow dips in *Fig. 13.1*, the dark region will disappear.

The inverse operation is then applied to remove biases caused by the dilation operation. Since the small dark objects have disappeared, this operation cannot restore them but instead will provide an estimate of the background illumination in the region of these objects based on adjacent pixels (*Fig. 13.4*).

One word of caution should be stated with respect to the ability of a given morphological operation to extract the background successfully. Unlike homomorphic filtering, in which

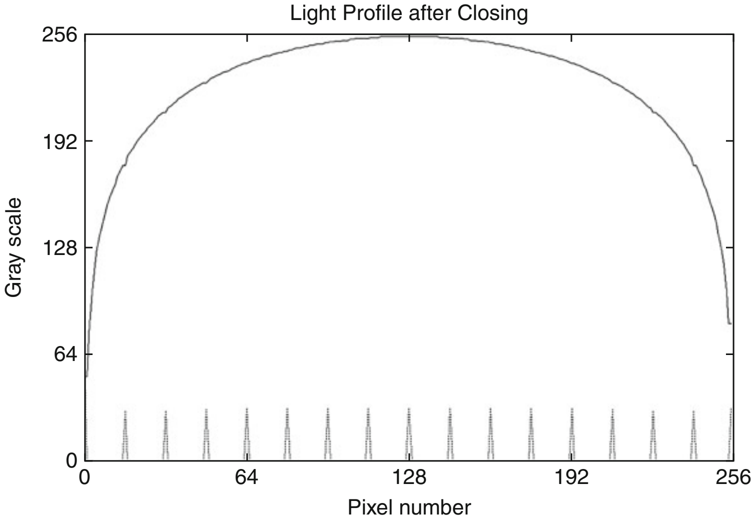

Fig. 13.4
The application of a gray-scale closing operation to the logarithmically transformed data of *Fig. 13.1* is shown in the top trace. The difference between the closed data and the logarithmically transformed data is given in the bottom trace

a linear filter is used, gray-scale morphological operations are highly nonlinear since they are based on min- and max-type functions. In addition, their output is generally biased so they do not preserve DC. Thus, no corresponding relationships exist comparable to the expressions in (➋ Eqs. 13.13–13.18) for morphological filters unless the background can be estimated with relatively little distortion.

13.3.3 Illumination-Invariant Adaptive Thresholding

Like morphological filters, adaptive thresholding can also be modified for illumination invariance. As in the previous approach, working with a density representation allows a straightforward means of decoupling the illumination and reflectance components in an image under a variety of conditions. Here again, the objective with illumination-invariant adaptive thresholding is to ensure that if a given feature in a bright area exceeds the threshold, then an equivalent feature in a dim area will also exceed it. With adaptive thresholding, the threshold at any given point in the image is based on some local average which is usually obtained by low-pass filtering the original image [2].

Using a density representation as the starting point for adaptive threshold processing, consider a low-pass filter that can provide a good estimate of the background $b[n]$. The threshold function $t[n]$ can be given as

$$t[n] = y_{loglp}[n] + T = \log(b[n]) + T. \tag{13.35}$$

Here, T is a sensitivity parameter. If T is large, a given gray-scale value will have to deviate substantially from the local average before the threshold is exceeded. The threshold decision function is *true* if

$$t[n] - \log(b[n]s[n]) < 0 \tag{13.36}$$

and substituting using equation (➋ Eq. 13.35)

$$\log(b[n]) + T - \log(s[n]) - \log(b[n]) < 0 \tag{13.37}$$

results in the following inequality:

$$T - \log(s[n]) < 0 \tag{13.38}$$

Whether or not the decision function is *true* depends only on T and $s[n]$ and is independent of the background illumination.

This operation produces the same bilevel image that is obtained using a constant threshold Ton an image generated by (➋ Eq. 13.7). However, an image obtained by applying (➋ Eq. 13.7) can provide more useful information for setup and adjustment. The high-pass filtered image can be viewed directly and the effect of threshold modification visualized immediately with standard image display hardware.

13.4 Hardware for Illumination-Invariant Processing

As can be seen from the previous discussion, there is a variety of ways to achieve illumination invariance. Some are significantly easier to implement in hardware than others or may have other advantages. Consider, for example, a hardware implementation of (➋ Eq. 13.7) in which the analog signal from the sensor is digitized by an analog-to-digital (A-D) converter and then filtered using a low-pass filter. Logarithmic conversion can be performed easily after digitization by means of a lookup table (LUT) using a memory chip.

13.4.1 Logarithmic Transformation Techniques

A potential disadvantage, however, exists with this approach. The digital logarithmic transform results in a large number of unrealizable values for low input-signal levels while multiple values at high input-signal levels are assigned to the same transformed value. Hence, the quantization is very coarse for low-amplitude signals and too fine at higher amplitudes with a corresponding decrease in dynamic range.

To illustrate this problem more fully, consider ➲ *Fig. 13.5*. The two ramp functions shown represent background illumination (higher ramp) and the foreground scene (lower ramp) with $s[n] = 0.05$. The other two traces represent density difference images. The nearly uniform horizontal trace is the result of performing an analog logarithmic transformation prior to digitizing the signal to obtain $y_a[n]$

$$y_a[n] = round(k_s \log(b[n])) - round(k_s \log(s[n]b[n])) \qquad (13.39)$$

The rounding function rounds its argument to the nearest integer to simulate the quantization error that results with A/D conversion. The scaling factor k_s for 8-bit quantization is calculated as

$$k_s = \frac{255}{\log(b_{\max})} \qquad (13.40)$$

where $b_{\max}$ is the maximum value of the background signal.

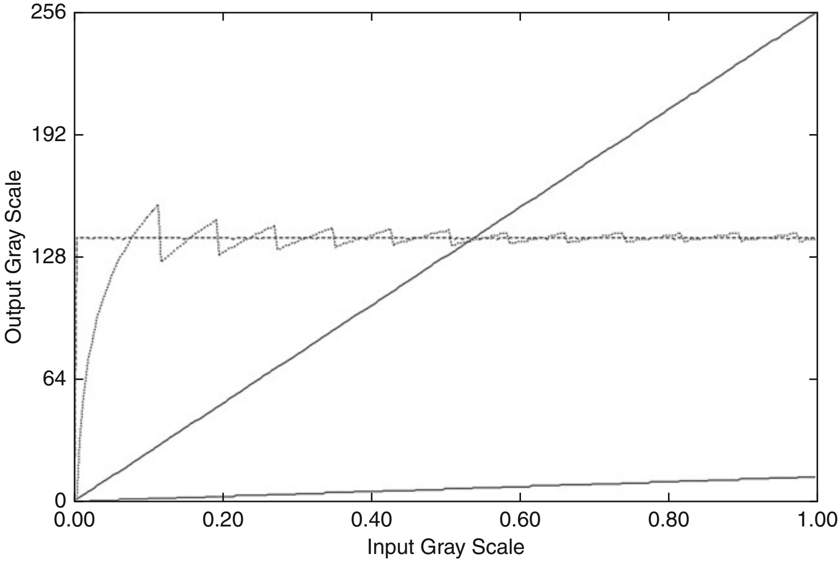

Fig. 13.5
Effects of quantization error when logarithmic transformation is performed before (nearly horizontal line) and after (approximately triangular waveform). The lower and higher ramps represent background and foreground data, respectively

The trace that oscillates in an approximately triangular fashion about the horizontal trace represents the results of digitization prior to logarithmic conversion. The output $y_d[n]$ is calculated as

$$y_d[n] = k_s \log(round(b[n]) - k_s \log(round(s[n]b[n])) \tag{13.41}$$

Since $s[n]$ is constant for all n, the output signal should be constant. Clearly, (Eq. 13.39) comes much closer to achieving this goal. Ignoring the meaningless result when the illumination is zero, a maximum error of two counts from the correct (rounded) value is observed. As indicated by the oscillating trace, however, digitization followed by logarithmic conversion causes substantially greater quantization errors, especially for low light-level conditions.

There are at least two ways to implement (Eq. 13.39) in hardware. Use of an analog logarithmic amplifier prior to digitization represents one approach. Here, the logarithmically-transformed signal is uniformly digitized over the range of acceptable voltages to the A/D converter. Sufficient resolution can be obtained for some applications with this approach using only 6-bit conversion [14].

The second approach is to use a nonlinear quantizer whose output values correspond to a logarithmic representation of the input. Theory covering nonlinear and optimal quantizers is well represented in the literature [10, 18]. However, a review of various manufacturers' data sheets indicates that nearly all A/D converters are implemented with uniform quantization including flash converters that are commonly used in real-time imaging applications.

Given the limitations with existing hardware, the best option is to use an analog logarithmic amplifier with a uniform quantizer. Analog adjustments can be performed to control the resolution per decade of the input signal and the range of input signals that can be digitized. The degree of amplification of the signal after logarithmic conversion determines the voltage range that will be digitized. Offsetting the transformed signal by a certain amount establishes the actual voltage endpoints that correspond to the minimum and maximum outputs of the quantizer.

This can be illustrated by considering the output voltage V_{out} of a logarithmic amplifier,

$$V_{out} = A \log(V_{in}) + V_{offset} \tag{13.42}$$

where A is the amplification, V_{in} is the input voltage and V_{offset} is a constant offset voltage. As the gain is increased, the resolution of the input signal is increased while the range of input voltages that can be converted is reduced. Generally, the offset voltage is adjusted so that the maximum camera signal will correspond to the maximum output value of the A/D converter.

Logarithmic conversion can be performed with standard op-amp circuits using a diode or transistor in the feedback circuit along with temperature compensation circuitry [16]. Alternatively, a monolithic logarithmic amplifier may also be used [9]. The dynamic range required for vision applications is usually not large since most video cameras have dynamic ranges less than 80 dB [6]. Therefore, except for bandwidth, performance requirements of logarithmic amplifier are fairly modest.

13.4.2 Camera Considerations

There are several factors that must be considered when designing a system with a logarithmic amplifier. Perhaps the most basic and obvious factor is the importance of minimizing DC offset errors. If very wide dynamic range is important in a given application, even relatively small DC offset errors can substantially reduce the accuracy of the results.

Video cameras often have substantial offset errors which can be measured by blocking all light from the sensor. The digitized results can be used to eliminate the offset errors by subtracting them on a pixel-by-pixel basis from the camera data [5, 12]. However, these techniques require the image to be digitized before correction is performed which is incompatible with analog logarithmic transformation. One approach that overcomes this limitation is to store the correction signal digitally but convert it back to analog format prior to subtraction and quantization.

Quantization errors can be minimized by increasing analog gain substantially when the offset errors are being acquired and rescaled for analog subtraction. By acquiring multiple images and averaging, the resulting dithering effect will also increase the effective resolution of the offset error image. Note that offset errors can be very temperature dependent with CCD cameras, especially if long integration times are used since correspondingly greater errors due to dark signal effects occur [6].

Background subtraction can be implemented in the same manner to increase the effective resolution of the system for detecting features with very low contrast [14]. The background image can be stored digitally in memory and converted back to analog format for subtraction and amplification prior to digitization. This provides even smaller quantization errors than digital subtraction after an analog logarithmic conversion. The background signal can be stored with substantially more resolution and converted back to analog form very cost effectively. The cost of a high-resolution D/A converter is relatively small compared to a flash converter with the same number of bits.

Note that this type of processing can only be justified with low-noise cameras. Typical television cameras have signal-to-noise ratios on the order of 46 dB which do not justify more than 8-bit representation [7]. With these cameras, lower amplitude signals are lost in the noise. The SNR for low-noise cameras, however, is on the order of 60–80 dB which justifies the additional analog processing [6].

One other caveat is worth noting here. Many cameras provide gamma correction to compensate for the nonlinear (power-law) brightness response of typical CRT displays with increasing grid-drive voltage [1]. The brightness B is given as

$$B = KE^{\gamma} \tag{13.43}$$

where K is a constant, E is the grid-drive voltage and γ is the value of the gamma parameter. Cameras with gamma correction provide the inverse operation

$$E' = \mathrm{E}^{1/\gamma}. \tag{13.44}$$

Values for γ range from 2.0 to 2.4 for typical CRT displays and flat-panel displays model this behaviour so cameras often use 1/2.2 = 0.45 as the correction factor.

Generally, gamma correction should be disabled if it is available on a given camera since a density representation can be obtained from a linear camera response as previously discussed. Also, the precision and stability of gamma correction is not necessarily very high. For typical video applications such as surveillance operations, where a person will observe the resulting image, the exact camera response is relatively unimportant [1]. Gamma correction is generally achieved with simple analog circuitry using PN junction properties to generate the desired function and consequentially is error prone.

In certain non-critical vision applications, however, it may be appropriate to use the gamma-corrected camera signal in place of a logarithmic transformation. Its general shape is similar to the logarithmic transformation as illustrated in ➋ *Fig. 13.6*. Performing background

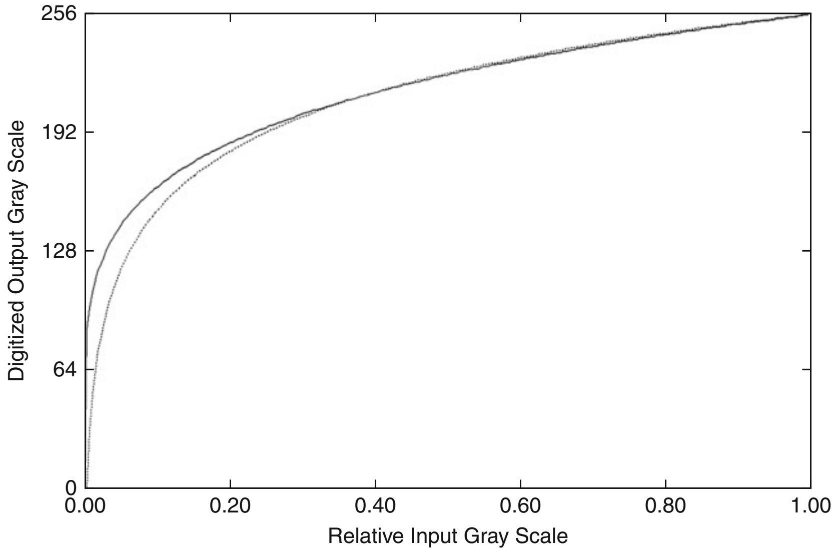

Fig. 13.6
Scaled gamma correction with an exponent of .45 (*top curve*) and logarithmic transformation function (*bottom curve*) are very similar except for low gray levels

subtraction with the original data of ➲ *Fig. 13.1* after gamma correction provides the results in ➲ *Fig. 13.7*. While there is some variation as a function of background illumination, the results are significantly better than the linear differencing results illustrated in ➲ *Fig. 13.2*.

It is also possible to remove the gamma correction digitally [5]. Although traditionally the objective has been to obtain a linear response to light intensity, a logarithmic response can be obtained in the same manner. The similarity of the curves plotted in ➲ *Fig. 13.6* indicate that relatively minor changes in signal levels are required. Quantization errors with this approach are almost as small as with a direct logarithmic transformation because of the similarity of the two curves. However, the problems noted earlier with regard to accuracy and stability may limit the usefulness with many cameras. Individual camera calibration may be performed if stability is not a problem [5].

13.5 Choice of Illumination-Invariant Techniques

A variety of approaches for achieving illumination invariance have been presented in this chapter. In the following section, considerations and tradeoffs for making appropriate choices are discussed for three applications. The first two applications deal with glass inspection.

13.5.1 Plate Glass Inspection

Glass is used in a variety of applications from windows to packaging and quality is often very important. The quality requirements for plate glass in automotive and architectural applications are high because of safety considerations which justify automatic flaw-detection

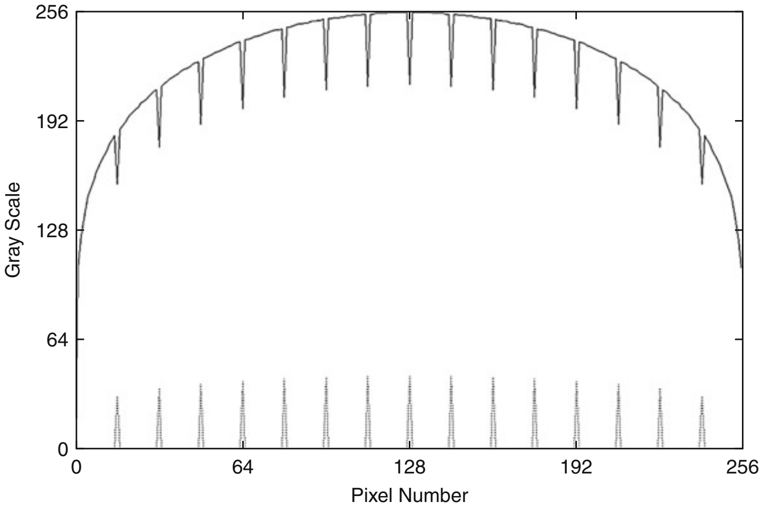

Fig. 13.7
If a camera provides gamma correction, the results are similar to those obtained with a logarithmic transformation shown in ➔ *Fig. 13.3*

techniques. Defects such as scratches, embedded particles, and bubbles need to be detected so that defective glass can be rejected. Glass bottles used for carbonated beverages represents another area where safety is a primary concern. Bottles with defects may explode when handled by the consumer with severe liability consequences.

The generally uniform nature of glass makes it a relatively easy material to inspect since only significant gray-scale changes from the normal background need to be evaluated for defect detection. If defects have sufficient contrast and lighting is reasonably uniform, simple thresholding will provide adequate results and no illumination compensation is required. If the illumination source exhibits temporal variations, the use of a reference region in conjunction with (➔ Eq. 13.29) is appropriate.

Many defects do not have high contrast relative to spatial illumination variations so more sophisticated processing is required. Under these conditions, providing illumination compensation becomes highly advantageous. As stated earlier, the primary objective is to estimate the background illumination by some means or measure it directly.

Direct measurement of the background is very compatible with plate glass because of the highly uniform nature of the material with no defects. Since transmission through a normal glass panel is spatially invariant, the background illumination may be measured directly with a defect-free piece of glass in place.

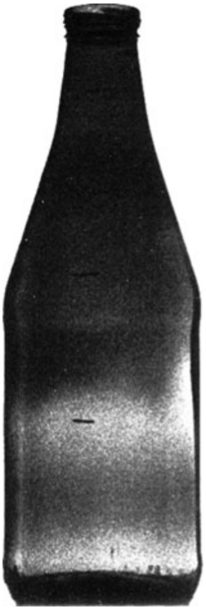
One problem with this approach is that the presence of dust and similar contaminants will introduce inaccuracies in the background measurement. A number of different good panels may be used and combined to create an improved estimate of the background illumination. Note that averaging the measurements together on a pixel-by-pixel basis may not provide the best results. Selecting the maximum gray-scale value at each pixel location will eliminate the attenuating effects of any contaminants present.

Alternatively, some kind of low-pass filtering may be used to minimize the effects of contaminants, especially if they are likely to be small. Since processing the background image will only need to be performed infrequently, more sophisticated off-line algorithms may be implemented for better background estimation. Note that an estimate based on multiple sampling may be spatially low-pass filtered if desired. Low-pass filtering of the estimate should not be performed however, if the sensor exhibits significant pixel-to-pixel sensitivity variations. Once a good estimate of the background has been obtained, it may be used in conjunction with (➲ Eqs. 13.30 and ➲ 13.34) to compensate for short-term illumination variations that may occur.

13.5.2 Amber Bottle Inspection

While many glass-inspection applications should be compatible with the direct background measurement approach, certain circumstances may require a different technique. Consider the amber bottle illustrated in ➲ *Fig. 13.8*. Large variations in light transmission are very evident due to normal sidewall glass-thickness differences that occur during manufacturing. Bottle inspection is typically performed by rotating the bottle in front of a linear camera to provide complete circumferential inspection [13]. As with plate glass, embedded defects are a serious concern and can be detected because they cause light levels to deviate from the normal background significantly. However, directly measuring the background is of no value here because glass thickness varies substantially in a random manner. Therefore, some type of real-time filtering is required to distinguish between normal background variations and defects.

Since the background variations occur at much lower spatial frequencies than defects do, linear high-pass filtering is very useful and effective. While a variety of filters may be useful



◘ Fig. 13.8

Significant variations in light transmission through amber bottles occur due to nonuniform glass thickness

here, consider the simple illumination-invariant filtering operation based on pixel differencing of a density image:

$$y_{diff}[n] = \log(b[n]s[n]) - \log(b[n-1]s[n-1]) \tag{13.45}$$

$$= \log(b[n]s[n]/(b[n-1]s[n-1])) \tag{13.46}$$

Since $b[n] \approx b[n-1]$ if the background is slowly varying,

$$y_{diff}[n] \approx \log(s[n]/s[n-1]) \tag{13.47}$$

which is illumination invariant since the filter output is not a function of $b[n]$. Because the filtering operation is linear, exponentiation of the results will provide homomorphic filtering. This filter is also DC removing as defined in Sect. 13.2. It may also be noted that $s[n]$ is not recovered with this filter.

Glass inspection and the general class of uniform field objects represent one type of application that can benefit significantly from illumination-invariant processing. Another application that requires similar processing is automatic furnace batch charge monitoring. Here, it is desired to measure the presence of batch material is measured with a vision system.

13.5.3 Batch Charge Monitoring

The major difficulty with automatic batch charge monitoring is the very large and temporally varying illumination gradients that are created by the flaming gas jets that are used to heat the furnace. Processing is needed to transform the original image so that a single threshold can detect unmelted batch material on the surface of the molten glass as illustrated in *Fig. 13.9a*. Recently injected unmelted batch material is visible at the far end of the furnace where it is not obscured by the large flame. This material gradually melts and mixes with the molten glass as it moves towards the bubblers. The bubblers are the very dark circular areas which mix the remaining unmelted batch material with the melted glass. No unmelted batch material should be present past the bubblers.

The objective here is to identify the areas of the furnace which are covered by batch material and determine whether or not it is covering the bubblers. Using an octagonal structuring element a closing operation was performed on the original image to estimate the background. The difference between the background estimate and the original image is shown in *Fig. 13.9c*. While it is clear that the low-frequency illumination variations have been removed, significant contrast variations remain since there is considerable variation in the brightness of the batch material as a function of illumination.

Using a logarithmic transformation, a density representation of *Fig. 13.9a* was obtained as shown in *Fig. 13.9b*. The density image was filtered by applying a 3 × 3 averaging filter 18 times. The difference between this image and the density image is given in *Fig. 13.9e*. A thresholded version of this image is given in *Fig. 13.9f*. While the effects of the illumination variations have been eliminated, the results are actually inferior to the traditional morphological filter because the background estimate is much poorer.

Morphological filtering of the density image provides the best results as shown in *Fig. 13.9g* and in its thresholded version given in *Fig. 13.9h*. The same morphological filtering operation used to generate *Fig. 13.9c* was performed here. A comparison of the three thresholded images given *Figs. 13.9d*, *13.9f* and *13.9h* shows that morphological filtering of the density image provides the best estimate for the presence of batch material.

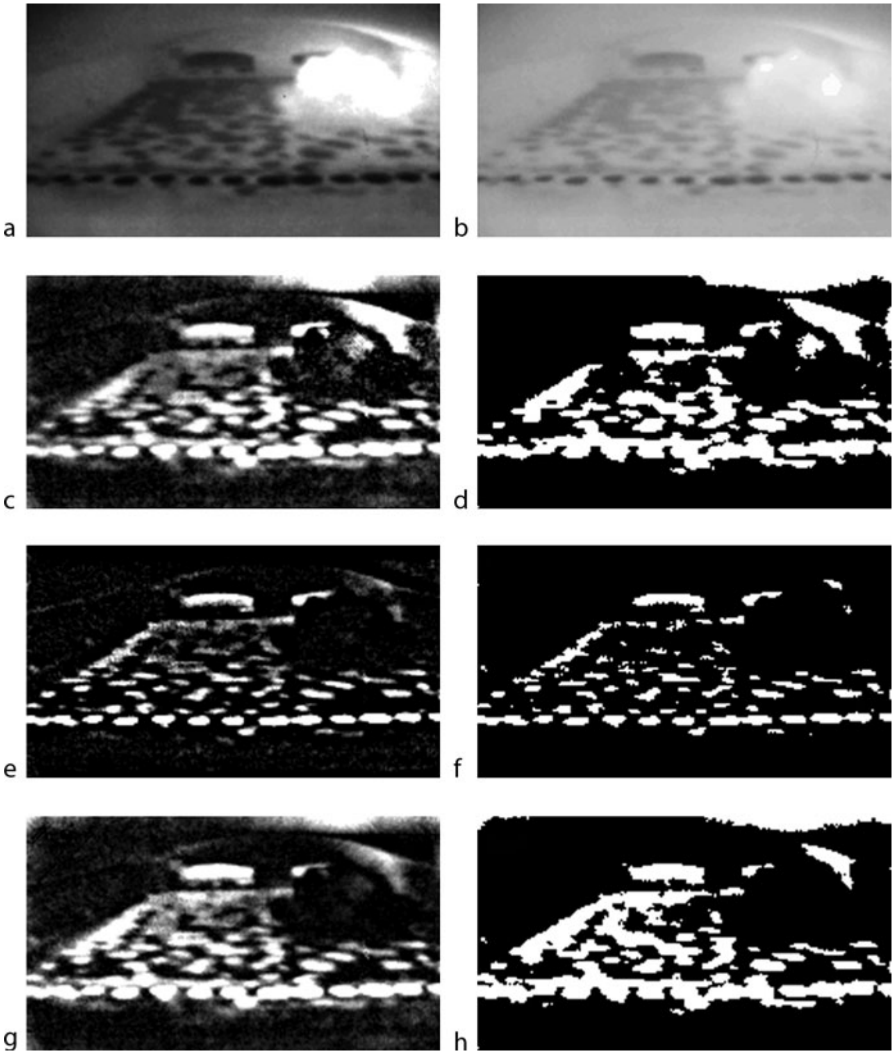


Fig. 13.9
Scene from a glass furnace is shown in (a). The same scene after logarithmic conversion is given in (b). Results obtained by closing (a) and subtracting are given in (c). Thresholding (c) provides the results shown in (d). Linearly filtering (b) results in images given in (e) and (f). Results obtained by closing (b) and subtracting are given in (g) and (h)

13.6 Conclusion

Illumination-invariant processing can be achieved in a variety of ways. The basic approach described here assumed that some method was available for measuring the background illumination. In some applications, background can be measured directly while in others low-pass filtering provides a good estimate. If direct but infrequent background measurements are performed, degradations associated with global short-term temporal variations can be removed by making adjustments based on spatially invariant regions of a scene.

The use of a logarithmic transformation to convert images from an intensity representation to a density representation is very important for illumination-invariant processing. The multiplicative effects of illumination becomes additive for density images so that the effects of nonuniform illumination can be removed by subtraction.

There are a variety of ways to obtain a density representation of an image. The most straightforward approach is to digitize the image and use a look-up table to perform the logarithmic transformation. Using an analog logarithmic amplifier prior to digitization results in a uniform distribution of quantization errors in density images and provides a much larger dynamic range for a given number of bits. In noncritical applications, digitization after gamma correction may provide suitably accurate results.

Abstract: A discussion of image processing must begin by considering how images are represented. The most commonly used format is that of a 2-dimensional array for monochrome images, while colour images are usually represented by three such arrays. The array format is generated by most cameras. While other representations present advantages in certain, rather restricted situations, they must usually be derived from an image array. Grey-scale image processing functions can be arranged into several major categories. The simplest, called *monadic* operators, process one image at a time, by performing a fixed intensity mapping from each of its pixels to the pixel at the corresponding position in the output image. *Dyadic* functions operate on two images; the intensities of pixels at corresponding addresses are combined to calculate a value for the pixel at the same address in the output image. *Local operators* process a single image. In order to calculate the intensity at a point (i,j) in the output image, several pixels surrounding point (i,j) in the input image are combined. For example, the average, maximum, or minimum intensity within the 3^*3 pixel neighbourhood surrounding point (i,j) might be computed. Such a process is repeated for all (i,j). Numerous filtering functions can be invented by extending the concept of "neighbourhood". The function that is applied to the pixel values within a given neighbourhood can be linear or non-linear. The latter gives rise to a useful family, given the name *morphology*. Another group is based on the application of a monadic function that is derived in some way from the intensity histogram, or other statistical features, of the input image. Another, varied family is based on Fourier, and other *integral transforms* of the 2-dimensional intensity function. *Image warping* and *geometric transforms* form another family of grey-scale image processing function. Some grey-scale operators have obvious counterparts for binary images. However, the latter also require functions such as object counting, feature detection, measurement of position, orientation, size and shape. Binary image processing operators do not fall neatly into well-defined categories but can often be described functionally by drawing on everyday concepts such as that of skeleton, rubber band, compass, ruler and our intuitive understanding of shape fitting. The processing of colour images is not covered here as it is discussed in detail elsewhere in this book (➲ Chap. 16). For the moment, let it suffice to say that grey-scale operators can be applied to the individual RGB, HSI or CMYK components of a colour image.

The purpose of this chapter is to outline some of the basic techniques used in the development of industrial machine vision systems. These are discussed in sufficient detail to understand the key ideas outlined elsewhere in this book. In the following discussion we will frequently indicate the equivalent QT operators for the vision techniques described. (QT is an interactive image processing system and is described in ➲ Chap. 21. ➲ Chap. 41 describes the function of each QT operator.) QT commands appear in square brackets. In certain cases, sequences of QT commands are needed to perform an operation and these are similarly listed.

14.1 Representations of Images

We will first consider the representation of *monochrome* (grey-scale) images. Let i and j denote two integers where $1 \leq i \leq m$ and $1 \leq j \leq n$. In addition, let f(i,j) denote an integer function such that $0 \leq f(i,j) \leq W$. (W denotes the white level in a grey-scale image.) The array **F** will be called a *digital image*:

$$F = \begin{vmatrix} f(1,1) & f(1,2) & \ldots & f(1,n) \\ f(2,1) & f(2,2) & \ldots & f(2,n) \\ f(3,1) & f(3,2) & \ldots & f(3,n) \\ \ldots & \ldots & \ldots & \ldots \\ f(m,1) & f(m,2) & \ldots & f(m,n) \end{vmatrix}$$

An address (i,j) defines a position in **F**, called a *pixel*, *pel* or *picture element*. The elements of **F** denote the intensities within a number of small rectangular regions within a real (i.e., optical) image (see ➋ *Fig. 14.1*). Strictly speaking, f(i,j) measures the intensity at a single point but if the corresponding rectangular region is small enough, the approximation will be accurate enough for most purposes. The array **F** contains a total of *mn* elements and this product is called the *spatial resolution* of **F** (➋ *Fig. 14.2*). We may *arbitrarily* assign intensities according to the following scheme:

$f(i,j) = 0$	Black
$0 \leq f(i,j) \leq 0.33W$	Dark grey
$0.33W < f(i,j) \leq 0.67W$	Mid-grey
$0.67W < f(i,j) < W$	Light grey
$f(i,j) = W$	White

Let us consider how much data is required to represent a grey-scale image in this form. Each pixel requires the storage of $\log_2(1+W)$ bits. This assumes that (1+W) is an integer power of two. If it is not, then $\log_2(1+W)$ must be rounded up to the next integer. This can be represented using the ceiling function $\lceil \cdots \rceil$. Thus, a grey-scale image requires the storage of $\lceil \log_2(1+W) \rceil$ bits. Since there are *mn* pixels, the total data storage for the entire digital image **F** is equal to $mn \lceil \log_2(1+W) \rceil$ bits. If $m = n \geq 128$, and $W \geq 64$, we can obtain a good image of a human face (➋ *Fig. 14.3*). Many of the industrial image processing systems in use nowadays manipulate images in which m and n are at least 512 and W is 255 (➋ *Fig. 14.4*). This leads to a storage requirement of 256 KB/image. A binary image is one in which only two

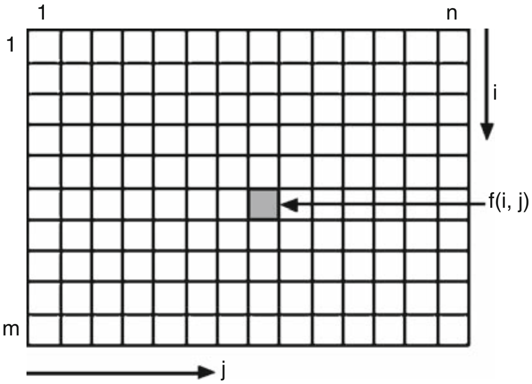

Fig. 14.1

A digital image consisting of an array of *mn* pixels. The pixel in the ith row and jth column (address *[i,j]*) has a intensity equal to *f(i,j)*

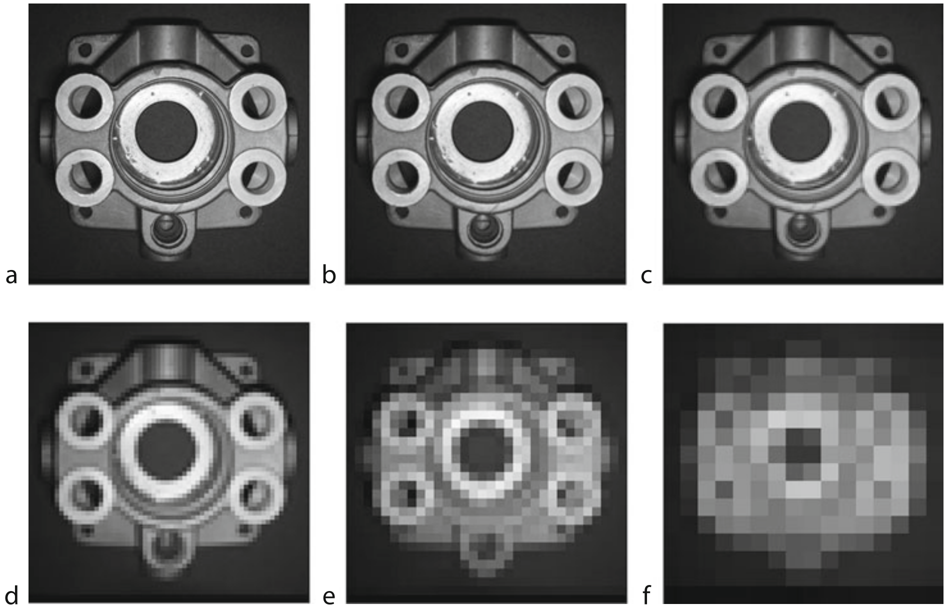

Fig. 14.2
Effects of varying resolution. In each case there are 256 possible grey levels. (a) 512 × 512 pixels, (b) 256 × 256 pixels, (c) 128 × 128 pixels, (d) 64 × 64 pixels, (e) 32 × 32 pixels, and (f) 16 × 16 pixels

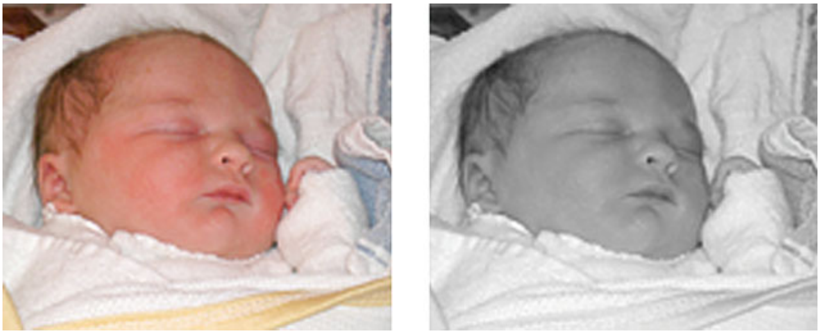

Fig. 14.3
A modest resolution, in this case 128 × 107 pixels, is sufficient to provide a reasonably good representation of human face. The colour image consists of 3 monochrome components, each 8 bits deep

intensity levels, black (0) and white (1), are permitted. This requires the storage of *mn* bits/image.

An impression of colour can be conveyed to the eye by superimposing *four* separate imprints. Cyan, magenta, yellow, and black inks are often used in printing (➔ *Fig. 14.5*). Ciné film operates in a similar way, except that when different colours of light, rather than ink, are added together, *three* components (red, green, and blue) suffice. Television operates

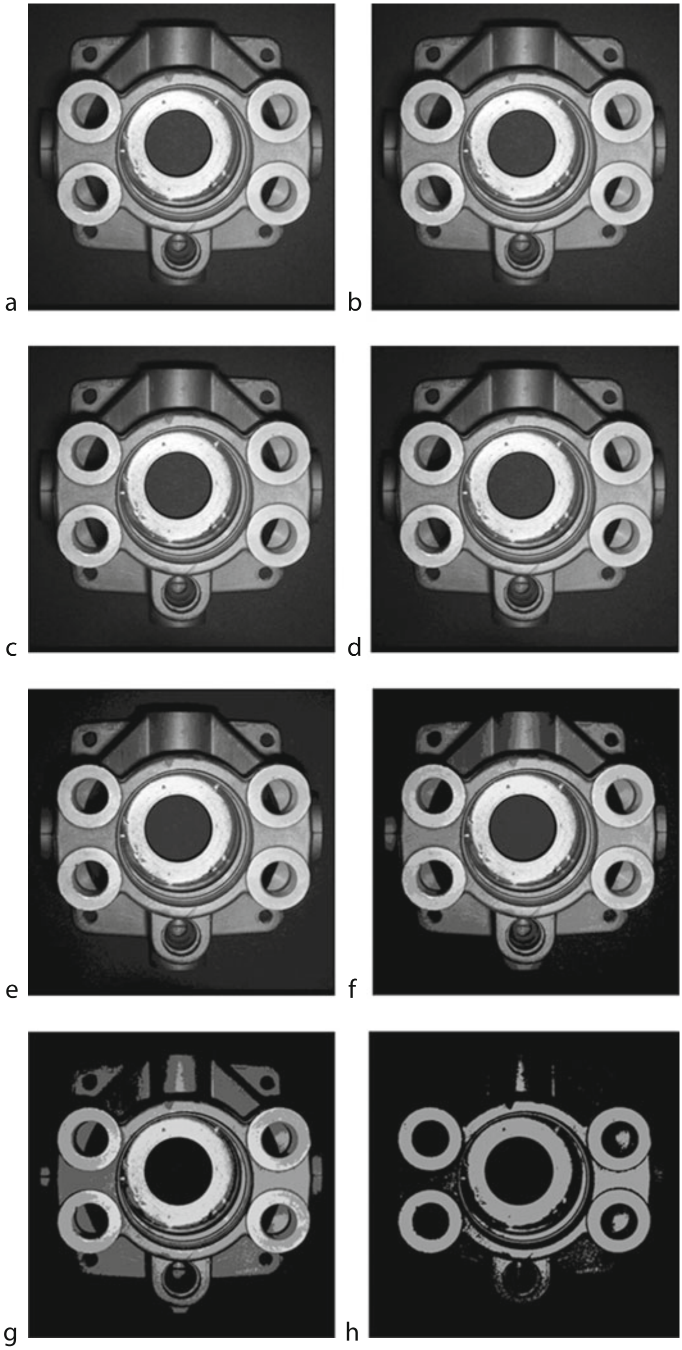

Fig. 14.4

Effects of varying the depth (number of bits needed to represent each intensity value). In each case there are 512 × 512 pixels. (a) 9 bits, (b) 7 bits, (c) 6 bits, (d) 5 bits, (e) 4 bits, (f) 3 bits, (g) 2 bits, and (h) 1 bit

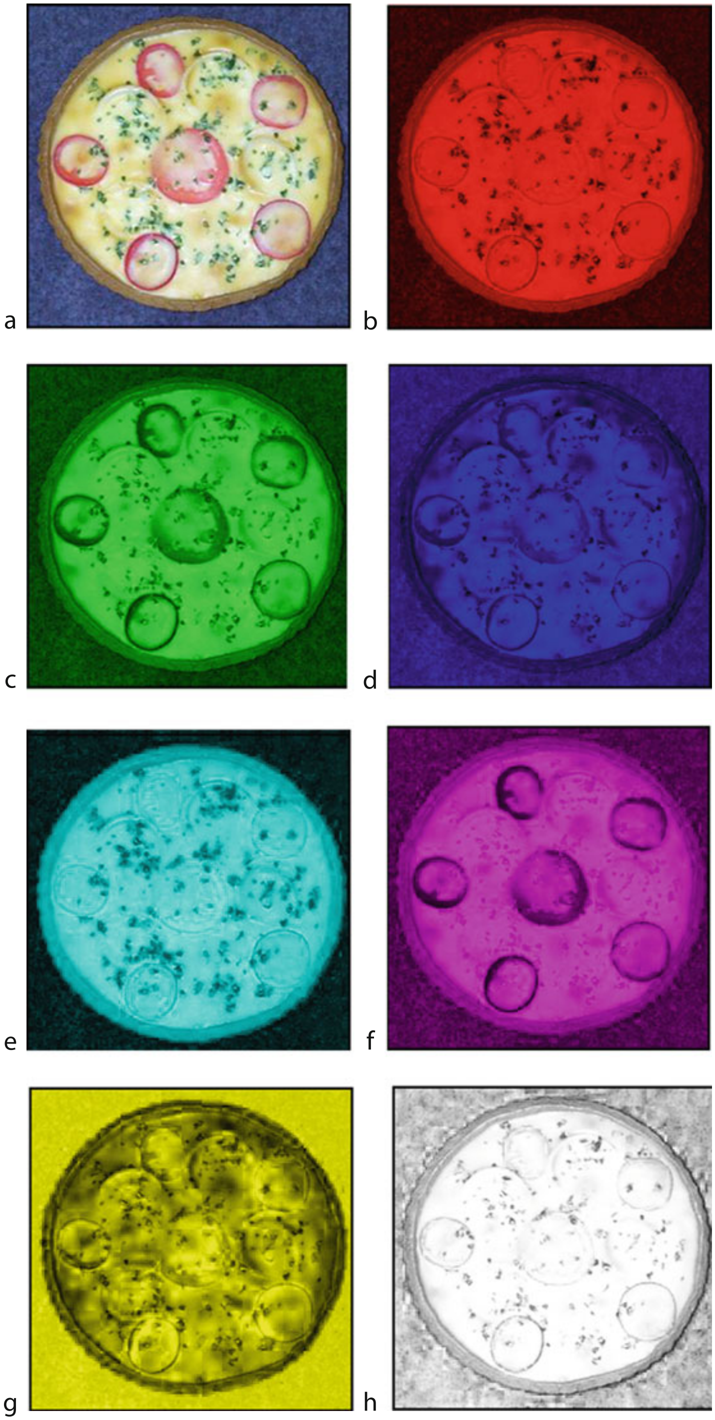

Fig. 14.5 (Continued)

in a similar way to film: the signal from a colour television camera may be represented using three components: **R** = *{r(i,j)}*; **G** = *{g(i,j)}*; **B** = *{b(i,j)}*, where **R, G** and **B** are defined in a similar way to **F**. The vector *{r(i,j), g(i,j), b(i,j)}* defines the intensity and colour at the point *(i,j)* in the colour image. (Colour image analysis is discussed in more detail in ➔ Chap. 16.) Multi-spectral images can also be represented using several monochrome images. The total amount of data required to code a colour image with *r* components is equal to $mnr\lceil \log_2(1+W) \rceil$ bits, where *W* is the maximum signal level on each of the channels.

In order to explain how moving scenes may be represented in digital form, ciné film and television will be referred to. A ciné film is, in effect, a time-sampled representation of the original moving scene. Each frame in the film is a standard monochrome or colour image, and can be coded as such. Thus, a monochrome ciné film may be represented digitally as a sequence of two-dimensional arrays [$\mathbf{F}_1$, $\mathbf{F}_2$, $\mathbf{F}_3$, $\mathbf{F}_4$,...]. Each $\mathbf{F}_i$ is an *mn* array of integers, as we defined above when discussing the coding of grey-scale images. If the film is in colour, then each of the $\mathbf{F}_i$ has three components. In the general case, when we have a spatial resolution of *mn* pixels, each spectral channel permits *(1+W)* intensity levels, there are *r* spectral channels, and *p* is the total number of "stills" in the image sequence, we require $mnpr\lceil \log_2(1+W) \rceil$ bits/image sequence.

We have considered only those image representations which are relevant to the understanding of simple image processing and analysis functions. Many alternative methods of coding images are possible but these are not relevant to this discussion.

14.2 Elementary Image Processing Functions

The following notation will be used throughout this section, in which we will concentrate upon grey-scale images, unless otherwise stated.

- *i* and *j* are row and column address variables and lie within the ranges $1 \leq i \leq m$ and $1 \leq j \leq n$ (➔ *Fig. 14.1*).
- **A** = {a(i,j)}, **B** = {b(i,j)} and **C** = {c(i,j)}.
- *W* denotes the white level.
- g(X) is a function of a single independent variable X.
- h(X,Y) is a function of two independent variables, X and Y.
- The assignment operator "←" will be used to define an operation that is performed upon one data element. The assignment operator "⇐" will be used to indicate that an operation is to be performed upon *all* pixels within an image.
- k, k1, k2, and k3 are constants.
- N(i,j) is that set of pixels arranged around the pixel (i,j) in the following way:

Fig. 14.5
Representing a colour image. (a) Original image, plastic replica of a quiche. (b) R component. (c) G component. (d) B component. Together the RGB components form the usual representation of colour used in video, film and Machine Vision. Notice that these are monochrome images. (e) Cyan (C) component. (f) Magenta (M) component. (g) Yellow (Y) component. (h) Black (K) component. Together the CMYK components form the representation that is often used in printing

(i–1, j–1)	(i–1, j)	(i–1, j+1)
(i, j–1)	(i, j)	(i, j+1)
(i+1, j–1)	(i+1, j)	(i+1, j+1)

Notice that N(i,j) forms a 3×3 set of pixels and is referred to as the *3×3 neighbourhood* of (i,j). In order to simplify some of the definitions, we will refer to the intensities of these pixels using the following notation:

A	B	C
D	E	F
G	H	I

Ambiguities over the dual use of A, B and C should not be troublesome, because the context will make it clear which meaning is intended. The points {A, B, C, D, F, G, H, I} are called the *8-neighbours* of E and are also said to be *8-connected* to E. The points {B, D, F, H)} are called the *4-neighbours* of E and are said to be *4-connected* to E.

14.2.1 Monadic, Pixel-by-Pixel Operators

These operators have a characteristic equation of the form

$$c(i,j) \Leftarrow g(a(i,j)) \text{ or } E \Leftarrow g(E)$$

Such an operation is performed for all (i,j) in the range [1,m],[1,n] (See ➜ *Fig. 14.6*). Several examples will now be described.

Intensity Shift (➜ *Fig. 14.7*) *[acn]*

$$c(i,j) \Leftarrow \left[\begin{array}{cc} 0 & a(i,j)+k<0 \\ a(i,j)+k & 0 \le a(i,j)+k \le W \\ W & W < a(i,\ j)+k \end{array} \right.$$

k is a constant, set by the system user. Notice that this definition was carefully designed to maintain c(i,j) within the same range as the input, viz [0,W]. This is an example of a process referred to as *intensity normalisation.* Normalisation is important because it permits iterative processing by this and other operators in a machine having a limited precision for arithmetic (e.g., 8-bits). Normalisation will be used frequently throughout this chapter.

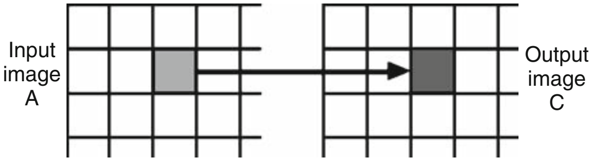

Fig. 14.6

Monadic pixel-by-pixel operator. The (i,j)th pixel in the input image has intensity a(i,j). This value is used to calculate c(i,j), the intensity of the corresponding pixel in the output image

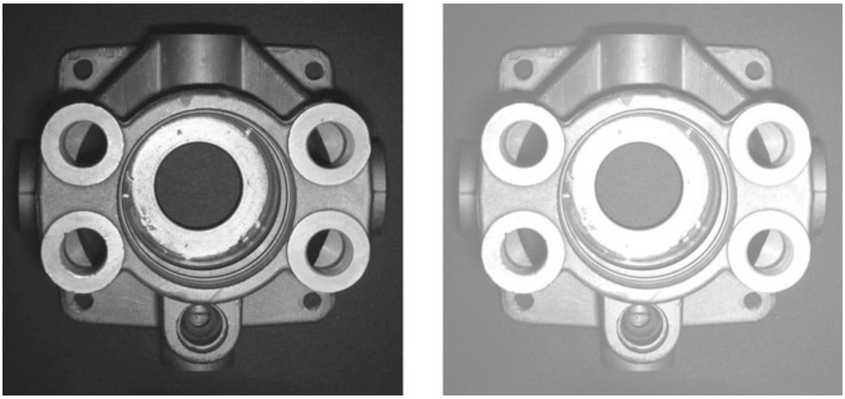

Fig. 14.7
Intensity shift. [*acn(100)*]. Notice that saturation occurs at level 255 (white)

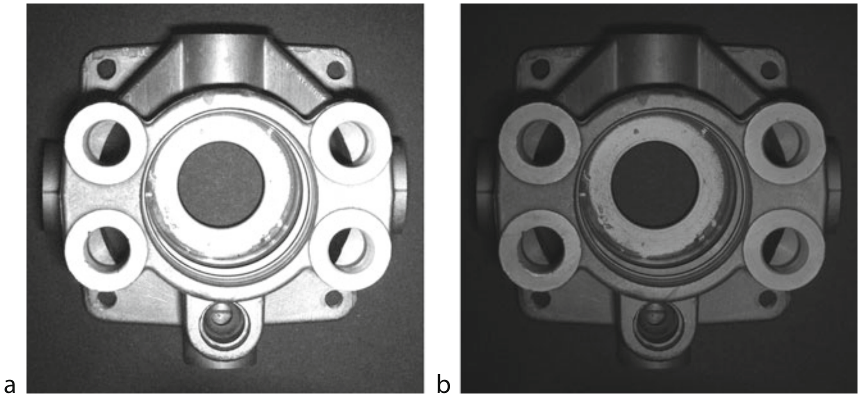

Fig. 14.8
Intensity multiply. (a) Intensities doubled [din]. (b) Intensities halved [*hin*. Also see *mcn*.]

Intensity Multiply (➋ *Fig. 14.8*) *[mcn]*

$$c(i,j) \Leftarrow \left[\begin{array}{cc} 0 & a(i,j)\cdot k < 0 \\ a(i,j)+k & 0 \le a(i,j)\cdot k \le W \\ W & W < a(i,j)\cdot k \end{array}\right.$$

Logarithm (➋ *Fig. 14.9*) *[log]*

$$c(i,j) \Leftarrow \left[\begin{array}{cc} 0 & a(i,j)=0 \\ W\dfrac{\log(a(i,j))}{\log(W)} & \text{otherwise} \end{array}\right.$$

This definition arbitrarily replaces the infinite value of log(0) by zero, and thereby avoids a difficult rescaling problem.

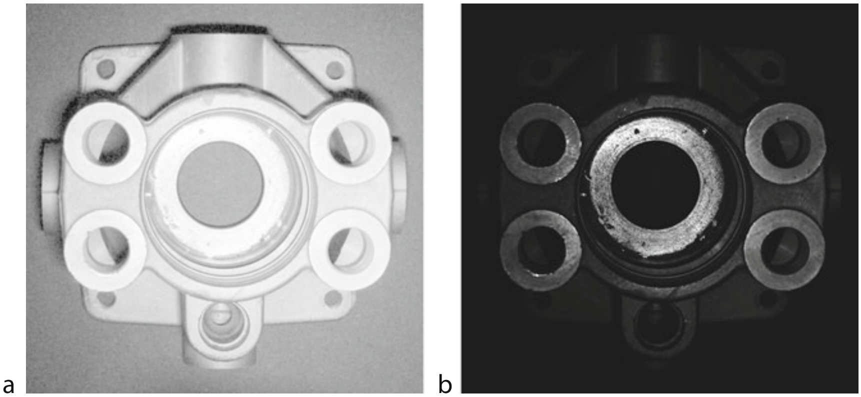

Fig. 14.9
(a) Logarithm of intensity [*nlg*]. (b) Antilogarithm (exponential) of intensity. [*alg*] Apart from zero intensity, these two operations are inverses of one another

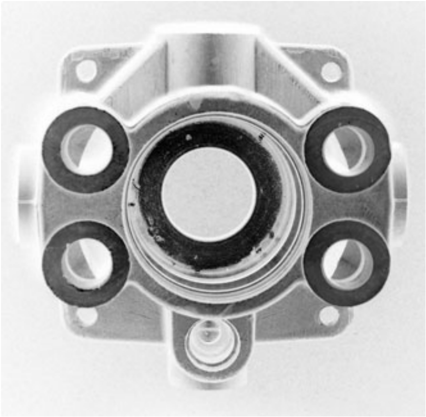

Fig. 14.10
Negation [*neg*]

Antilogarithm (exponential) (Fig. 14.9) *[exp]*

$$c(i, j) \Leftarrow W\exp(a(i, j))/\exp(W)$$

Negate (Fig. 14.10) *[neg]*

$$c(i, j) \Leftarrow W - a(i, j)$$

Threshold (Fig. 14.11) *[thr]*

$$c(i, j) \Leftarrow \begin{bmatrix} W & k1 \le a(i, j) < k2 \\ 0 & \text{otherwise} \end{bmatrix}$$

This is an important function, which converts a grey-scale image to a binary format. Unfortunately, it is often difficult or even impossible to find satisfactory values for the parameters *k1* and *k2*.

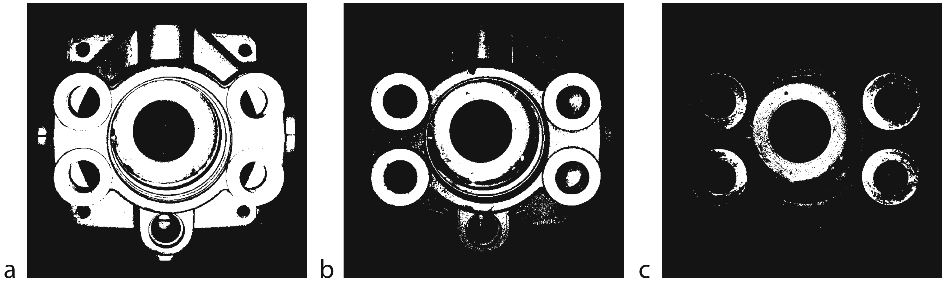

Fig. 14.11
Thresholding. (a) Thresholding at level 64. [thr(64)], (b) Thresholding at level 128. [*thr*, or *thr(128)*], and (c) Thresholding at level 192. [*thr(192)*]

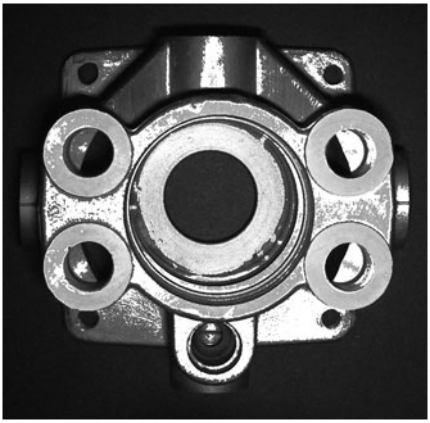

Fig. 14.12
Highlight. [*hil(100,150,255)*]

Highlight (Fig. 14.12) *[hil]*

$$c(i,j) \Leftarrow \begin{bmatrix} k3 & k1 \le a(i,j) < k2 \\ a(i,j) & \text{otherwise} \end{bmatrix}$$

Squaring (Fig. 14.13) *[sqr]*

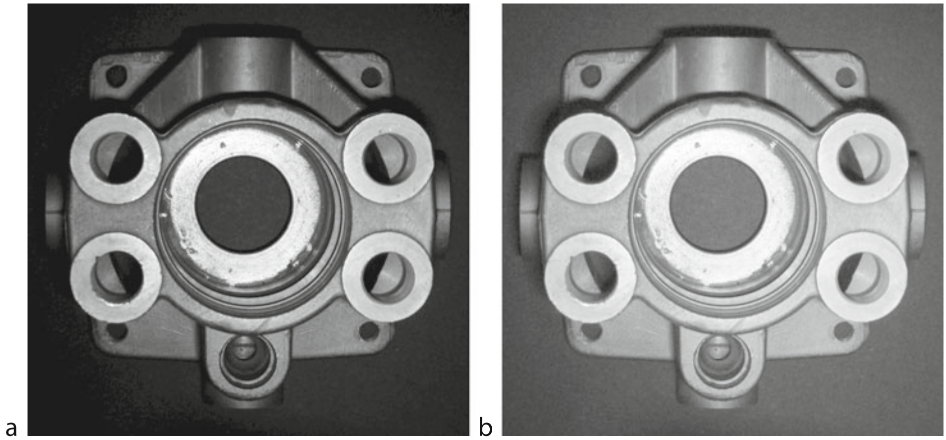
$$c(i,j) \Leftarrow [a(i,j)]^2/W$$

14.2.2 Dyadic, Pixel-by-Pixel Operators

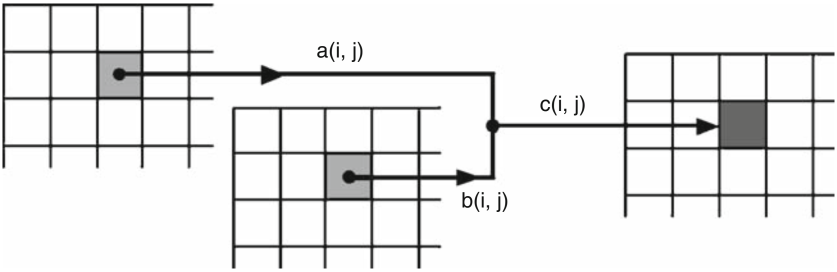
Dyadic operators have a characteristic equation of the form

$$c(i,j) \Leftarrow h(a(i,j),\ b(i,j))$$

There are two input images: **A** = {a(i,j)} and **B** = {b(i,j)} (Fig. 14.14), while the output image is ***C*** = {c(i,j)}. It is important to realise that c(i,j) depends upon only a(i,j) and b(i,j). Here are some examples of dyadic operators.



◘ Fig. 14.13
(a) Square intensities. [*sqr*] (b) Square root of intensities. [*sqt*]. These two operations are inverses of one another



◘ Fig. 14.14
Dyadic pixel-by-pixel operator. The intensities of the (i,j)th pixels in the two input images are combined to calculate the intensity c(i,j) at the corresponding address in the output image

Add (➔ *Fig. 14.15*) *[add]*

$$c(i,j) \Leftarrow [a(i,j) + b(i,j)]/2$$

Subtract (➔ *Fig. 14.16*) *[sub]*

$$c(i,j)[(a(i,j) - b(i,j)) + W]/2$$

Multiply (➔ *Fig. 14.17*) *[mul]*

$$c(i,j) \Leftarrow [a(i,j).b(i,j)]/W$$

Maximum (➔ *Fig. 14.18*) *[max]*

$$c(i,j) \Leftarrow \mathrm{MAX}[a(i,j), b(i,j)]$$

When the maximum operator is applied to a pair of binary images, the *union* (OR function) of their white areas is computed. This function may also be used to *superimpose* white writing onto a grey-scale image.

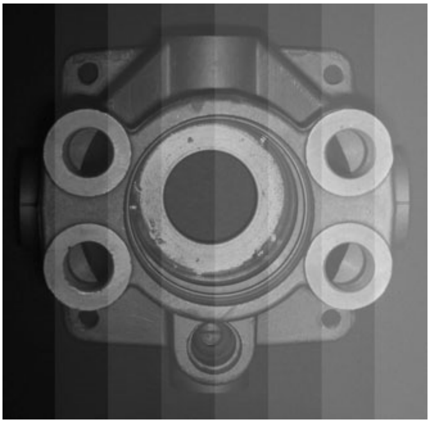


Fig. 14.15
Adding two images. [*adi*] The second image is a so-called "stair case", in which the intensity increases in doscrete steps along the X axis

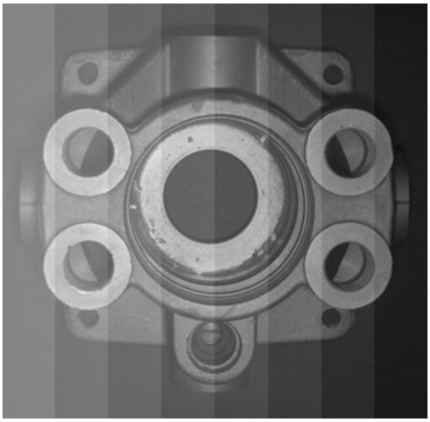

Fig. 14.16
Subtracting two images [*sub*]

Minimum (Fig. 14.19) *[min]*

$$c(i,j) \Leftarrow \mathrm{MIN}[a(i,j), b(i,j)]$$

When A and B are both binary, the *intersection* (AND function) of their white areas is calculated.

14.2.3 Local Operators

Figure 14.20 illustrates the principle of the operation of local operators. Notice that the intensities of several pixels are combined in order to calculate the intensity of just one pixel.

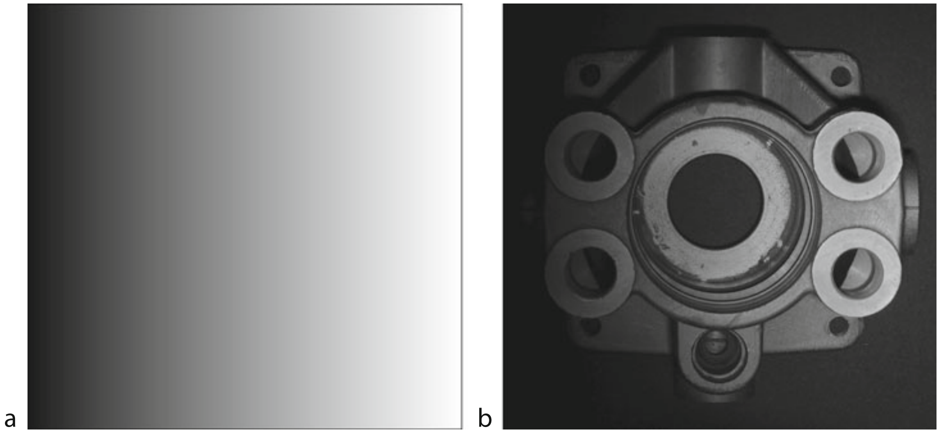

Fig. 14.17
Multiplying two images. (a) ''Intensity wedge''. The intensity varies linearly along the X axis. (b) Result of multiplying two images [*mul*]

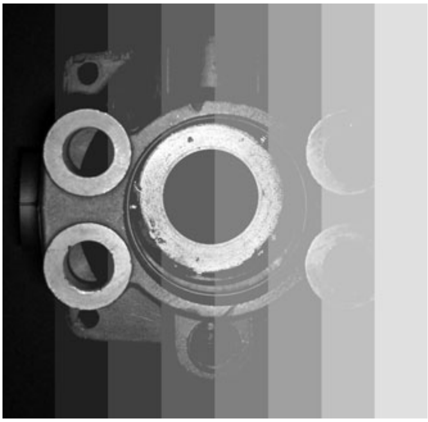

Fig. 14.18
Intensity maximum, using the ''stair case'' image [*mxi*]

Among the simplest of the local operators are those using a set of 9 pixels arranged in a 3×3 square. These 3×3 operators have a characteristic equation of the following form:

$$\begin{aligned} c(i,j) \Leftarrow g(&a(i-1,\ j-1), a(i-1,j), a(i-1,j+1), a(i,j-1), a(i,j),\\ &a(i,j+1), a(i+1,j-1), a(i+1,j), a(i+1,j+1)) \end{aligned}$$

where g(●) is a function of nine variables. This local operator is said to have a *3×3 processing window*. That is, it computes the value for one pixel on the basis of the intensities within a region containing 3×3 (= 9) pixels. Other local operators employ larger windows and we will discuss these briefly later. In the simplified notation which we introduced earlier, the above definition reduces to

$$E \Leftarrow g(A, B, C, D, E, F, G, H, I).$$

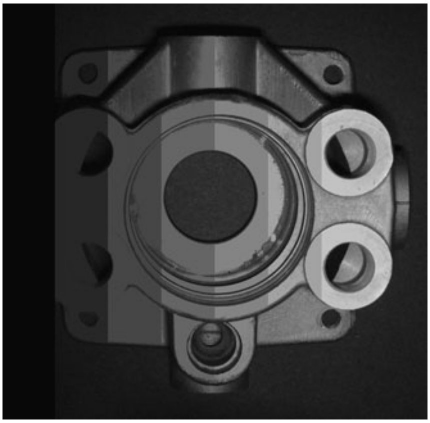

Fig. 14.19
Intensity minimum, using the "stair case" image [*mni*]

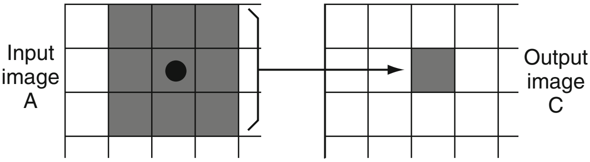

Fig. 14.20
Local operator. In this instance, the intensities of 9 pixels arranged in a 3×3 window are combined using linear or non-linear processes. Local operators may be defined which uses other, possibly larger, windows, which may or may not be square

14.2.4 Linear Local Operators

An important sub-set of the local operators is that group which performs a linear weighted sum, and which are therefore known as *linear local operators*. For this group, the characteristic equation is:

$$E \Leftarrow kl\,(A\,W1 + B\,W2 + C\ W3 + D\,W4 + E\,W5 \\ + F\,W6 + G\,W7 + H\,W8 + I\,W9) + k2$$

where W1, W2,...,W9 are weights, which may be positive, negative, or zero. Values for the normalisation constants k1 and k2 are given later. The matrix illustrated below is termed the *weight matrix*, and is important because it determines the properties of the linear local operator.

W1	W2	W3
W4	W5	W6
W7	W8	W9

The following rules summarise the behavior of this type of operator. They exclude the case where *all* the weights and normalisation constants are zero, since this would result in a null image:

1. If all weights are either positive or zero, the operator will *blur* the input image. Blurring is referred to as *low-pass filtering*. Subtracting a blurred image from the original results in

a highlighting of those points where the intensity is changing rapidly and is termed *high-pass filtering*.

2. If W1 = W2 = W3 = W7 = W8 = W9 = 0, and W4, W5, W6 > 0, then the operator blurs along the rows of the image. Horizontal features, such as horizontal edges and streaks, are not affected.
3. If W1 = W4 = W7 = W3 = W6 = W9 = 0, and W2, W5, W8 > 0, then the operator blurs along the columns of the image. Vertical features are not affected.
4. If W2 = W3 = W4 = W6 = W7 = W8 = 0, and W1, W5, W9 > 0, then the operator blurs along the diagonal (top-left to bottom-right). There is no smearing along the orthogonal diagonal.
5. If the weight matrix can be reduced to a matrix product of the form **PQ**, where

P =

0	0	0
V4	V5	V6
0	0	0

and

Q =

0	V1	0
0	V2	0
0	V3	0

the operator is said to be "separable." This is important because in such cases it is possible to apply two simpler operators in succession, with weight matrices **P** and **Q**, to obtain the same effect as that produced by the separable operator.

6. The successive application of linear local operators which use windows containing 3×3 pixels produces the same results as linear local operators with larger windows. For example, applying that operator which uses the weight shown below (left) twice in succession results in an image similar to that obtained from the 5×5 operator with the weight matrix shown below (centre). (For simplicity, normalisation has been ignored here.) Applying the same 3×3 operator three times in succession is equivalent to using the 7×7 operator shown below (right).

1	1	1
1	1	1
1	1	1

1	2	3	2	1
2	4	6	4	2
3	6	9	6	3
2	4	6	4	2
1	2	3	2	1

1	3	6	7	6	3	1
3	9	18	21	18	9	3
6	18	36	42	36	18	6
7	21	42	49	42	21	7
6	18	36	42	36	18	6
3	9	18	21	18	9	3
1	3	6	7	6	3	1

Notice that all of these operators are also separable. Hence it would be possible to replace the last-mentioned 7×7 operator with six simpler operators: 3×1, 3×1, 3×1, 1×3, 1×3, and 1×3, applied in any order. It is not always possible to replace a large-window operator with a succession of 3×3 operators. This becomes obvious when one considers, for example, that a 7×7 operator uses 49 weights and that three 3×3 operators provide only 27 degrees of freedom. Separation is often possible, however, when the larger operator has a weight matrix with some redundancy; for example, when it is symmetrical.

7. In order to perform normalisation, the following values are used for k1 and k2.

$$k1 \leftarrow 1/\left(\sum_{p,q} \left|W_{p,q}\right|\right)$$

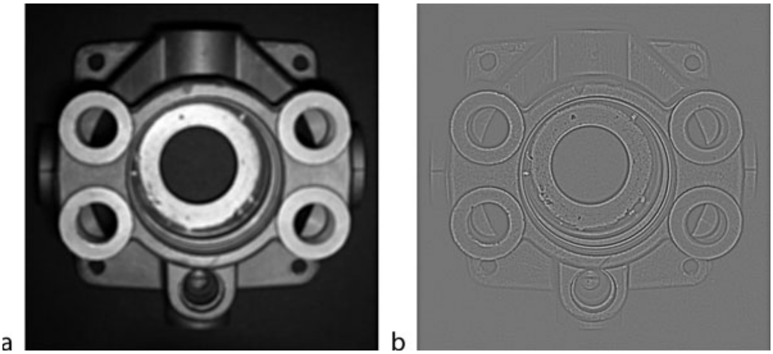

Fig. 14.21
Linear convolution filtering. (a) Low-pass (2D blurring) filter. [*raf(11,11)*] (b) High-pass filter. [*raf(11,11)sub*]

$$k2 \leftarrow \left| 1 - \left[\left(\sum_{p,q} W_{p,q} \right) \Big/ \left(\sum_{p,q} |W_{p,q}| \right) \right] \right|$$

8. A filter using the following weight matrix performs a *local averaging function* over an 11×11 window [*raf(11,11)*] (*Fig. 14.21*).

1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1
1	1	1	1	1	1	1	1	1	1	1

This produces quite a severe 2-directional blurring effect. Subtracting the effects of a blurring operation from the original image generates a picture in which spots, streaks and intensity steps are all emphasised. On the other hand, large areas of constant or slowly changing intensity become uniformly grey. This process is called *high-pass filtering*, and produces an effect similar to unsharp masking, which is familiar to photographers.

14.2.5 Nonlinear Local Operators

Largest Intensity Neighbourhood Function (*Fig. 14.22*) *[lnb]*

$$E \Leftarrow \mathbf{MAX}(A, B, C, D, E, F, G, H, I)$$

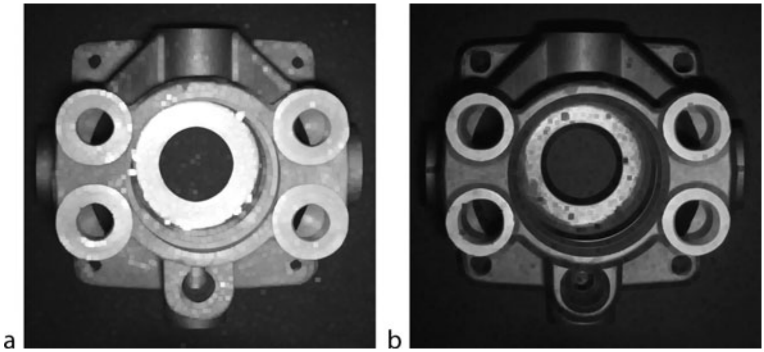

Fig. 14.22
Neighbourhood intensity operations (a) Largest neighbour. [*lnb(5)*]. (b) Smallest neighbour. [*snb(5)*]

This operator has the effect of spreading bright regions and contracting dark ones.

Edge Detector (Fig. 14.23) [lnb, sub]

$$E \Leftarrow \mathbf{MAX}(A, B, C, D, E, F, G, H, I) - E$$

This operator is able to highlight edges (i.e., points where the intensity is changing rapidly).

Median Filter (Fig. 14.24) *[mdf(5)]*

$$E \Leftarrow \mathbf{FIFTH\_LARGEST}\ (A, B, C, D, E, F, G, H, I)$$

This filter is particularly useful for reducing the level of noise in an image. Noise is generated from a range of sources, such as video cameras and x-ray detectors, and can be a nuisance if it is not eliminated by hardware or software filtering.

Crack Detector (Fig. 14.25) [*crk*. This is equivalent to applying the sequence *lnb, lnb, neg, lnb, lnb, neg* and then subtracting the result from the original image]. This detector is able to detect thin dark streaks and small dark spots in a grey-scale image; it ignores other features, such as bright spots and streaks, edges (intensity steps) and broad dark streaks. (This is an example of an operator that can be described far better using computer notation rather than mathematical notation.)

Roberts edge Detector (Fig. 14.23) *[red]* The Roberts gradient is calculated using a 2×2 pixel mask. This will determine the edge gradient in two diagonal directions. It is defined as.

$$E \Leftarrow \sqrt{(A - E)^2 + (B - D)^2}$$

The following approximation to the Roberts gradient magnitude is called the *Modified Roberts operator*. This is simpler and faster to implement and it more precisely defines the QT operator *red*. It is defined as

$$E \Leftarrow \{|A - E| + |B - D|\}/2$$

Sobel edge Detector (Fig. 14.23) *[sed]* This popular operator highlights the edges in an image; points where the intensity gradient is high are indicated by bright pixels in the output image. The Sobel edge detector uses a 3×3 mask to determine the edge gradient.

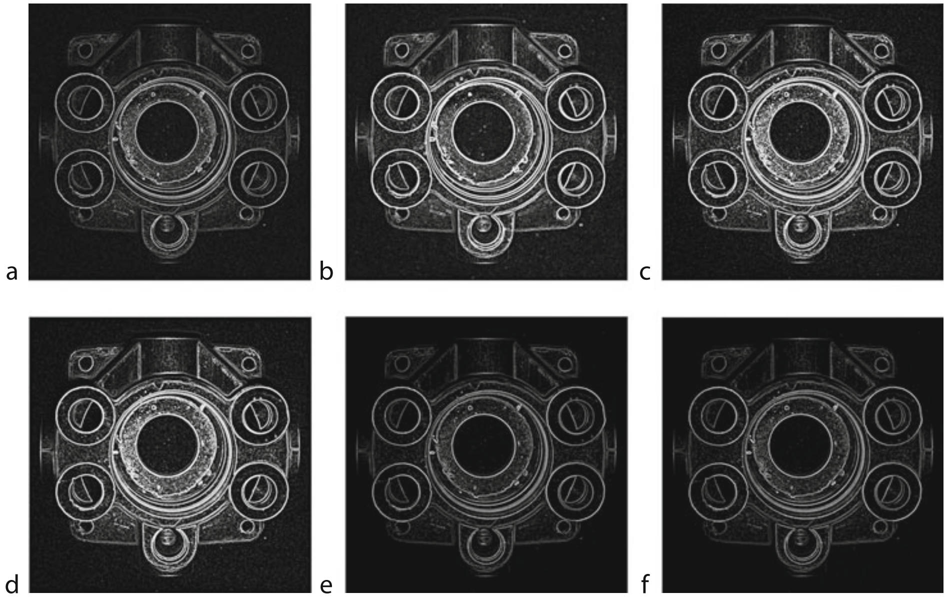

Fig. 14.23
Edge detectors. (a) Non-linear neighbourhood operator [*lnb,sub,neg,enc,din*]. (b) Another non-linear neighbourhood operator [*lnb(7), sub,neg, enc, din*]. (c) Roberts operator. [*red*] (d) Sobel operator [*sed*] (e) Prewitt operator [*wri, glc([−1,−1,−1;0,0,0;1,1,1]), abv, wri(1), rei, yxt, glc([−1,−1,−1;0,0,0;1,1,1]), yxt, abv,, rei(1), adi, enc*] (f) Frei-Chen operator [*wri, glc([−1,−1.4142,−1;0,0,0; 1,1.4142,1]), abv, wri(1), rei, yxt, glc([−1,−1.4142,−1;0,0,0; 1,1.4142,1]), yxt, abv,, rei(1), adi, enc*]

$$E \Leftarrow \sqrt{[(A+2B+C)-(G+2H+I)]^2+[(A+2D+G)-(C+2F+I)]^2}$$

The following approximation is simpler to implement in software and hardware and more precisely defines the QT operator *sed*:

$$E \Leftarrow \{|(A+2B+C)-(G+2H+I)|+|(A+2D+G)-(C+2F+I)|\}/6$$

See *Fig. 14.23* for a comparison of the Roberts and Sobel edge detector operators when applied to a sample monochrome image. Note that, while the Roberts operator produces thinner edges, these edges tend to break up in regions of high curvature. The primary disadvantage of the Roberts operator is its high sensitivity to noise, since fewer pixels are used in the calculation of the edge gradient. There is also a slight shift in the image when the Roberts edge detector is used. The Sobel edge detector does not produce such a shift.

Prewitt Edge Detector (*Fig. 14.23*) The Prewitt edge detector is similar to the Sobel operator, but is more sensitive to noise because it does not possess the same inherent smoothing. This operator uses the two 3×3 weighting matrices shown below to determine the edge gradient.

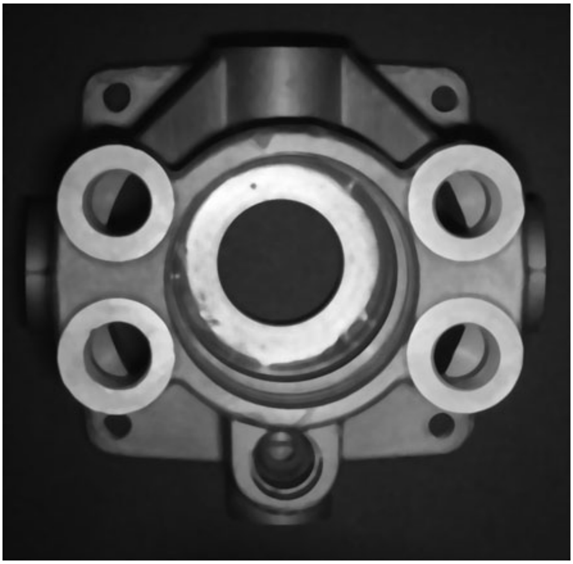

Fig. 14.24
Median filter, based on an 11×11 pixel window. [*mdf(11)*]

P_1:

–1	–1	–1
0	0	0
1	1	1

P_2:

–1	0	1
–1	0	1
–1	0	1

The Prewitt gradient magnitude is defined as $E \Leftarrow \surd(P_1{}^2 + P_2{}^2)$, where P_1 and P_2 are the values calculated from each mask, respectively.

Frei and Chen Edge Detector (➔ *Fig. 14.23*) This operator uses the two 3×3 masks shown below to determine the edge gradient.

F_1:

–1	–√2	–1
0	0	0
1	√2	1

F_2:

–1	0	1
–√2	0	√2
–1	0	1

The Frei and Chen gradient magnitude is defined as $E \Leftarrow \surd(F_1{}^2 + F_2{}^2)$, where F_1 and F_2 are the values calculated from each mask, respectively.

Rank Filters (➔ *Fig. 14.26*) *[mdf, rid]* The generalised 3×3 rank filter is

$$\begin{aligned} c(i,j) \Leftarrow\ & k1(A'W1 + B'W2 + C'W3 + D'W4 + E'W5 \\ & + F'W6 + G'W7 + H'W8 + I'W9) + k2 \end{aligned}$$

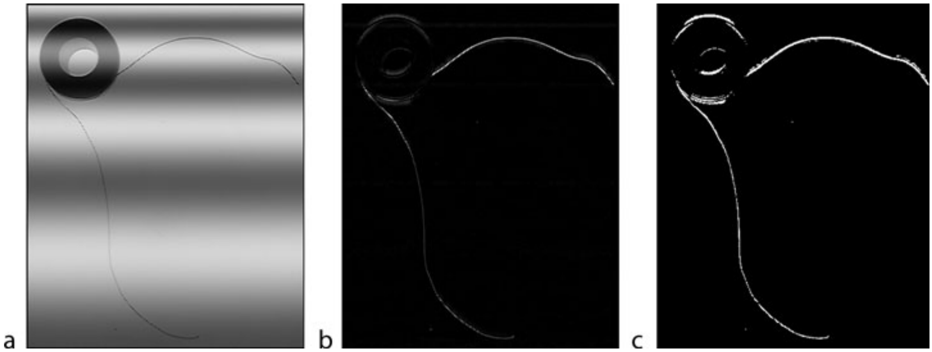

Fig. 14.25
Crack detector function. (a) Original image, specially contrived to show the power of this operator. (b) Crack detector operator applied. Contrast was increased for easier viewing. [*crk(5), enc*] (c) Thesholding applied to previous image shows that the crack detector creates an image with sufficient contrast to enable the thin dark streaks (wires) to be isolated

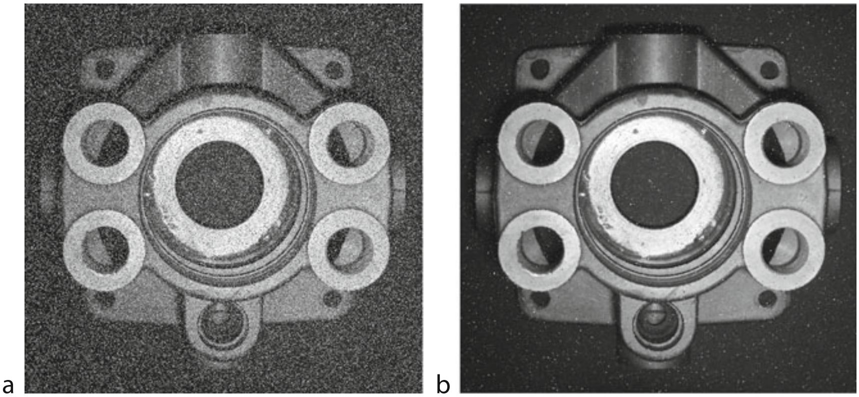

Fig. 14.26
Rank filter. (a) Original image. Noise was added specially to show the power of this operator. (b) Rank filter applied [*rcf([0,0,1,2,3,2,1,0,0]*)]

where

A′ = **LARGEST** (A, B, C, D, E, F, G, H, I)
B′ = **SECOND_LARGEST** (A, B, C, D, E, F, G, H, I)
C′ = **THIRD_LARGEST** (A, B, C, D, E, F, G, H, I)
…
I′ = **NINTH_LARGEST** (A, B, C, D, E, F, G, H, I)

and k1 and k2 are the normalisation constants defined previously. With the appropriate choice of weights (W1, W2,...,W9), the rank filter can be used for a range of operations including edge detection, noise reduction, edge sharping, and image enhancement.

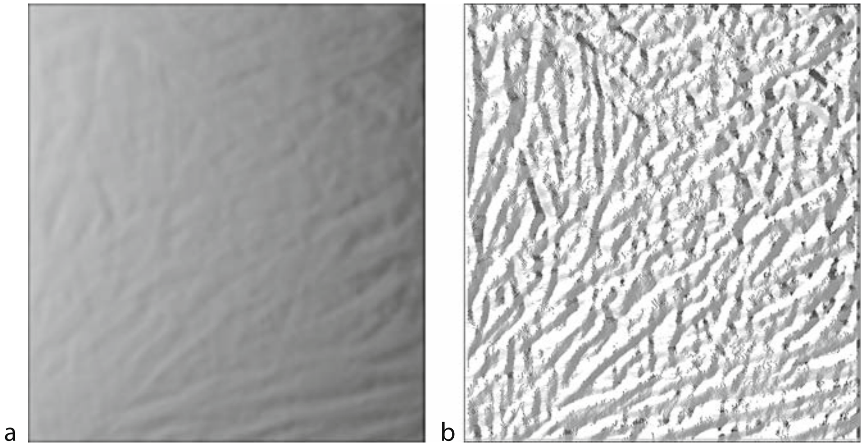

Fig. 14.27

Direction of brightest neighbour. (a) Original image (creased fabric). (b) Operator applied. [*mdf(5), caf(5), dbn,enc*] (The command sequence [*mdf(5), caf(5)*] reduces noise and thereby produces a "smoother" result.)

Direction Codes (Fig. 14.27) *[dbn]* This function can be used to detect the *direction* of the intensity gradient. A direction code function DIR_CODE is defined thus:

$$\mathrm{DIR\_CODE(A,B,C,D,F,G,H,I)} \Leftarrow \left[\begin{array}{ll} 1 & \text{if } \mathrm{A} \geq (\mathrm{MAX(B,C,D,F,G,H,I)} \\ 2 & \text{if } \mathrm{B} \geq (\mathrm{MAX(A,C,D,F,G,H,I)} \\ 3 & \text{if } \mathrm{C} \geq (\mathrm{MAX(A,B,D,F,G,H,I)} \\ 4 & \text{if } \mathrm{D} \geq (\mathrm{MAX(A,B,C,F,G,H,I)} \\ 5 & \text{if } \mathrm{F} \geq (\mathrm{MAX(A,B,C,D,G,H,I)} \\ 6 & \text{if } \mathrm{G} \geq (\mathrm{MAX(A,B,C,D,F,H,I)} \\ 7 & \text{if } \mathrm{H} \geq (\mathrm{MAX(A,B,C,D,F,G,I)} \\ 8 & \text{if } \mathrm{I} \geq (\mathrm{MAX(A,B,C,D,F,G,H)} \end{array}\right.$$

Using this definition, the operator *dbn* may be defined as

$$\mathrm{E} \Leftarrow \mathrm{DIR\_CODE(A,B,C,D,F,G,H,I)}$$

14.2.6 N-Tuple Operators

The N-tuple operators are closely related to the local operators and have a large number of linear and non-linear variations. N-tuple operators may be regarded as generalised versions of local operators. In order to understand the N-tuple operators, let us first consider a *linear* local operator which uses a large processing window, say r^*s pixels, with most of its weights equal to zero. Only N of the weights are non-zero, where N $\ll$ r^*s. This is an N-tuple filter (see Fig. 14.28). These filters are usually designed to detect specific patterns. In this role, they are able to locate a simple feature, such as a corner, an annulus, the numeral "2" in any position, etc. However, they are sensitive to changes of orientation and scale. The N-tuple can be regarded as a sloppy template which is convolved with the input image.

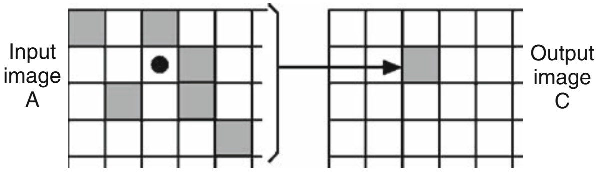

Fig. 14.28
An N-tuple filter operates much like a local operator. The only difference is that the pixels whose intensities are combined do not form a compact set. An N-tuple filter can be regarded as being equivalent to a local operator with a large window in which many of the weights are zero

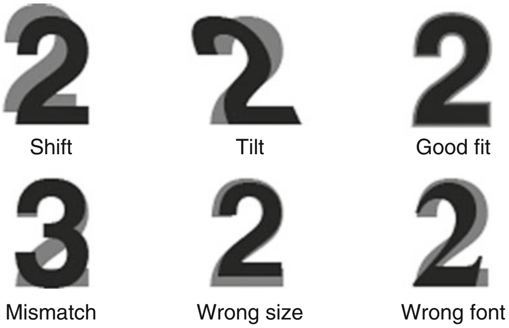

Fig. 14.29
Recognising a numeral "2" using an N-tuple

Nonlinear N-tuple operators may be defined in a fairly obvious way. For example, we may define operators which compute the average, maximum, minimum, or median values of the intensities of the N pixels covered by the N-tuple. An important class of such functions is the *morphological operators* (see Sects. 14.4 and 14.5). *Figure 14.29* illustrates the recognition of the numeral "**2**" using an N-tuple. Notice how the goodness of fit varies with the shift, tilt, size, and font. Another character ("**Z**" in this case) may give a score that is close to that obtained from a "**2**", thus making these two characters difficult to distinguish reliably.

14.2.7 Edge Effects

All local operators and N-tuple filters are susceptible to producing peculiar effects around the edges of an image. The reason is simply that, in order to calculate the intensity of a point near the edge of an image, we require information about pixels outside the image, which of course are simply not present. In order to make some attempt at calculating values for the edge pixels, it is necessary to make some assumptions, for example that all points outside the image are black, or have the same values as the border pixels. This strategy, or whatever one we adopt, is perfectly arbitrary and there will be occasions when the edge effects are so pronounced that there is nothing that we can do but to remove them by masking (*Fig. 14.30*) [*edg*]. Edge

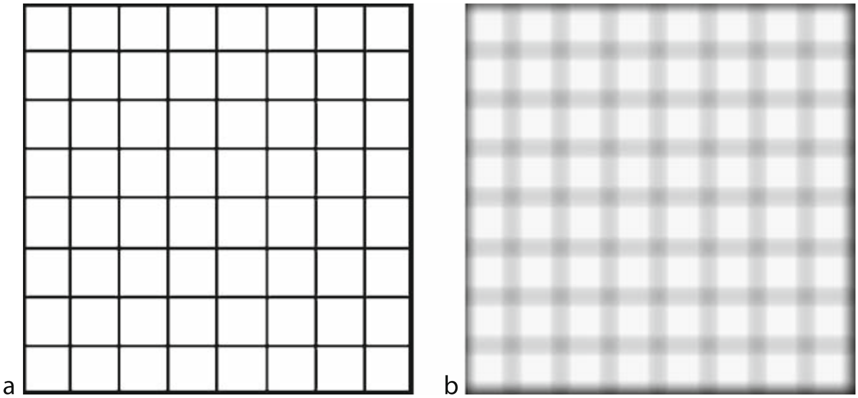

Fig. 14.30
Edge effects of a local operator. (a) Input image. (b) Blurring filter applied. Pixels near the edge do not have meaningful intensity values

effects are important because they require us to make special provisions for them when we try to patch several low-resolution images together.

14.2.8 Intensity Histogram (Fig. 14.31) *[hpi, hgi, hge, hgc]*

The intensity histogram is defined in the following way:

(a) Let

$$s(p,i,j) \leftarrow \begin{bmatrix} 1 & a(i,j) = p \\ 0 & \text{otherwise.} \end{bmatrix}$$

(b) Let h(p) be defined thus:

$$h(p) \leftarrow \sum_{i,j} s(p,i,j)$$

It is not, in fact, necessary to store each of the *s(p,i,j)*, since the calculation of the histogram can be performed as a serial process in which the estimate of *h(p)* is updated iteratively as we scan through the input image. This *cumulative histogram, H(p)*, can be calculated using the following recursive relation:

$$H(p) = H(p-1) + h(p), \text{ where } H(0) = h(0).$$

Both the cumulative and the standard histograms have a great many uses, as will become apparent later. It is possible to calculate various intensity levels which indicate the occupancy of the intensity range [*pct*]. For example, it is a simple matter to determine that intensity level *p(k)* which, when used as a threshold parameter, ensures that a proportion *k* of the output image is black. *p(k)* can be calculate using the fact that *H(p(k)) = m n k*. The *mean intensity* [*avg*] is equal to

$$avg = \sum_{p} (h(p) \times p)/(m \times n)$$

while the *maximum intensity* [*gli*] is equal to *MAX*(p | h(p) > 0) and the *minimum intensity* is equal to *MIN*(p | h(p) > 0).

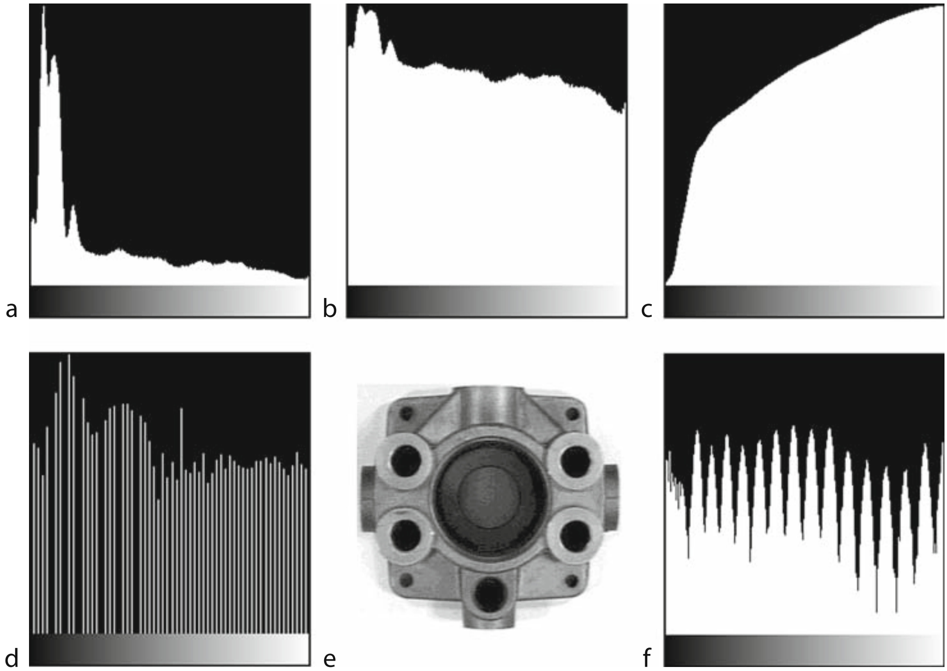

Fig. 14.31

Histograms. (a) Histogram of the image shown in *Fig. 14.2a*. [*hgm(1)*] (b) Histogram plotted with logarithmic ordinate scale. [*hgm(2)*] (c) Cumulative histogram. (This has the same shape as the mapping function required for histogram equalisation.) [*hgm(5)*] (d) Histogram equalisation. [*heq*] (e) Another image. (f) Histogram of (e) has a strange form, despite the apparently good image quality

One of the principal uses of the histogram is in the selection of threshold parameters. It is useful to plot *h(p)* as a function of *p*. It is often found from this graph that a suitable position for the threshold can be related directly to the position of the "foot of the hill" or to a "valley" in the histogram.

An important operator for image enhancement is given by the transformation

$$c(i,j) \Leftarrow [W\,H(a(i,j))]/(m \times n)$$

This has the interesting property that the histogram of the output image {c(i,j)} is flat, giving rise to the name *histogram equalisation* [*heq*]. Notice that histogram equalisation is a *data-dependent* monadic pixel-by-pixel operator.

An operation known as *local area histogram equalisation* relies upon the application of histogram equalisation within a small window (*Fig. 14.32*) [lhq]. The number of pixels in a small window that are darker than the central pixel is counted. This number defines the intensity at the equivalent point in the output image. This is a powerful filtering technique, which is particularly useful in texture analysis. (Sect. 14.7)

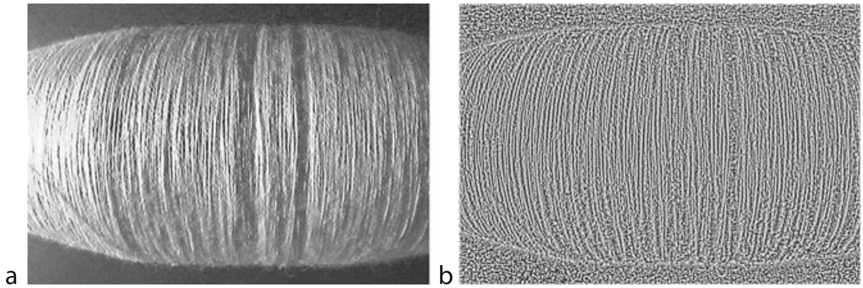

Fig. 14.32
Local area histogram equalisation. (a) Original image. (Cotton wound on a bobbin.) (b) After processing. Notice that the camera noise has been enhanced too. (The contrast was increased to improve visibility.) [*lhq,enc*]

14.3 Binary Images

For the purposes of this description of binary image processing, it will be convenient to assume that a(i,j) and b(i,j) can assume only two values: 0 (black) and 1 (white). The operator "+" denotes the Boolean *OR* operation, "×" represents the *AND* operation, "⊗" denotes the Boolean *Exclusive OR* operation, and #(i,j) denotes the number of white points addressed by N(i,j), including (i,j) itself.

Inverse (▶ *Fig. 14.33*) *[not]*

$$c(i,j) \Leftarrow ; \mathrm{NOT}(a(i,j))$$

AND (▶ *Fig. 14.34*) [mni]

$$c(i,j) \Leftarrow a(i,j) \times b(i,j)$$

OR (▶ *Fig. 14.35*) [mxi]

$$c(i,j) \Leftarrow a(i,j) + b(i,j)$$

Exclusive OR (▶ *Fig. 14.36*) [exr]

$$c(i,j) \Leftarrow a(i,j) \otimes b(i,j)$$

This finds differences between white regions.

Expand White Areas (▶ *Fig. 14.37*) *[dil]*

$$\begin{aligned} c(i,j) \Leftarrow\ & a(i-1,\ j-1) + a(i-1,j) + a(i-1,j+1) + a(i,j-1) + a(i,j) \\ & + a(i,j+1) + a(i+1,j-1) + a(i+1,j) + a(i+1,j+1) \end{aligned}$$

Notice that this is closely related to the local operator *lnb* defined earlier. This equation may be expressed in the simplified notation:

$$E \Leftarrow A + B + C + D + E + F + G + H + I$$

Shrink White Areas (▶ *Fig. 14.37*) *[ero]*

$$\begin{aligned} c(i,j) \Leftarrow\ & a(i-1,\ j-1) \times a(i-1,j) \times a(i-1,j+1) \times a(i,j-1) \times a(i,j) \\ & \times a(i,j+1) \times a(i+1,j-1) \times a(i+1,j) \times a(i+1,j+1) \end{aligned}$$

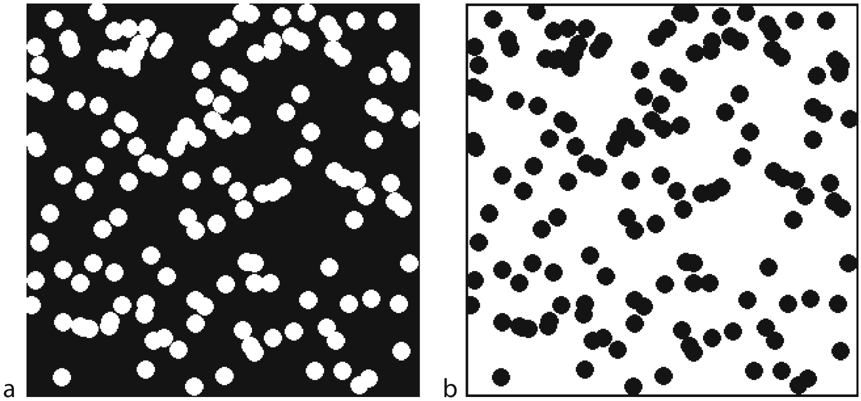

Fig. 14.33

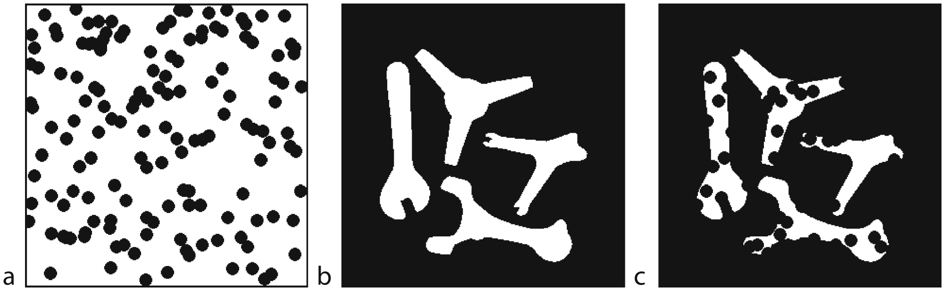

Fig. 14.34
ANDing two images. (a) Image 1. (b) Image 2. (c) Result of processing [*mni*. The grey-scale operators, neg *(NOT), mni (AND)* and *mxi (OR*) are also able to process binary images.]

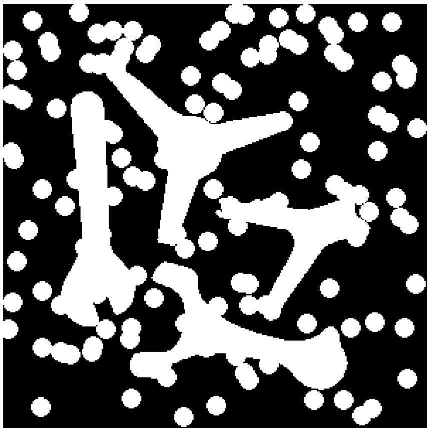

Fig. 14.35
ORing two images. The "spots" image in *Fig. 14.33a* was negated before the OR operation was performed [mxi]

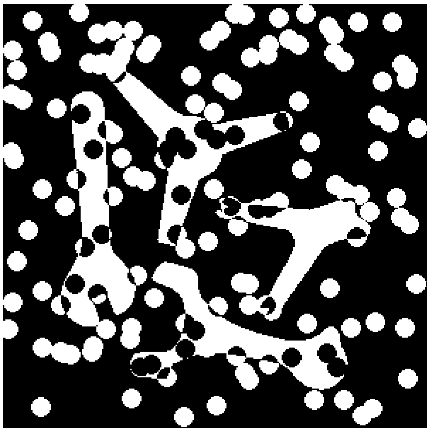

Fig. 14.36
Exclusive OR of two images: *Fig. 14.33a,b*

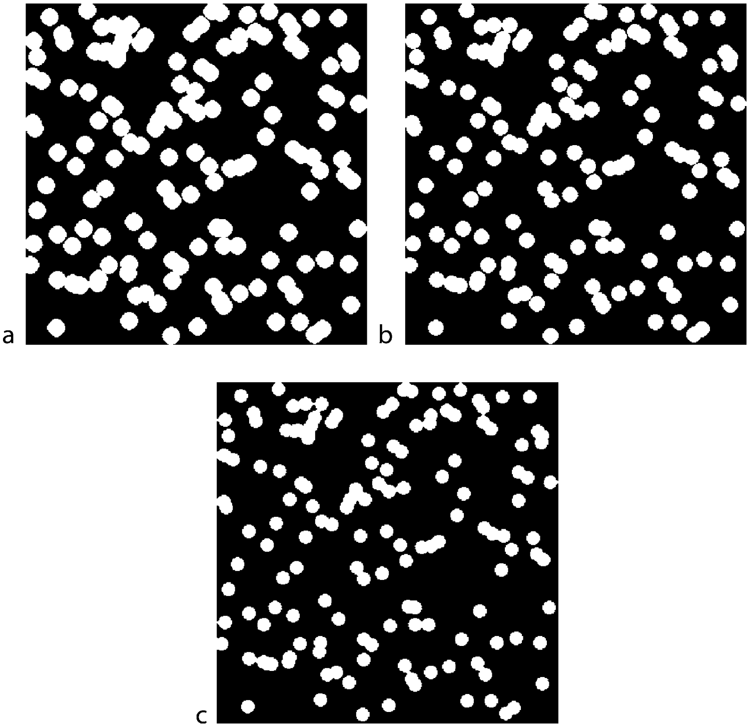

Fig. 14.37
Expanding (dilating) and shrinking (eroding) white regions in a 3×3 pixel neighbourhood. (a) Expansion. [*dil*]. (b) Original image. (c) Erosion [*ero*]

or more simply

$$c(i,j) \Leftarrow A \times B \times C \times D \times E \times F \times G \times H \times I$$

Expanding and shrinking white areas will be discussed again but in more general terms later in this chapter.

Edge detector (➲ *Fig. 14.38*) *[bed]*

$$c(i,j) \Leftarrow E \times \mathrm{NOT}(A \times B \times C \times D \times F \times G \times H \times I)$$

Remove Isolated White Points [cln]

$$c(i,j) \Leftarrow \left| \begin{array}{ll} 1 & a(i,j) \cdot (\#(i,j) > 1) \\ 0 & \text{otherwise} \end{array} \right.$$

Count White Neighbours (➲ *Fig. 14.39*) *[cnw]*

$$c(i,j) \Leftarrow N(i,j)$$

where #(Z) is the number of times Z occurs. This results in a grey-scale image.

Connectivity Detector (➲ *Fig. 14.39*) *[cny]* Consider the following pattern:

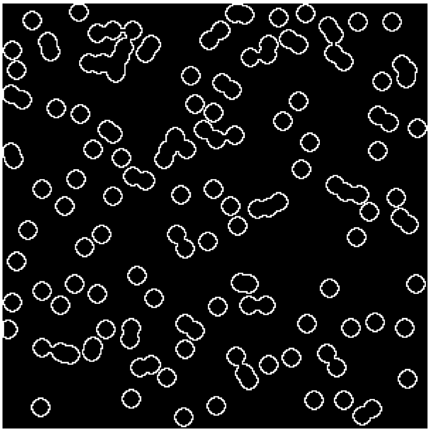
1	0	1
1	X	1
1	0	1

If X = 1, then all of the 1s are 8-connected to each other. Alternatively, if X = 0, then they are not connected. In this sense, the point marked X is *critical for connectivity.* This is also the case in the following examples:

1	0	0
0	X	1
0	0	0

1	1	0
0	X	0
0	0	1

0	0	1
1	X	0
1	0	1



▪ Fig. 14.38

Binary edge. This is the exclusive OR of ➲ *Fig. 14.37a, b* [*bed*]

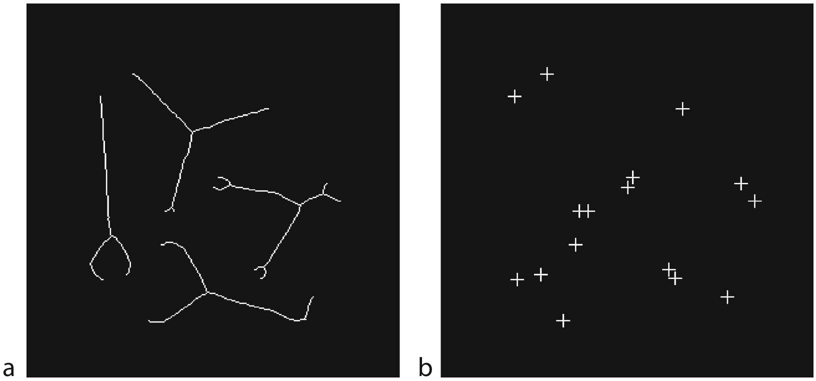


Fig. 14.39

Counting white neighbours. (a) Original image. This is the result of applying the thinning operator [thn] to *Fig. 14.34b*. (b) Limb ends [*lmb*] are white points that have exactly one white 8-neighbour. Joints are white points that have more than two white 8-neighbours. Since both limb ends and joints [*jnt*] are single pixels, they are too small to be visible and are represented here by crosses

However, those points marked X below are not critical for connectivity, since setting X = 0 rather than 1 has no effect on the connectivity of the remaining 1s.

1	1	1
1	X	1
0	0	1

0	1	1
1	X	0
1	1	1

0	1	1
1	X	0
0	1	1

A connectivity detector shades the output image with 1s to indicate the position of those points which are critical for connectivity and which were white in the input image. Black points and those which are not critical for connectivity are mapped to black in the output image.

Euler Number [eul] The Euler number is defined as the number of connected components (blobs) minus the number of holes in a binary image. The Euler number represents a simple method of counting blobs in a binary image, provided they have no holes in them. Alternatively, it can be used to count holes in a given object, providing they have no "islands" in them. The reason why this approach is used to count blobs, despite the fact that it may seem a little awkward to use, is that the Euler number is very easy and fast to calculate. It is also a useful means of classifying shapes in an image. The Euler number can be computed by using three local operators. Let us define three numbers N1, N2 and N3, where Nα, $\alpha = 1, 2$ or 3, indicates the number of times that one of the patterns in the pattern set α occurs in the input image.

0	0	0	0
0	1	1	0
0	1	1	0

1	1	1	1

Pattern Set 3 (N3)

The *8-connected* Euler number, where holes and blobs are defined in terms of 8-connected figures, is defined as *(N1-2 N2-N3)/4*. It is possible to calculate the *4-connected* Euler number using a slightly different formula, but this parameter can give results which seem to be anomalous when we compare them to the observed number of holes and blobs.

Filling Holes (➋ *Fig. 14.40*) [blf] Consider a white blob-like figure containing a hole (lake), against a black background. The application of the hole-filling operator will cause all of the holes to be *filled in* by setting all pixels in the holes to white. This operator will not alter the outer edge of the figure.

Region Labelling (➋ *Fig. 14.41*) *[ndo]* Consider an image containing a number of separate blob-like figures. A region-labelling operator will shade the output image so that each blob is given a separate intensity value. We could shade the blobs according to the order in which they

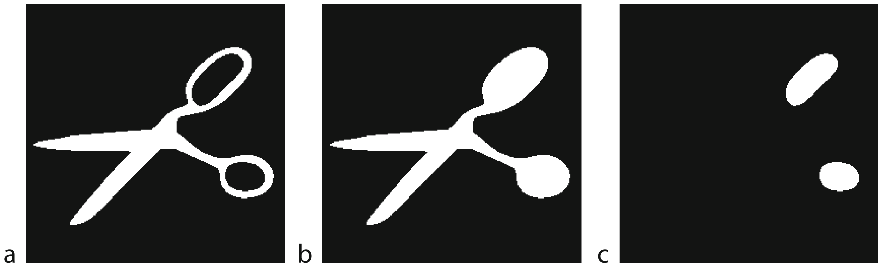

Fig. 14.40
Filling holes (lakes). (a) Original image. This has an Euler number of −1, since there is one object present and there are two lakes. (b) Result of filling. [*blf*] (c) Lakes identified using exclusive OR. [*blf,exr*]

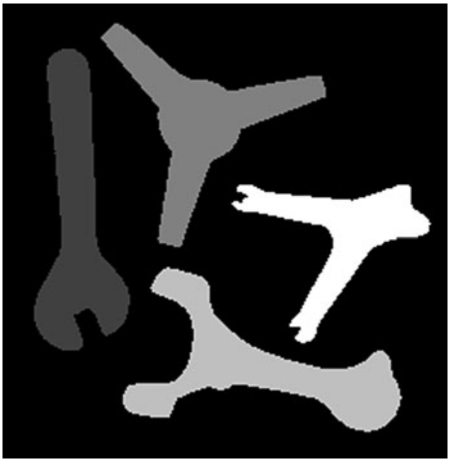

Fig. 14.41
Region labelling [*ndo*]

are found during a conventional raster scan of the input image. Alternatively, the blobs could be shaded according to their areas, the biggest blobs becoming the brightest. This is a very useful operator, since it allows objects to be separated and analysed individually. Small blobs can also be eliminated from an image using this operator [also *kgr*]. Region labelling can also be used to count the number of distinct binary blobs in an image. Unlike the Euler number, blob counting based on region labelling is not affected by the presence of holes.

Other Methods of Detecting/Removing Small Spots A binary image can be thought of as a grey-scale image in which only two grey levels, 0 and W, are allowed. The result of the application of a conventional low-pass (blurring) filter to such an image is a grey-scale image in which there is a larger number of possible intensity values. Pixels which were well inside large white areas in the input image are mapped to very bright pixels in the output image. Pixels which were well inside black areas are mapped to very dark pixels in the output image. However, pixels which were inside small white spots in the input image are mapped to mid-grey intensity levels (➲ *Fig. 14.42*). Pixels on the edge of large white areas are also mapped to mid-grey intensity levels. However, if there is a cluster of small spots, which are closely spaced together, some of them may also disappear.

This technique is generally easier and faster to implement than the blob shading technique described previously (➲ *Fig. 14.43*). Although it may not achieve precisely the desired result, it can be performed at high speed.

An N-tuple filter having the weight matrix illustrated below, can be combined with simple thresholding to distinguish between large and small spots. Assume that there are several small white spots within the input image and that they are spaced well apart. All pixels within a spot which can be contained within a circle of radius three pixels will be mapped to white by this particular filter. Pixels within a larger spot will become darker than this. The image is then thresholded at white to separate the large and small spots.

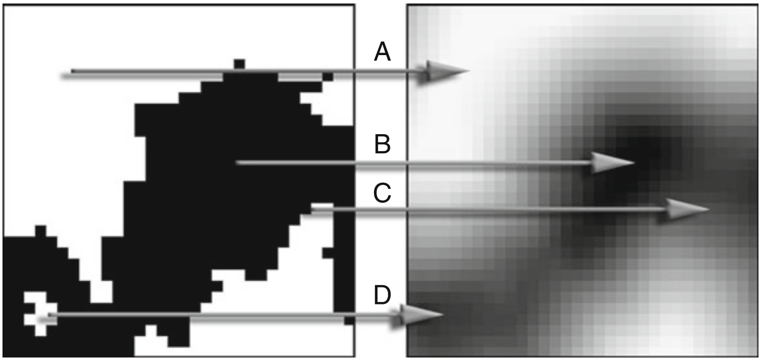

Fig. 14.42

Edge smoothing by low-pass filtering (blurring) and thresholding. *Left*: Original image. *Right*: Filtered image. A – points well within the white region are mapped to white. B – points well within the black region are mapped to black. C – points near the edge are mapped to grey; the intensity level depends on how many white points are in its immediate neighbourhood. D – small white spots are mapped to a low intensity and are eliminated by thresholding

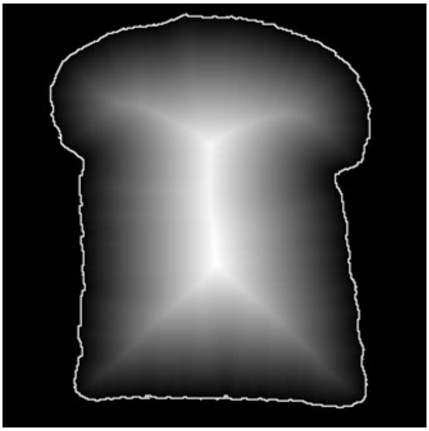
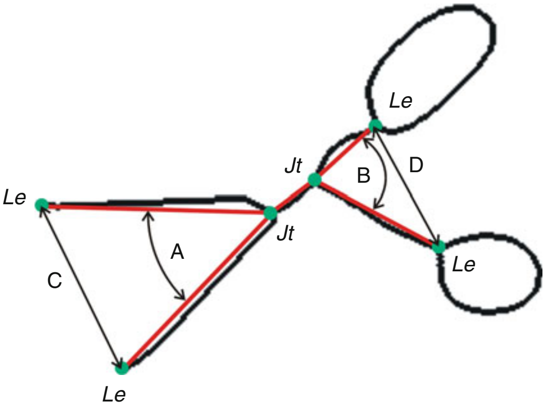
Grass-fire Transform and Skeleton [gft, ske & thn] Consider a binary image containing a single white blob, ➲ *Fig. 14.44*. Imagine that a fire is lit at all points around the blob's outer edge and the edges of any holes it may contain. The fire will burn inwards, until at some instant, advancing fire lines meet. When this occurs, the fire becomes extinguished locally. An output image is generated and is shaded in proportion to the time it takes for the fire to reach each point. Background pixels are mapped to black.

The importance of this transform, referred to as the *grass-fire* transform, lies in the fact that it indicates distances to the nearest edge point in the image [1]. It is therefore possible to distinguish thin and fat limbs of a white blob. Those points at which the fire lines meet are known as *quench* points. The set of quench points form a "match-stick" figure, usually referred to as a *skeleton* or *medial axis transform*. These figures can also be generated in a number of different ways (➋ *Fig. 14.45*).



◘ Fig. 14.44

Grassfire transform. The white contour shows the outer edge of the object. (slice of bread) [*gft*] The medial axis is the bright "spine"



◘ Fig. 14.45

Analysing the skeleton of a blob-like object. *Jt* repesents a joint on the skeleton and *Le* a limb end. Various measurements can be made on the skeleton, for example the distances between limb ends (C and D) and angles (A and B)

One such approach is described as *onion-peeling*. Consider a single white blob and a "bug" which walks around the blob's outer edge, removing one pixel at a time. No edge pixel is removed, if by doing so we would break the blob into two disconnected parts. In addition, no white pixel is removed, if there is only one white pixel among its 8-neighbours. This simple procedure leads to an undesirable effect in those instances when the input blob has holes in it; the skeleton which it produces has small loops in it which fit around the holes like a tightened noose. More sophisticated algorithms have been devised which avoid this problem.

Edge Smoothing and Corner Detection Consider three points B1, B2, and B3 which are placed close together on the edge of a single blob in a binary image (see ➋ *Fig. 14.46*). The perimeter distance between B1 and B2 is equal to that between B2 and B3. The point P is at the centre of the line joining B1 and B3. As the three points now move around the edge of the blob, keeping the spacing between them constant, the locus of P traces a smoother path than that followed by B2. This forms the basis of a simple edge smoothing procedure.

A related algorithm, used for corner detection, shades the edge according to the distance between P and B2. This results in an image in which the corners are highlighted, while the smoother parts of the image are much darker (➋ *Fig. 14.47*).

Many other methods of edge smoothing are possible. For example, we may map white pixels which have fewer than, say, three white 8-neighbours to black. This has the effect of

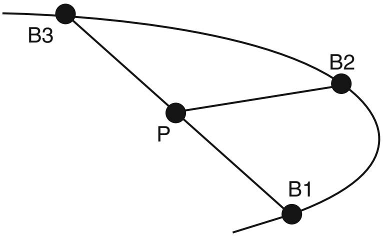


Fig. 14.46
Edge smoothing and corner detection

eliminating "hair" around the edge of a blob-like figure. One of the techniques described previously for eliminating small spots offers another possibility. A third option is to use the processing sequence: [*exw, skw, skw, exw*], where *exw* represents expand white areas and *skw* denotes shrink white areas.

Convex Hull [chu] Consider a single blob in a binary image. The convex hull is that area enclosed within the smallest convex polygon which will enclose the shape (➋ *Fig. 14.48*). This can also be described as the region enclosed within an elastic string stretched around the blob. The area enclosed by the convex hull but not within the original blob is called the *convex deficiency*, which may consist of a number of disconnected parts and includes any holes and indentations. If we regard the blob as being like an *island*, we can understand the logic of referring to the former as *lakes* and the latter as *bays*.

14.3.1 Measurements on Binary Images

To simplify the following explanation, we will confine ourselves to the analysis of a binary image containing a single blob. The area of the blob can be measured by the total number of object (white) pixels in the image. However, we must first define two different types of edge points, in order to measure an object's perimeter.

The *4-adjacency* convention (➋ *Fig. 14.49*) allows only the four main compass points to be used as direction indicators, while *8-adjacency* uses all eight possible directions. If the 4-adjacency convention is applied to the image segment given in ➋ *Fig. 14.49c*, then none of the four shaded segments (two horizontal and two vertical) will appear as touching, i.e., they are not connected. Using the 8-adjacency convention, these four segments are now connected, but we have the ambiguity that the inside of the shape is connected to the outside. Neither convention is satisfactory, but because 8-adjacency allows diagonally-adjacent pixels to be regarded as connected, it leads to a more faithful perimeter measurement.

Assuming that the 8-adjacency convention is used, we can generate a coded description of the blob's edge. This is referred to as the *chain code* or *Freeman code* [*fcc*]. As we trace around the edge of the blob, we generate a number, 0–7, to indicate which of the eight possible directions we have taken, relative to the centre shaded pixel in ➋ *Fig. 14.49b*. Let N_o indicate how many *odd-numbered* code values are produced as we code the blob's edge, and N_e represent

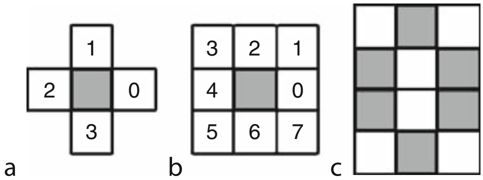

Fig. 14.49
Chain code. (a) 4-adjacency coding convention. (b) 8-adjacency coding convention. (c) Image segment

the number of *even-numbered* values found. The *perimeter* of the blob is given *approximately* by the formula $N_e + 2N_o$.

This formula will normally suffice for use in those situations where the perimeter of a smooth object is to be measured. The *centroid* of a blob [*cgr*] determines its position within the image and can be calculated using the formulae:

$$\bar{I} \leftarrow \sum_j \sum_i (i(a(i,j)))/N_{i,j}$$

$$\bar{J} \leftarrow \sum_j \sum_i (j(a(i,j)))/N_{i,j}$$

$$\text{where} \quad N_{i,j} \leftarrow \sum_j \sum_i a(i,j)$$

Although we are considering images in which the a(i,j) are equal to 0 (black) or 1 (white), it is convenient to use a(i,j) as an ordinary arithmetic variable as well.

14.3.2 Shape Descriptors (➋ *Fig. 14.50*)

The following are just a few of the shape descriptors that have been proposed:

(a) The distance of the furthest point on the edge of the blob from the centroid.
(b) The distance of the closest point on the edge of the blob from the centroid.
(c) The number of protuberances, as defined by that circle whose radius is equal to the average of the parameters measured in (a) and (b). This circle is located at the blob centroid.
(d) Circularity = Area/Perimeter. This will tend to zero for irregular shapes with ragged boundaries, and has a maximum value of $1/4\pi$ for a circle.
(e) The distances of points on the edge of the blob from the centroid, as a function of angular position. This describes the silhouette in terms of polar co-ordinates. (This is not a single-valued function.)
(f) The number of holes. (Use *eul* and [*blf, exr, ndo*] to count them.)
(g) The number of bays.
(h) The ratio of the area of the original blob to that of its convex hull.
(i) The ratio of the area of the original blob to that of its circumcircle.
(j) The ratio of the area of the blob to the square of the total limb-length of its skeleton.
(k) The distances between joints and limb ends of the skeleton.
(l) The ratio of the projections onto the major and minor axes.

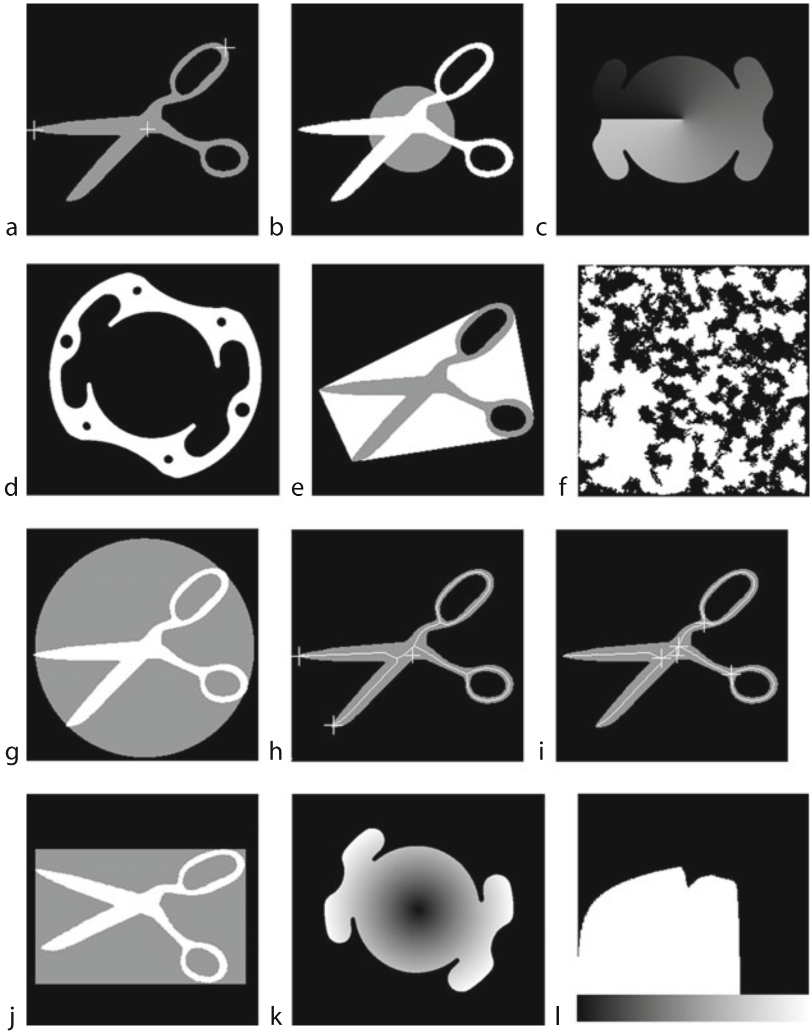

Fig. 14.50

Features and measurements on binary images (also see *Fig. 14.45*). (a) Distance from the centroid (central cross) to the furthest edge points. (b) Counting/ measuring protuberances (regions outside the circle of equivalent area). (c) Angular distribution of "mass" after normalising position and orientation. (This "object" is the lake in (d).) (d) Euler number (−6) provides a way to check the number of lakes. (This object is a stamping for the stator of a small electric motor.) (e) Relative areas of bays and lakes. (f) For very complex images, the Euler number is a rapid way to estimate the number of blobs. The result is approximate, since there may be some lakes formed by the nearly random process that created this image. (g) The ratio of the area of the circumcircle to that of the original blob provides a measure of shape. (h) Skeleton limb ends. (i) Skeleton joints. (j) Minimum enclosing rectangle after normalising orientation allows the object's aspect ratio to be measured. (k) Radial distribution of "mass", measured from the centroid. (l) Histogram of (k) provides a shape description vector that is independent of orientation. Notice that we treat the parts of (d) as objects in their own right

14.4 Binary Mathematical Morphology

The basic concept involved in mathematical morphology is simple: an image is probed with a template shape, called a structuring element, to find where it fits, or does not fit [2] (➲ *Fig. 14.51*). By marking the locations where the template shape fits, structural information can be gleaned about the image. The structuring elements used in practice are usually geometrically simpler than the image they act on, although this is not always the case. Common structuring elements include small groups of isolated points, point pairs, lines, squares, octagons, discs, rhombi, and rings. Since shape is a prime carrier of information in machine vision applications, mathematical morphology has an important role to play in industrial systems [5].

The language of binary morphology is derived from that of set theory [6]. General mathematical morphology is normally discussed in terms of Euclidean *N*-space, but in digital image analysis we are only interested in a discrete or digitised equivalent in two-space. The following analysis is therefore restricted to binary images in a digital two-dimensional integer space, Z2. The image set (or scene) under analysis will be denoted by *A*, with elements *a = (a1, a2)*. The shape parameter, or structuring element, that will be applied to scene *A* will be denoted by *B*, with elements *b = (b1, b2)*. The primary morphological operations that we will examine are dilation, erosion, opening, and closing.

Dilation (also referred to as *filling* and *growing*) is the expansion of an image set *A* by a structuring element *B*. It is a generalisation of the process of expanding white areas described in ➲ Sect. 14.3. Dilation is formally viewed as the combination of the two sets using vector addition of the set elements. The dilation of an image set *A* by a structuring element *B* will be denoted *A* ⊗ *B*, and can be represented as the union of translates of the structuring element *B* [6]:

$$A \oplus B = \bigcup_{a \in B} B_a$$

where ∪ represents the union of a set of points and the translation of *B* by point *a* is given by $B_a = \{c \in Z^2 | c = (b + a)\}$ for some $b \in B$.

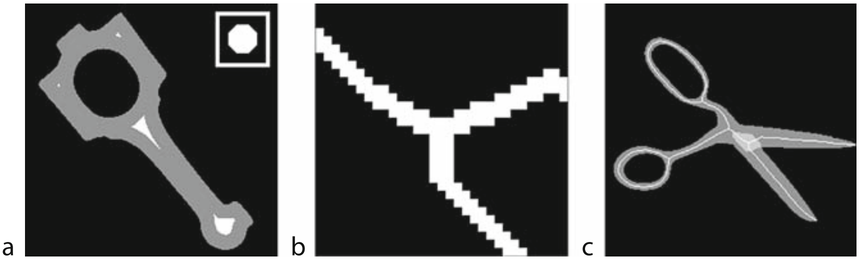

Fig. 14.51

Binary erosion with an arbitrary structuring element. (a) The structuring element (inset) fits within the object (automobile con-rod) at those places indicated by white pixels, which form four blob-like regions. (b) Structuring element, derived from the skeleton of the dark grey object (scissors) in (c). (c) The structuring element fits within the silhouette of the scissors at many points but these are all connected and form a single blob. (light grey) Making the structuring element bigger, for example by including both skeleton joints, will make it more selective

This is best explained by visualising a structuring element B moving over an image A in a raster fashion. Whenever the origin of the structuring element coincides with one of the image pixels in A, then the entire structuring element is placed in the output image at that location. For example, in *Fig. 14.52* the image is dilated by a cross-shaped structuring element contained within a 3×3 pixel grid.

Erosion is the dual morphological operation of dilation and is equivalent to the shrinking (or reduction) of the image set A by a structuring element B. It is a generalisation of shrinking as described in Sect. 14.3. Erosion is a morphological transformation which combines two sets using vector subtraction of set elements [6]. The erosion of an image set A by a structuring element B, denoted $A \ominus B$, can be represented as the intersection of the negative translates:

$$A \ominus B = \bigcap_{\mathrm{b}\in \mathrm{B}} \mathrm{A}_{-\mathrm{b}}$$

where ∩ represents the intersection of a set of points. Erosion of the image A by B is the set of all points for which B translated to a point x is contained in A. This consists of sliding the structuring element B across the image A, and where B is fully contained in A (by placing the origin of the structuring element at the point x) then x belongs to the eroded image $\mathrm{A} \ominus \mathrm{B}$. For example, in *Fig. 14.53* the image is eroded by a cross-shaped structuring element contained within a 3×3 pixel grid.

A duality relationship exists between certain morphological operators, such as erosion and dilation. This means that the equivalent of such an operation can be performed by its dual on the complement (negative) image and by taking the complement of the result [5].

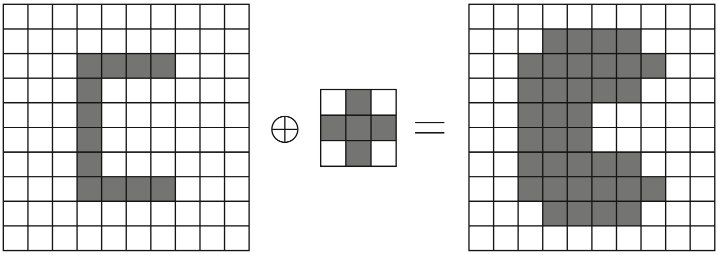

Fig. 14.52
Dilation of an image by a "cross" structuring element

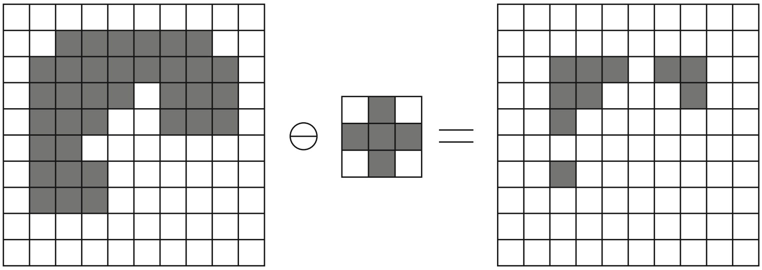

Fig. 14.53
Erosion of an image by a cross-shaped structuring element

Although duals, the erosion and dilation operations are not inverses of each other. Rather, they are related by the following duality relationships:

$$(A \ominus B)^C = A^C \oplus \bar{B} \qquad (A \oplus B)^C = A^C \ominus \bar{B}$$

where A^c refers to the complement of the image set *A* and

$$\bar{B} = \{x| \text{ for some } b \in B,\ x = -b\}$$

refers to the reflection of B about the origin. ([9] refers to this as the *transpose* of the structuring element.)

14.4.1 Opening and Closing Operations

Erosion and dilation tend to be used in pairs to extract or impose structure on an image. The most commonly found erosion-dilation pairings occur in the *opening* and *closing* transformations.

Opening is a combination of erosion and dilation operations that have the effect of removing isolated spots in the image set *A* that are smaller than the structuring element *B* and those sections of the image set *A* narrower than *B*. This is also viewed as a geometric *rounding* operation (➲ *Fig. 14.54*). The opening of the image set *A* by the structuring element B, is denoted $A \circ B$, and is defined as $(A \ominus B) \oplus B$.

Closing [cls] is the dual morphological operation of opening. This transformation has the effect of filling in holes and blocking narrow valleys in the image set *A*, when a structuring element *B* (of similar size to the holes and valleys) is applied. The closing of the image set *A* by the structuring element B is denoted $A \bullet B$, and is defined as $(A \oplus B) \ominus B$.

One important property that is shared by both the opening and closing operations is *idempotency*. This means that successful reapplication of the operations will not change the previously transformed image [5]. Therefore, $A \circ B = (A \circ B) \circ B$ and $A \bullet B = (A \bullet B) \bullet B$.

Unfortunately, the application of morphological techniques to industrial tasks, which involves complex operations on "real-world" images, can be difficult to implement. Practical imaging applications tend to have structuring elements that are unpredictable in shape and size. In practice, the ability to manipulate arbitrary structuring elements usually relies on their decomposition into component parts.

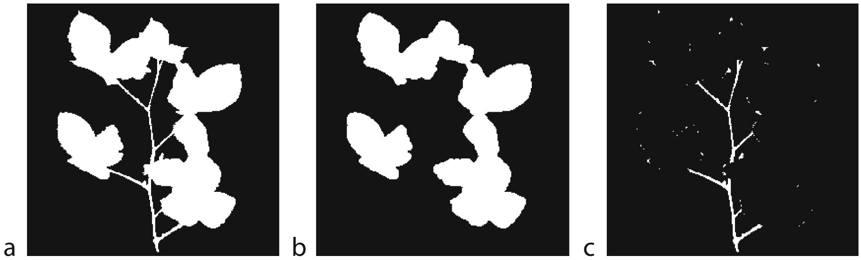

Fig. 14.54
Binary opening. (a) Original image (small plant). (b) Opening. [*ero(5), dil(5)*] (c) Exclusive OR of (a) and (b)

14.4.2 Structuring Element Decomposition

Some vision systems [3, 11, 12] can perform basic morphological operations very quickly in a parallel and/or pipelined manner. Implementations that involve such special purpose hardware tend to be expensive, although there are some notable exceptions [13]. Unfortunately, some of these systems impose restrictions on the shape and size of the structuring elements that can be handled. Therefore, one of the key problems involved in the application of morphological techniques to industrial image analysis is the generation and/or decomposition of large structuring elements. Two main strategies are used to tackle this problem.

The first technique is called *dilation* or *serial decomposition*. This decomposes certain large structuring elements into a sequence of successive erosion and dilation operations, each step operating on the preceding result. Unfortunately, the serial decomposition of large structuring elements into smaller ones is not always possible. Furthermore, those decompositions that are possible are not always easy to identify and implement.

If a large structuring element *B* can be decomposed into a chain of dilation operations, $B = B_1 \oplus B_2 \oplus \cdots \oplus B_N$ (➔ *Fig. 14.55*), then the dilation of the image set *A* by *B* is given by

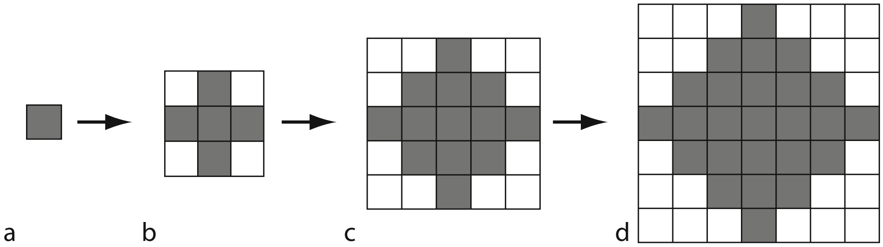
$$A \oplus B = A \oplus (B_1 \oplus B_2 \oplus \cdots \oplus B_N) = (((A \oplus B_1) \oplus B_2) \cdots) \oplus B_N.$$

Similarly, using the so-called chain rule [16], which states that $A \ominus (B \oplus C) = (A \ominus B) \ominus C$, the erosion of *A* by *B* is given by

$$A \ominus\ B = A \ominus\ (B_1 \oplus B_2 \oplus \cdots \oplus B_N) = (((A \ominus B_1) \ominus B_2) \cdots) \ominus B_N.$$

A second approach to the decomposition problem is based on "breaking up" the structuring element, B, into a union of smaller components, $B_1,\ldots, B_N$. We can think of this approach as "tiling" of the structuring element by sub-structuring elements (➔ *Fig. 14.56*). Since the "tiles" do not need to be contiguous or aligned, any shape can be specified without the need for serial decomposition of the structuring element, although the computational cost of this approach is proportional to the area of the structuring element [12]. This is referred to as *union* or *parallel decomposition*. Therefore, with B decomposed into a union of smaller structuring elements, $B = B_1 \cup B_2 \cup \cdots \cup B_N$, then the dilation of an image A by the structuring element B can be rewritten as

$$A \oplus B = A \oplus (B_1 \cup B_2 \cup \cdots \cup B_N) = (A \oplus B_1) \cup (A \oplus B_2) \cup \cdots \cup (A \oplus B_N).$$



■ **Fig. 14.55**

Construction of a 7×7 structuring element by successive dilation of a 3×3 structuring element. (a) Initial pixel. (b) 3×3 structuring element and the result of the first dilation. (c) Result of the second dilation. (d) Result of the third dilation [12]

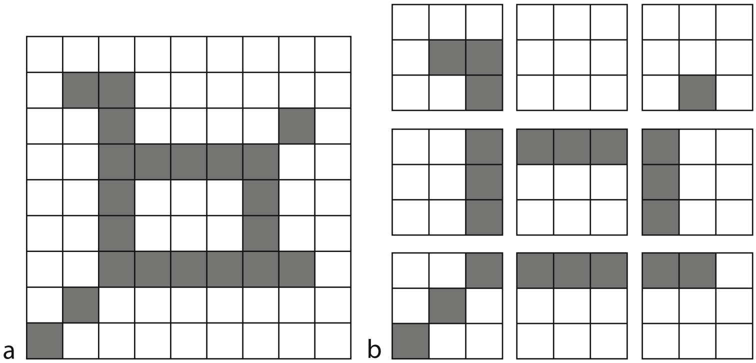


Fig. 14.56
Tiling of a 9×9 arbitrary structuring element. (a) The initial 9×9 structuring element. (b) Tiling with nine 3×3 sub-structuring elements [12]

Likewise, the erosion of *A* by the structuring element *B* can be rewritten as

$$A \ominus B = A \ominus (B_1 \cup B_2 \cup \cdots \cup B_N) = (A \ominus B_1) \cap (A \ominus B_2) \cap \cdots \cap (A \ominus B_N).$$

This makes use of the fact that $A \ominus (B \cup C) = (A \ominus B) \cap (A \ominus C)$ [5]. Due to the nature of this decomposition procedure, it is well suited to implementation on parallel computer architectures.

Waltz [12] compared these structural element decomposition techniques, and showed that the serial approach has a 9:4 speed advantage over its parallel equivalent. (This was based on an arbitrarily specified 9×9 pixel structuring element, when implemented on a commercially available vision system.) However, the parallel approach has a 9:4 advantage in the number of degrees of freedom. (Every possible 9×9 structuring element can be achieved with the *parallel decomposition*, but only a small subset can be realised with the serial approach.) Although slower than the serial approach, it has the advantage that there is no need for serial decomposition of the structuring element.

Classical parallel and serial methods mainly involve the numerous scanning of image pixels and are therefore inefficient when implemented on conventional computers. This is so because the number of scans depends on the total number of pixels (or edge pixels) in the shape to be processed by the morphological operator. Although the parallel approach is suited to some customised (parallel) architectures, the ability to implement such parallel approaches on *serial* machines is discussed by Vincent [14].

14.5 Grey Scale Morphology

Binary morphological operations can be extended naturally to process grey scale imagery by the use of neighbourhood minimum and maximum functions [5]. Heijmans [7] presents a detailed study of grey scale morphological operators, in which he outlines how binary morphological operators and thresholding techniques can be used to build a large class of useful grey scale morphological operators. Sternberg [11], discusses the application of such morphological techniques to industrial inspection tasks.

In ➋ *Fig. 14.57*, a one-dimensional morphological filter operates on an analogue signal (equivalent to a grey scale image). The input signal is represented by the thin curve and the output by the thick black curve. In this simple example, the structuring element has an approximately parabolic form. In order to calculate a value for the output signal, the structuring element is pushed upwards from below the input curve. The height of the top of the structuring element is noted. This process is then repeated by sliding the structuring element sideways. Notice how this particular operator attenuates the intensity peak but follows the input signal quite accurately everywhere else. Subtracting the output signal from the input would produce a result in which the intensity peak is emphasised and all other variations would be reduced.

The effect of the basic morphological operators on two-dimensional grey scale images can also be explained in these terms. Imagine the grey scale image as a landscape, in which each pixel can be viewed in 3-D. The extra height dimension represents the grey scale value of a pixel. We generate new images by passing the structuring element above/below this landscape (see ➋ *Fig. 14.57*).

Grey Scale Dilation This is computed as the maximum of translations of the grey surface. Grey level dilation of image *A* by the structuring element *B* produces an image *C* defined by

$$\mathrm{C(r,c) = MAX_{(i,j)}\{A(r-i,c-j)+B(i,j)\} = (A \oplus B)(r,c)}$$

where *A*, *B* and *C* are grey level images. Commonly used grey level structuring elements include rods, disks, cones and hemispheres. This operation is often used to smooth small negative-contrast grey level regions in an image. *[lnb]* is an example of a dilation operator (➋ *Fig. 14.22*).

Grey Scale Erosion The grey value of the erosion at any point is the *maximum* value for which the structuring element centred at that point, still fits entirely within the foreground under the surface. This is computed by taking the *minimum* of the grey surface translated by all the points of the structuring element. Grey level erosion of image *A* by the structuring element *B* produces an image *C* defined by

$$\mathrm{C(r,c) = MIN_{(i,j)}\{A(r+i,c+j)-B(i,j)\} = (A\emptyset}B\mathrm{)(r,c)}$$

This operation is commonly used to smooth small positive-contrast grey level regions in an image. [*snb*] is an example of an erosion operator.

Grey Scale Opening This operation is defined as the grey level erosion of the image followed by the grey level dilation of the eroded image. That is, it will cut down the peaks in the grey level topography to the highest level for which the elements fit under the surface.

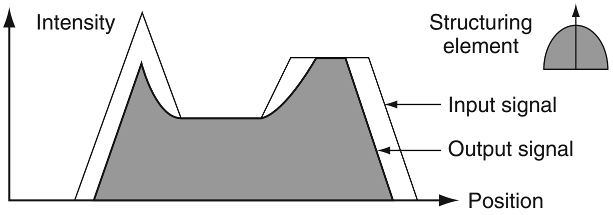

Fig. 14.57
A one-dimensional morphological filter eroding an analogue signal

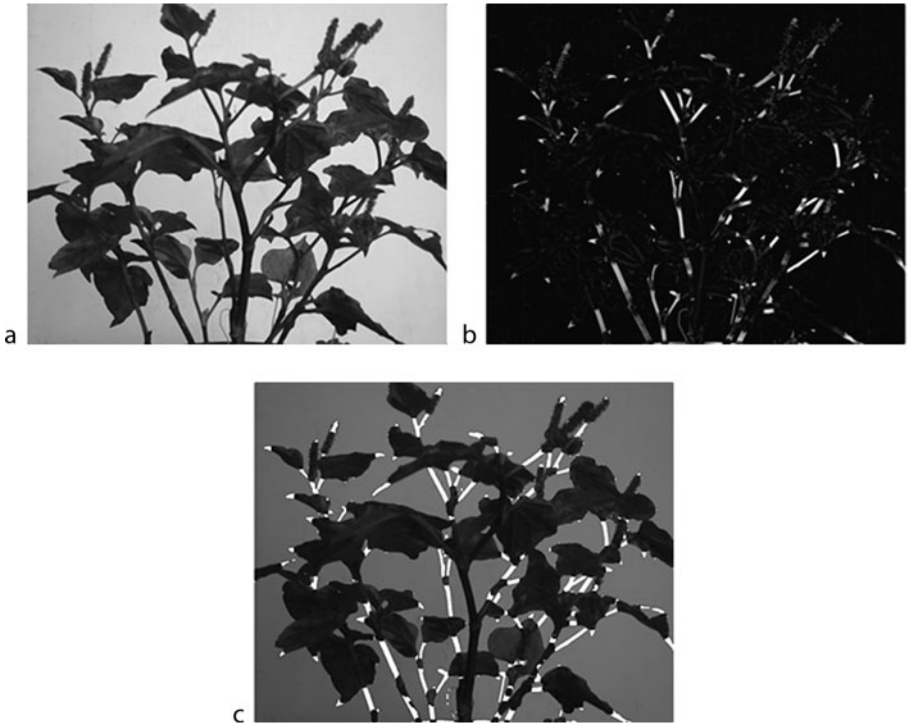

Fig. 14.58

Grey-scale closing. (a) Original image. (b) Result of closing. The structuring element was a disc of uniform height and diameter 13 pixels. [*crk(7)*] (c) Image in (b) thresholded and superimposed on the original. Notice that the operator is highly selective for size and detects thin "linear" features (stems) and the triangular tips of large wedge-like objects (leaves)

Grey Scale Closing (*Fig. 14.58*) This operation is defined as the grey level dilation of the image followed by the grey level erosion of the dilated image. Closing fills in the valleys to the maximum level for which the element fails to fit above the surface. For a more detailed discussion on binary and grey scale mathematical morphology, see Haralick and Shapiro [6] and Dougherty [2]. The crack detector [*crk/1*] is an example of a closing operator (*Fig. 14.25*).

14.6 Global Image Transforms

An important class of image processing operators is characterised by an equation of the form **B** ⇐ f(**A**), where **A** = {a(i,j)} and **B** = {b(p,q)}. Each element in the output picture **B** is calculated using all or at least a large proportion of the pixels in **A**. The output image **B** may well look quite different from the input image **A**. Examples of this class of operators are *lateral shift, rotation, warping, Cartesian-to-Polar co-ordinate conversion, Fourier transform*, and *Hough transform.*

Integrate Intensities Along Image Rows (➲ *Fig. 14.59*) *[rin]* This operator is rarely of great value when used on its own, but can be used with other operators to good effect, for example detecting horizontal streaks and edges. The operator is defined recursively:

$$b(i,j) \Leftarrow b(i,j-1) + (a(i,j)/n) \text{ where } b(0,0) = 0.$$

Row Maximum (➲ *Fig. 14.60*) *[rox]* This function is often used to detect local intensity minima.

Geometric Transforms Algorithms exist by which images can be shifted [*psh* and *psw*], rotated [*tur*], magnified [*pex* and *psq*] and warped (Figs. 14.61 and 14.62) [*ctp* and *ptc*]. The reader should note that certain operations, such as rotating a digital image, can cause some difficulties because pixels in the input image are not mapped exactly to pixels in the output image. This can cause smooth edges to appear stepped. To avoid this effect, interpolation may be used, but this has the unfortunate effect of blurring edges. (See [BAT91a] for more details.)

The utility of axis transformations is evident when we are confronted with the examination of circular objects, or those displaying a series of concentric arcs, or streaks radiating from a fixed point. Inspecting such objects is often made very much easier, if we first convert from

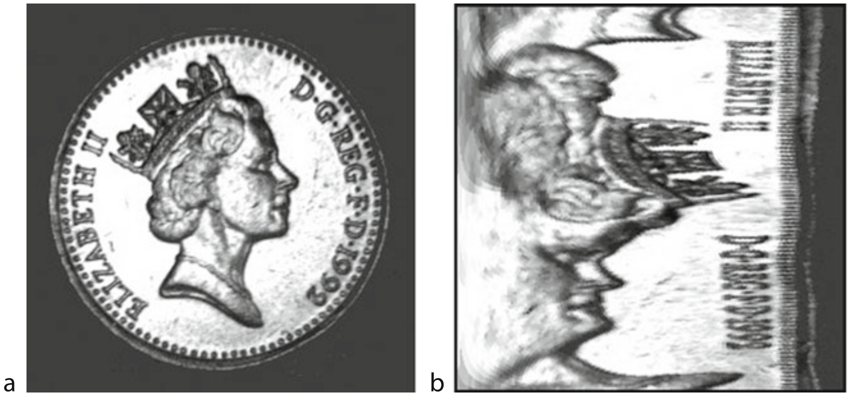

Fig. 14.61

Cartesian to *Polar* co-ordinates (➲ *Fig. 14.61*). Warping is also useful in a variety of situations. For example, it is possible to compensate for *barrel* or *pin-cushion* distortion in a camera. Geometric distortions introduced by a wide-angle lens, or trapezoidal distortion due to viewing the scene from an oblique angle, can also be corrected. Another possibility is to convert simple curves of known shape into straight lines, in order to make subsequent analysis easier.

14.6.1 Hough Transform

The Hough transform provides a powerful and robust technique for detecting lines, circles, ellipses, parabolas, and other curves of pre-defined shape, in a binary image. Let us begin our discussion of this fascinating topic by describing the simplest version, the basic Hough Transform, which is intended to detect straight lines. Actually, our objective is to locate *nearly linear* arrangements of disconnected white spots and "*broken*" *lines.* Consider that a straight line in the input image is defined by the equation $r = x\ \mathrm{Cos}\ \phi + y\ \mathrm{Sin}\ \phi$, where r and ϕ are two unknown parameters whose values are to be found. Clearly, if this line intersects the point (x_i, y_i), then $r = x_i\ \mathrm{Cos}\ \phi + y\ \mathrm{Sin}\ \phi$ can be solved for many different values of (r, ϕ). So, each white point (x_i, y_i) in the input image may be associated with a *set* of (r, ϕ) values. Actually, this set of points forms a *sinusoidal curve* in (r, ϕ) space. The latter is called the *Hough Transform (HT)* image. Since each point in the input image generates such a sinusoidal curve, the whole of that image creates a multitude of overlapping sinusoids in the resulting HT image. In many instances, a large number of sinusoidal curves are found to converge on the same spot in the HT image. The (r, ϕ) address of such a point indicates the slope ϕ and position r of a straight line that can be drawn through a large number of white spots in the input image.

The implementation of the Hough transform for line detection begins by using a two-dimensional accumulator array, $A(r, \phi)$, to represent quantised (r, ϕ) space. (Clearly, an important choice to be made is the step size for quantising r and ϕ. However, we will not dwell on such details here.) Assuming that all the elements of $A(r, \phi)$ are initialised to zero, the Hough Transform is found by computing a set $S(x_i, y_i)$ of (r, ϕ) pairs satisfying the equation $r = x_i\ \mathrm{Cos}\phi + y_i\ \mathrm{Sin}\ \phi$. Then, for all (r, ϕ) in $S(x_i, y_i)$, we increment $A(r, \phi)$ by one. This process is then repeated for all values of i such that the point (x_i, y_i) in the input image is white. We repeat that bright spots in the HT image indicate "linear" sets of spots in the input image. Thus, line detection is transformed to the rather simpler task of finding local maxima in the accumulator array $A(r, \phi)$. The co-ordinates (r, ϕ) of such a local maximum give the parameters of the equation of the corresponding line in the input image. The HT image can be displayed, processed, and analysed just like any other image, using the operators that are now familiar to us.

The robustness of the HT techniques arises from the fact that, if part of the line is missing, the corresponding peak in the HT image is simply not quite so bright. This occurs because fewer sinusoidal curves converge on that spot and the corresponding accumulator cell is incremented less often. However, unless the line is almost completely obliterated, this new darker spot can also be detected. In practice, we find that "nearly straight lines" are transformed into a *cluster* of points, with a spreading of the intensity peaks in the HT image, due to noise and quantisation effects. In this event, to calculate the parameters of the straight line in the input image we threshold the HT image and then find the centroid of the resulting spot. Pitas [8] gives a more detailed description of this algorithm. ➲ *Figure 14.63* illustrates how this approach can be used to find a line in a noisy binary image.

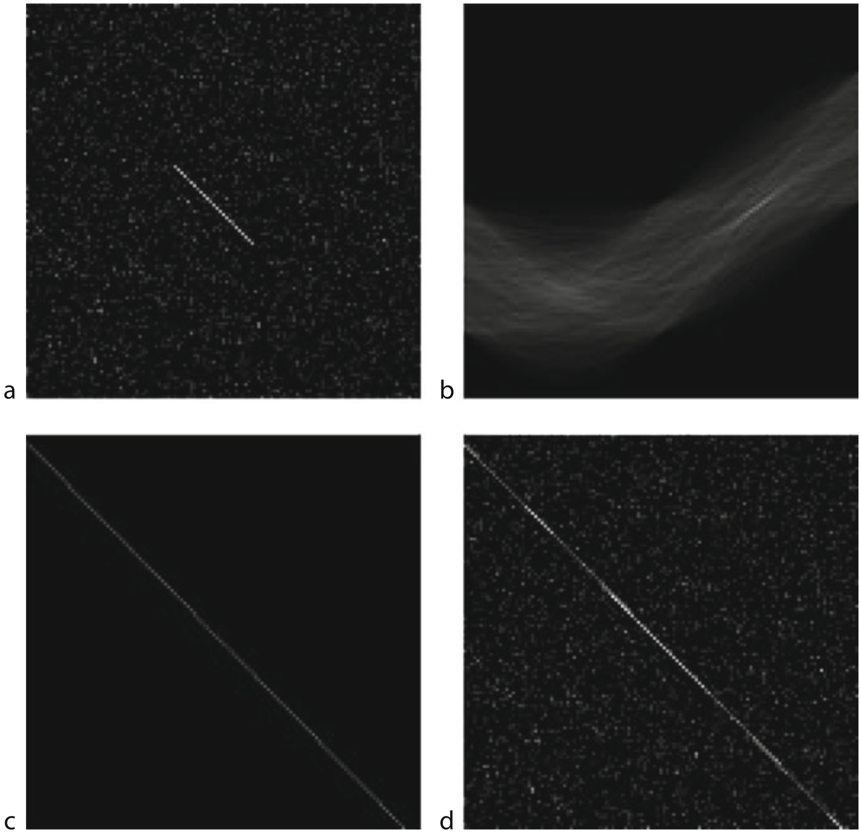

Fig. 14.63

Hough transform. (a) Original image. (b) Hough transform. (c) Inverse Hough applied to a single white pixel located at the point of maximum intensity in (b). (d) Inverse transform superimposed on original image. Notice how accurately this process locates the line in the input image, despite the presence of a high level of noise

The Hough transform can also be generalised to detect groups of points lying on a curve. In practice, this may not be a trivial task, since the complexity increases very rapidly with the number of parameters needed to define the curve. For circle detection, we define a circle parametrically as: $r^2 = (x - a)^2 + (y - b)^2$ where (a, b) determines the co-ordinates of the centre of the circle and r is its radius. This requires a *three-dimensional* parameter space, which, of course, cannot be represented and processed as a single image. For an arbitrary curve, with no simple equation to describe its boundary, a look-up table is used to define the relationship between the boundary coordinates, an orientation, and the Hough transform parameters. (See [10] for more details.)

14.6.2 Two-Dimensional Discrete Fourier Transform

We have just seen how the transformation of an image into a different domain can sometimes make the analysis task easier. Another important operation to which this remark applies is the

Fourier Transform. Since we are discussing the processing of images, we will discuss the *two-dimensional Discrete Fourier Transform (DFT)*. This operation allows spatial periodicities in the intensity within an image to be investigated, in order to find, among other features, the dominant frequencies. The two-dimensional DFT of an N×N image f(x,y) is defined as follows:

$$F(u,v) = \frac{1}{N} \cdot \sum_{x=0}^{N-1} \sum_{y=0}^{N-1} f(x,y) \exp[-i2\pi(ux+vy)/N] \quad \text{where } 0 \leq u,v \leq N-1.$$

The inverse transform of F(u,v) is defined as

$$f(x,y) = \frac{1}{N} \cdot \sum_{u=0}^{N-1} \sum_{v=0}^{N-1} F(u,v)) \exp[i2\pi(ux+vy)/N] \quad \text{where } 0 \leq x,y \leq N-1.$$

Several algorithms have been developed to calculate the two-dimensional DFT. The simplest makes use of the fact that this is a *separable* transform, which therefore can be computed as a sequence of two one-dimensional transforms. Thus, we can generate the two-dimensional transform by calculating the one-dimensional Discrete Fourier Transform along the image rows and then repeating this on the resulting image but, this time, operating on the columns. This reduces the computational overhead when compared to direct two-dimensional implementations. The sequence of operations is as follows:

$$f(x,y) \rightarrow \text{Row Transform} \rightarrow F_1(x,v) \rightarrow \text{Column Transform} \rightarrow F_2(u,v)$$

Although this is still computationally slow compared to many other shape measurements, the Fourier transform is quite powerful. It allows the input to be represented in the frequency domain, which can be displayed as a *pair* of images. (It is not possible to represent both amplitude and phase using a single monochrome image.) Once the frequency domain processing is complete, the inverse transform can be used to generate a new image in the original, so-called, *spatial* domain.

The Fourier power spectrum, or amplitude spectrum, plays an important role in image processing and analysis. This can be displayed, processed, and analysed as an intensity image. Since the Fourier transform of a real function produces a complex function:

$$F(u,v) = R(u,v) + iI(u,v)$$

the frequency spectrum of the image is the magnitude function

$$|F(u,v)| = \sqrt{[R^2(u,v) + I^2(u,v)]}$$

and the power spectrum (spectral density) is defined as

$$P(u,v) = |F(u,v)|^2.$$

➋ *Figure 14.64* illustrates how certain textured features can be highlighted using the two-dimensional Discrete Fourier Transform. The image is transformed into the frequency domain and an ideal band-pass filter (with a circular symmetry) is applied. This has the effect of limiting the frequency information in the image. When the inverse transform is calculated, the resultant textured image has a different frequency content, which can then be analysed. For more details on the Fourier transform and its implementations, see [8].

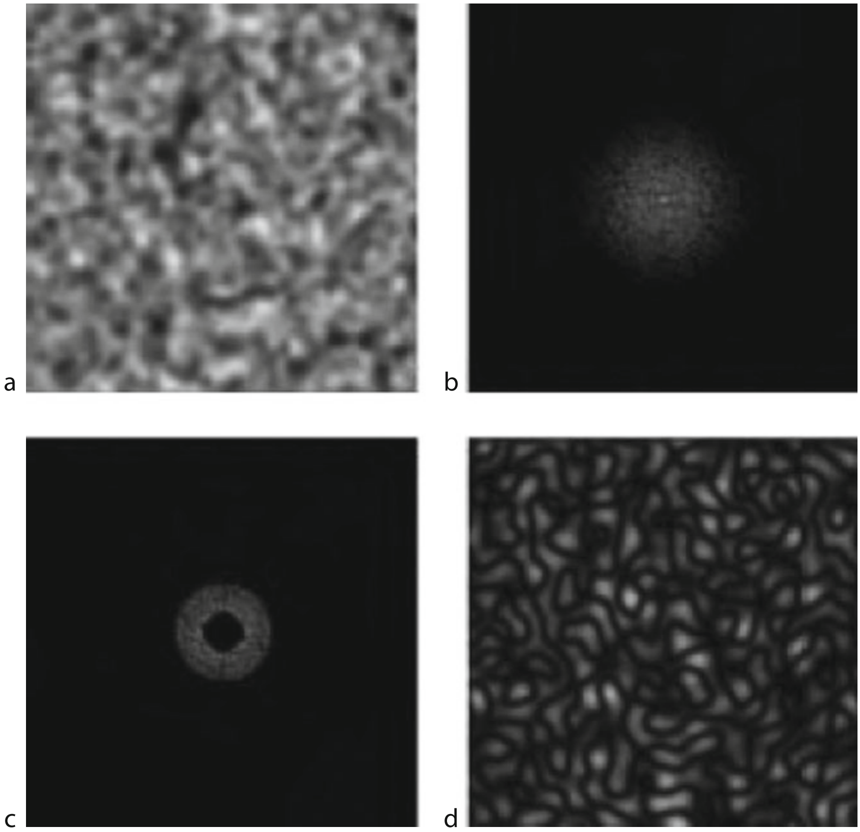

Fig. 14.64
Filtering a textured image in the frequency domain. (a) Original textured image. (b) Resultant transformed image after using the two-dimensional DFT. (The image is the frequency spectrum shown as an intensity function.) (c) Resultant frequency domain image after an ideal band-pass filter is applied to image. (d) The resultant spatial domain image after the inverse two-dimensional discrete Fourier transform is applied to the band-pass filtered image in (c)

14.7 Texture Analysis

Texture is observed in the patterns of a wide variety of synthetic and natural surfaces (e.g., wood, metal, paint and textiles). If an area of a textured image has a large intensity variation, then the dominant feature of that area would be *texture*. If this area has little variation in intensity, then the dominant feature within the area is *tone*. This is known as the *tone-texture concept*. Although a precise formal definition of texture does not exist, it may be described subjectively using terms such as *coarse, fine, smooth, granulated, rippled, regular, irregular*, and *linear*. These features are used extensively in manual region segmentation. There are two main classification techniques for texture: *statistical* and *structural*.

14.7.1 Statistical Approaches

The statistical approach is well suited to the analysis and classification of random or natural textures. A number of different techniques have been developed to describe and analyse such textures [4], a few of which are outlined below.

14.7.1.1 Auto-Correlation Function (ACF)

Auto-correlation derives information about the basic 2-dimensional tonal pattern that is repeated to yield a given periodic texture. The auto-correlation function A(δx,δy) of an image matrix [I(i,j)] is defined as follows:

$$A(\delta x, \delta y) = \left(\sum_{i,j} [(I(i,j))(I(i+\delta x, j+\delta y))]\right) \Big/ \left(\sum_{i,j} [I(i,j)]^2\right)$$

Although useful at times, the ACF has severe limitations. It cannot always distinguish between textures, since many subjectively-different textures have the same ACF. The variables (i, j) are restricted to lie within a specified window outside which the intensity is zero. Incremental shifts of the image are given by (δx,δy). It is worth noting that the ACF and the power spectral density are Fourier transforms of each other.

14.7.1.2 Fourier Spectral Analysis

The Fourier spectrum is well suited to describing the directionality and period of repeated texture patterns, since they give rise to high energy narrow peaks in the power spectrum (see ➲ Sect. 14.6.2 and ➲ *Fig. 14.64*). Typical Fourier descriptors of the power spectrum include *the location of the highest peak, mean, variance*, and *the difference in frequency between the mean and the highest value of the spectrum*. This approach to texture analysis is often used in aerial/ satellite and medical image analysis. The main disadvantage of this approach is that the procedures are not invariant, even under monotonic transforms of its intensity.

14.7.1.3 Edge Density

This is a simple technique in which an edge detector or high pass filter is applied to the textured image. The result is then thresholded and the edge density is measured by the average number of edge pixels per unit area. Two-dimensional or directional filters/edge detectors may be used, as appropriate.

14.7.1.4 Histogram Features

This useful approach to texture analysis is based on the intensity histogram of all or part of an image. Common histogram features include *moments, entropy dispersion, mean* (an estimate of the average intensity level), *variance* (this second moment is a measure of the dispersion of the region intensity), *mean square value* or *average energy, skewness* (the third moment which gives an indication of the histograms symmetry), and *kurtosis* (cluster prominence or "peakness"). For example, a narrow histogram indicates a low contrast region, while two peaks with a well-defined valley between them indicates a region that can readily be separated by simple thresholding.

Texture analysis based solely on the grey scale histogram suffers from the limitation that it provides no information about the *relative position* of pixels to each other. Consider two binary images, where each image has 50% black and 50% white pixels. One of the images might be a checkerboard pattern, while the second one may consist of a salt and pepper noise pattern. These images generate exactly the same grey level histogram. Therefore, we cannot distinguish them using first order (histogram) statistics alone. This leads us naturally to the examination of the co-occurrence approach to texture measurement.

14.7.2 Co-occurrence Matrix Approach

The co-occurrence matrix technique is based on the study of *second-order grey level spatial dependency statistics*. This involves the study of the grey level spatial interdependence of pixels and their spatial distribution in a local area. Second order statistics describe the way grey levels tend to occur together, in pairs, and therefore provide a description of the type of texture present. A *two-dimensional* histogram of the spatial dependency of the various grey level picture elements within a textured image is created. While this technique is quite powerful, it does not describe the shape of the primitive patterns making up the given texture.

The co-occurrence matrix is based on the estimation of the second order joint conditional probability density function, *f(p,q,d,a)*. This is the probability of going from one pixel with grey level *p* to another with grey level *q*, given that the distance between them is *d* and the direction of travel between them is given by the angle *a*. (For an image with N_g grey levels, the size of the co-occurrence matrix will be $N_g \times N_g$.) For example, assuming the intensity distribution shown in the sub-image given below, we can generate the co-occurrence matrix for *d = 1* and *a* is taken as 0 degrees.

2	3	3	3
1	1	0	0
1	1	0	0
0	0	2	2
2	2	3	3

Sub-image with 4 grey-levels.

Grey scale	0	1	2	3
0	6	2	1	0
1	2	4	0	0
2	1	0	4	2
3	0	0	2	6

Co-occurrence matrix {f(p,q,1,0)} for the sub-image.

A co-occurrence distribution that changes rapidly with distance *d* indicates a fine texture. Since the co-occurrence matrix also depends on the image intensity range, it is common practice to normalise the grey scale of the textured image prior to generating the co-occurrence matrix. This ensures that first-order statistics have standard values and avoids confusing the effects of first- and second-order statistics of the image.

A number of texture measures (also referred to as texture attributes) have been developed to describe the co-occurrence matrix numerically and allow meaningful comparisons between various textures [4] (see Fig. 14.65). Although these attributes are computationally intensive, they are simple to implement. Some sample texture attributes for the co-occurrence matrix are given below.

Energy, or angular second moment, is a measure of the homogeneity of a texture. It is defined thus:

$$\text{Energy} = \sum_p \sum_q [f(p, q, d, a)]^2$$

In a uniform image, the co-occurrence matrix will have few entries of large magnitude. In this case the *Energy* attribute will be large.

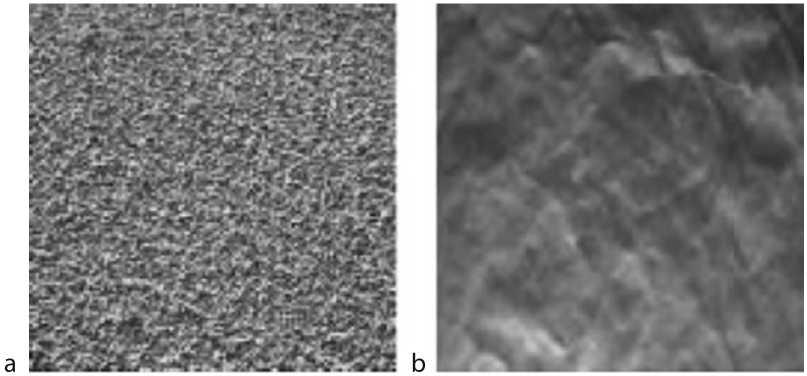
Entropy is a measure of the complexity of a texture and is defined thus:

$$\text{Entropy} = -\sum_p \sum_q [f(p, q, d, a) \log(f(p, q, d, a))]$$

It is commonly found that what a person judges to be a complex image tends to have a higher *Entropy* value than a simple one.

Inertia is the measurement of the moment of inertia of the co-occurrence matrix about its main diagonal. This is also referred as the *contrast* of the textured image. This attribute gives an indication of the amount of local variation of intensity present in an image.

$$\text{Inertia} = \sum_p \sum_q \left[(p - q)^2 f(p, q, d, a)\right]$$



c

	Sand	Sand	Paper	Paper
	f(p,q,1,0)	f(p,q,1,90)	f(p,q,1,0)	f(p,q,1,90)

Inertia ($\times 10^8$)	5.4	6.5	0.181	0.304

Fig. 14.65
Co-occurrence based texture analysis. (a) Sand texture. (b) Paper texture. (c) Texture attributes

14.7.3 Structural Approaches

Certain textures are deterministic in that they consist of identical *texels* (basic texture element), which are placed in a repeating pattern according to some well-defined but unknown placement rules. To begin the analysis, a texel is isolated by identifying a group of pixels having certain invariant properties, which repeat in the given image. A texel may be defined by its *grey level, shape*, or *homogeneity of some local property*, such as size or orientation. Texel spatial relationships may be expressed in terms of *adjacency, closest distance*, and *periodicities.*

This approach has a similarity to language; with both image elements and grammar, we can generate a syntactic model. A texture is labelled *strong* if it is defined by deterministic placement rules, while a *weak* texture is one in which the texels are placed at random. Measures for placement rules include *edge density, run lengths of maximally connected pixels*, and the *number of pixels per unit area* showing grey levels that are locally maxima or minima relative to their neighbours.

14.7.4 Morphological Texture Analysis

Textural properties can be obtained from the erosion process (➋ Sects. 14.4 and ➋ 14.5) by appropriately parameterising the structuring element and determining the number of elements of the erosion as a function of the parameters value [2]. The number of white pixels of the morphological opening operation as a function of the size parameter of the structuring element **H** can determine the size distribution of the *grains* in an image. Granularity of the image **F** is defined as

$$G(d) = 1 - (\#[F \bigcirc H_d]/\#F)$$

where $\mathbf{H}_d$ is a disk structuring element of diameter *d* or a line structuring element of length *d*, and #F is the number of elements in **F**. This measures the proportion of pixels participating in grains smaller than *d*.

14.8 Further Remarks

The image processing operators described in this chapter have all found widespread use in industrial vision systems. It should be understood that they are always used in combination with one another. Other areas of application for image processing may well use additional algorithms to good effect. Very often, these can be formulated in terms of the procedures described above, and implemented as a sequence of QT commands. Two key features of industrial image processing systems are the cost and speed of the target system (i.e., the one installed in a factory). It is common practice to use a more versatile and slower system for problem analysis and prototyping, whereas the target system must continue to operate in an extremely hostile environment. (It may be hot, greasy, wet, and/or dusty.) It must also be tolerant of abuse and neglect. As far as possible, the target system should be self-calibrating and able to verify that it is “seeing” appropriate images. It should provide enough information to ensure that the factory personnel are able to trust it; no machine system should be built that is a viewed by the workers as a mysterious black box. Consideration of these factors is as much a part of the design process as writing the image processing software.

In many industry applications, the image processing tools with input images in 2-D format may find themselves lacking the power of dimensional measurement in a space that has to deal with a third dimension. For an example of typical pick-and-place process on a manufacturing line, a robot tries to grab an unpolished engine block from a bin and the robot controller should give the guidance to the robot arm so that the orientation of the engine block is input to the robot arm prior to its movement. In such a scenario, range information of the engine block, or the depth in the *Z*-direction, should be part of the input images. The conventional imaging methods for capturing and analyzing grayscale images are inadequate for this type of application.

Range imaging deals with *Z*-directional data. When many call it 3-D, it is in fact 2.5-D, since we cannot get image data on the negative *Z*-direction; therefore, it is more pertinent to call it range imaging. There are several techniques that are found to be valid approaches to get range images. In this chapter, we introduce two imaging devices that produce 3-D images and applications using these imaging devices for industry automation.

15.1 Imaging Devices

In range image data collection, the pixel information within an image consists at least of the relative distances from a sensor to imaged points on objects. A conventional means to do so is to derive the range data by processing images acquired with structured light, triangulation or stereo pairs. These image acquisition methods employ industry-standard CCD cameras and require strict lighting environment and are limited to geometric properties of imaged objects.

The laser radar technology provides another valid tool for acquiring range image data [1–3]. A typical approach uses a modulated laser beam and collects the phase differentials between light source (laser) and collected infrared signal to postulate relative distance of surface geometry. With this approach, a classical design methodology employs a point-of-light, collecting point by point the imaged object to form pixel by pixel in a range image [4–10]. The modulating frequency determines the ambiguity distance, which is typically a fraction of actual distance from sensor to object. When the distance is required, additional measuring has to be performed with other means.

The laser radar imaging has been developed over the past few decades, and the scannerless laser radar was developed in the early 1990s. Just a few years after the invention of the laser, workers at Hughes Aircraft demonstrated the first application of pulse lasers for distance measurement. By photographically recording oscilloscope traces of the output pulse from a ruby laser and its subsequent echo from the remote target, they were able to measure the distance to the target. Now over 30 years later, laser rangefinder technology has matured, and a variety of instruments are commercially available. For many applications, however, the state of the art in laser rangefinders is still relatively primitive: data acquisition rates are too slow for the three-dimensional (3-D) imaging required for industrial applications, and the equipment is often too delicate and bulky for many applications.

The principle of CW radar, as illustrated in ➋ *Fig. 15.1*, relies on the measurement of the phase difference between an intensity-modulated probe beam and its return from the target. The range to the target, *R*, is calculated from

$$R = \frac{c\phi}{4\pi f_m} \tag{15.1}$$

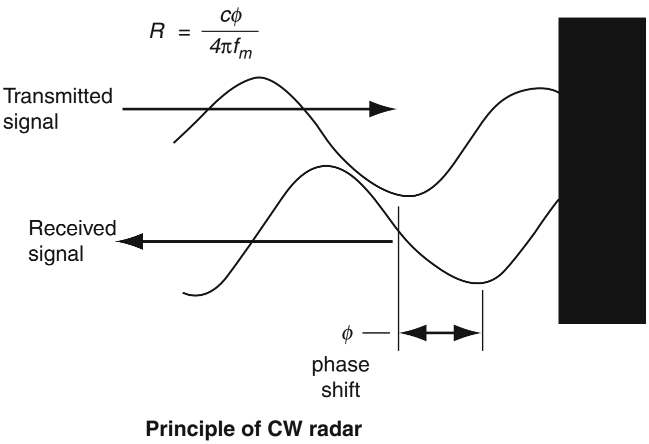

Fig. 15.1
Continuous wave (CW) laser radar works by measuring the relative phase shift between a transmitted modulated signal and the signal received after reflection from the object of interest. The range to the target, *R*, is calculated from $R = c\phi/4\pi f_m$, where *c* is speed of light, ϕ is the round-trip phase shift, and f_m is the modulation frequency

where *c* is the speed of light, ϕ is the round-trip phase shift and f_m is the modulation frequency. In a CW radar (or laser radar), the range resolution is limited by the resolution to which the relative phase shift of the return signal can be measured.

15.1.1 Scanning Based Laser Radar Imaging

A classical approach to the scanning based laser radar imaging is typical of radar application. The lighting source, or active lighting, is from a laser source. This laser source is typically designed using infrared lasers. Infrared lasers work well within the near infrared spectrum, and the key issue of eye safety has been addressed for many years, and the technology has improved, so that the issue is no longer a major concern.

In continuous-beam laser sensors, a continuous-beam laser is used rather than a pulsed one. The phase shift in the return signal is used to measure the distance. A range image is generated by scanning the laser beam horizontally and vertically across the scene. A representative laser radar system is illustrated in *Fig. 15.2*. The principle of image acquisition works as follows. A laser beam is sent out onto faceted polygon and is then reflected onto a nodding mirror. The mirror reflects the beam to the targeted object, as shown in direction *Z* in *Fig. 15.2*. The imaging object is within the viewing scope of area on the mirror. When the laser beam returned from the object is received at the mirror, it is transmitted to the sensor and then to the demodulation processor. The laser beam is modulated on a continued amplitude of a sinusoidal wave with a consistent frequency. The phase shift is compared and interpreted as the geometrical differentiation pixel by pixel on the received image grids, and such phase shift parameters are then translated into the range information.

The mechanism of range imaging is illustrated in ➲ *Fig. 15.2*. The laser source produces a laser beam that is projected onto faceted rotating mirror. Within a fraction of a millisecond, it reflects the incoming beam, r_1, onto a nodding mirror, as in r_2. The nodding mirror projects the beam r_3 toward the object. The light beam r_2 acts similar to a scanning line of TV frame. The nodding mirror moves through an angle, β, which determines the viewing range vertically. The scanning angle, α, determines the viewing range horizontally. The nodding mirror will be in initial position after the beam r_3 travels up and down, limited by the viewing angle range, thus completing a frame of imaging procedure.

The range image is therefore referenced as a 3-D image with X-Y as the imaging plane, as shown in ➲ *Fig. 15.3*, when the range of a single point at (i, j) is inferred through intensity modulation on a continued waveform, as indicated by (➲ 15.2)–(➲ 15.12).

Each pixel in the range image, denoted by $r(i, j)$, $0 \leq i < R(\text{rows})$ and $0 \leq j < C$ (columns), is converted to Cartesian coordinates as follows:

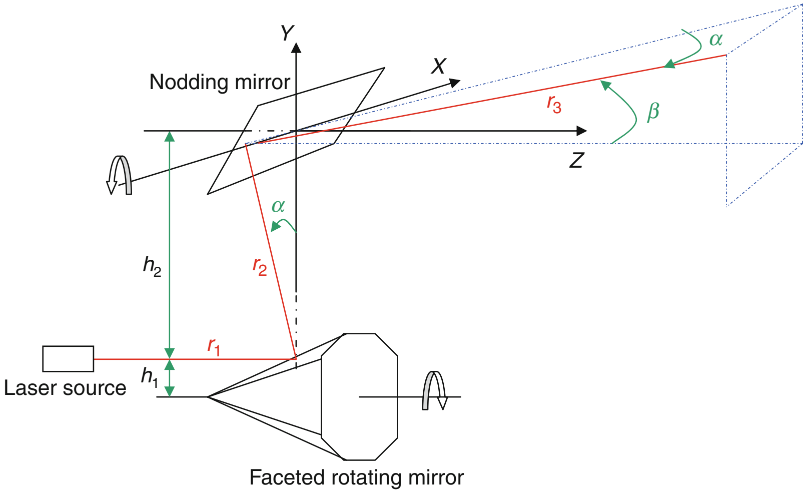

Fig. 15.2
Illustration of range image data acquisition using continuous scanning laser technology

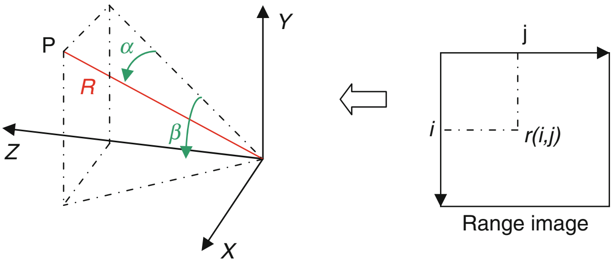

Fig. 15.3
Illustration of range image in 3-D imaging space and on imaging plane in X-Y

$$x(i,j) = dx + r_3 .\, \sin\alpha \tag{15.2}$$

$$y(i,j) = dy + r_3 .\, \cos\alpha .\, \sin\beta \tag{15.3}$$

$$z(i,j) = dz + r_3 .\, \cos\alpha .\, \cos\beta \tag{15.4}$$

$$r_1 = (dx - h_2)/\,\delta \tag{15.5}$$

$$r_2 = \left(\sqrt{(dx)^2 + (h_2 + dy)^2}\right) \Big/ \delta \tag{15.6}$$

$$r_3 = (r\,(i,\,j) + r_0 - (r_1 + r_2)).\,\delta \tag{15.7}$$

$$\beta = \frac{\left(\frac{R-1}{2} - i\right)}{R}.V \tag{15.8}$$

$$\alpha = \frac{\left(\frac{C-1}{2} - j\right)}{C}.\,H \tag{15.9}$$

$$dx = (h_2 + dy).\ \tan\alpha \tag{15.10}$$

$$dy = dz.\tan\left(\theta + \frac{\beta}{2}\right) \tag{15.11}$$

$$dz = -h_1\,.\,(1 - cos\,\alpha)\,/\,tan\,\gamma \tag{15.12}$$

In (➲ 15.8) and (➲ 15.9), H and V, respectively, represent the horizontal and vertical fields of view; r_0 the standoff distance (length of the laser beam at the point where $r = 0$); γ the slope of the facets of the rotating mirror with respect to the z-axis; and θ the angle of the nodding mirror with respect to the z-axis when $\beta = 0$.

➲ *Figure 15.4* shows a pair of images. The left is similar to the conventional intensity image, where on the right is its corresponding range image. In the range image, the brightness represents the closeness of the object surface points to the sensor; therefore, the range is defined, which is further inferred into Z-direction measure.

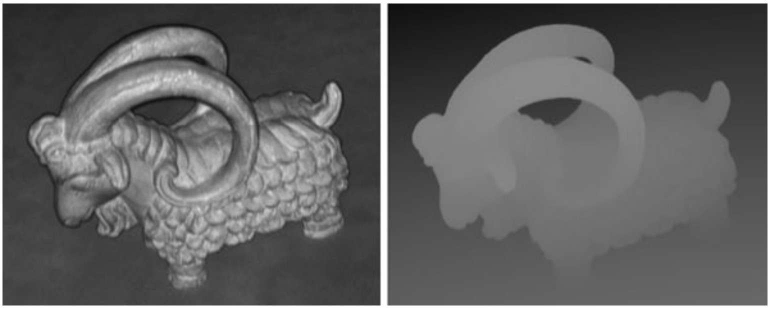

Fig. 15.4
On the *left* is an intensity image, and on the *right* is its corresponding range image

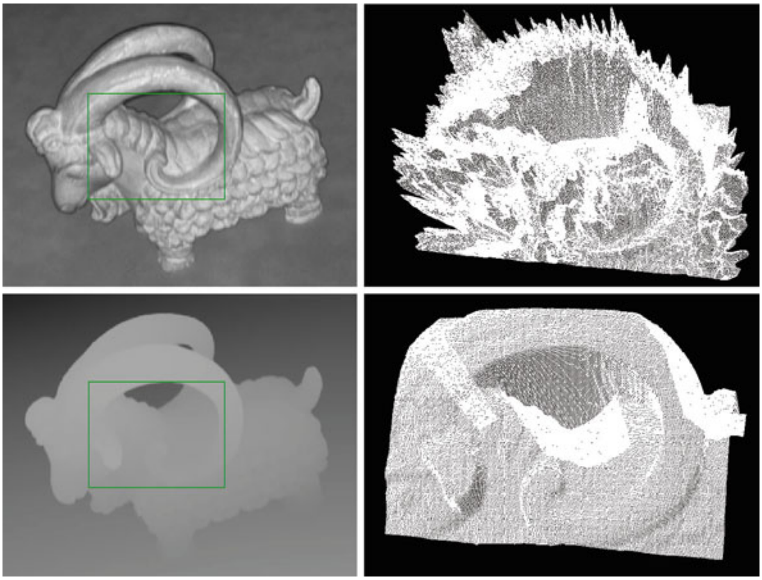

Fig. 15.5

On the *top* row, the region of interest in the status is within the squared, and its corresponding intensity is plotted with a wireframe as shown on its *right*. On the *bottom* row, the region of interest in the range image (*left*) is plotted in the *right*

To further illustrate the difference between two images in *Fig. 15.5*, we use the plots to enhance the views of these two images. On the top row, the region of interest in the status is within the squared, and its corresponding intensity is plotted with a wireframe as shown its right. On the bottom row, the region of interest in the range image (left) is plotted in the right. It is clear that the range image has the representation of the *Z*-direction range where the intensity image is meaningful to human perception but its data representation is rather much less meaningful. *Figure 15.6* shows another illustrative pair of images that are used for testing pick-and-place operations on manufacturing assembly lines (*Fig. 15.6*).

15.1.2 Scannerless Laser Radar Imaging

Shown schematically in *Fig. 15.7*, the scannerless laser radar illuminates the entire field of view at once with sinusoidally intensity-modulated laser light. Light scattered from the scene is collected by a lens and imaged onto a microchannel plate image intensifier tube. The gain of the image intensifier is modulated synchronously with, and at the same frequency as, the laser illuminator, and the optical output of the modulated image intensifier tube is then integrated and recorded by a two-dimensional (2-D) charge-coupled device (CCD) detector. Each pixel in the CCD contains information about the phase shift (and thus the range) to its image point in the scene. The net result is a phase-sensitive detector that operates on an entire image at once instead of scanning and sequentially measuring the phase shift to each pixel in the image.

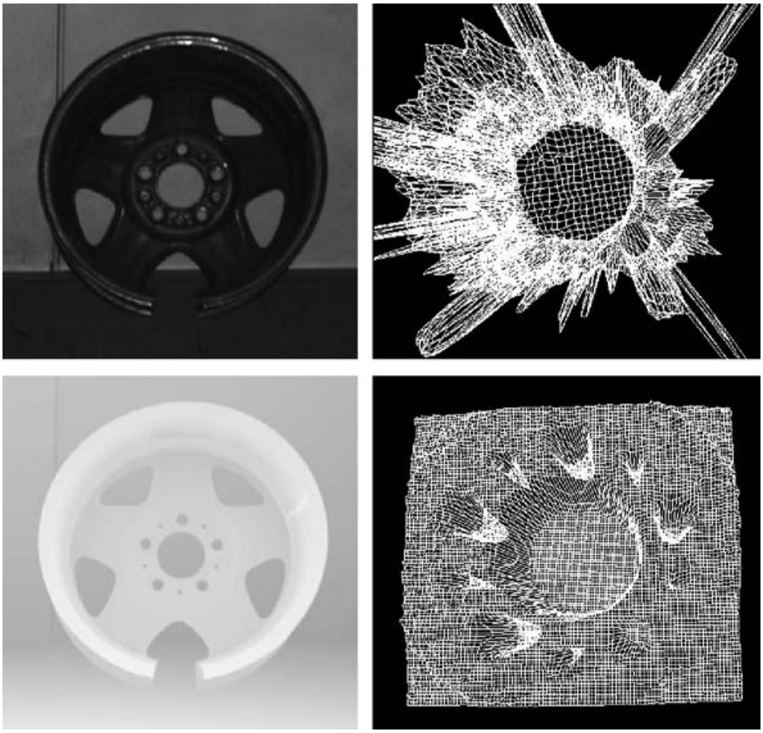

Fig. 15.6
On the *top* row, the region of interest in the *left* intensity image is plotted in wireframe at the *right*. On the *bottom* row, the region of interest in the range image (*left*) is plotted in the *right*

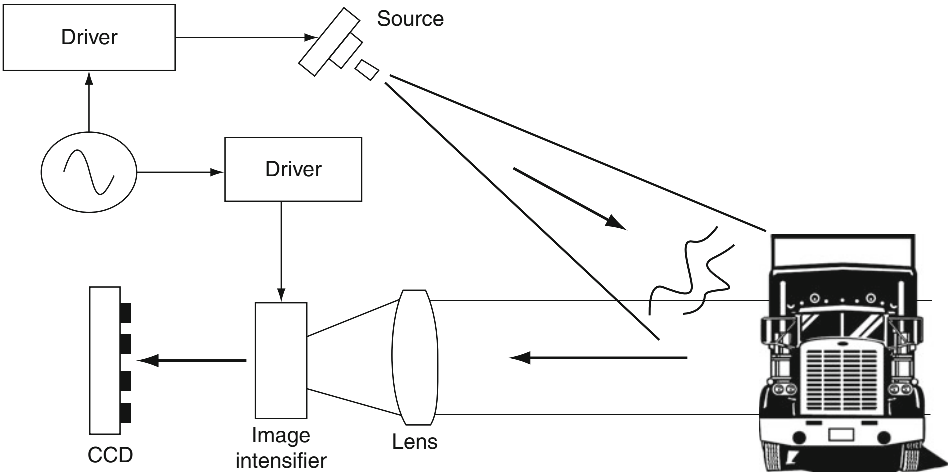

Fig. 15.7

15.1.2.1 Theory of Operation

Continuous wave (CW) rangefinders work by measuring the phase difference between an intensity-modulated transmitted laser beam and its return from the target. As shown in *Fig. 15.1*, the spatial wavelength, λ, of the sinusoidally modulated beam is given by

$$\lambda = \frac{c}{f_m} \tag{15.13}$$

where c is the speed of light and f_m is the modulation frequency. The light travels from the transmitter to the target, and some of the light is backscattered by the target and collected by the receiver optics. In its round trip to the target and back, the light acquires a phase shift relative to the transmitted beam of

$$\phi = \frac{4\pi f_m R}{c} \tag{15.14}$$

where R is the distance (range) to the target. In order to measure the range to the target, the CW rangefinder measures the relative phase shift, ϕ, and computes the range using the equation

$$R = \frac{c\phi}{4\pi f_m} \tag{15.15}$$

Since relative phase is a periodic function (with period 2π), ranges that produce round-trip phase shifts of $\phi \geq 2\pi$ are not distinguishable from ranges with phase shifts $\phi - 2\pi$. Thus, with a CW rangefinder, one must ensure that the modulation frequency is selected to produce unambiguous range measurements for the expected maximum range interval. In CW radar, it is common to define an ambiguity interval, R_{amb}. This is the range interval over which the round-trip phase delay will be $\phi \leq 2\pi$, and distance measurements will be unambiguous. R_{amb} is given by

$$R_{\text{amb}} = \frac{c}{2f_m} = \frac{\lambda}{2} \tag{15.16}$$

The theorem within the scannerless laser radar imaging can be expressed in the following equations and illustrated with *Fig. 15.8*. The signal flows are as follows:

$$P_t = P_o[1 + m_l \sin(\omega t)] \tag{15.17}$$

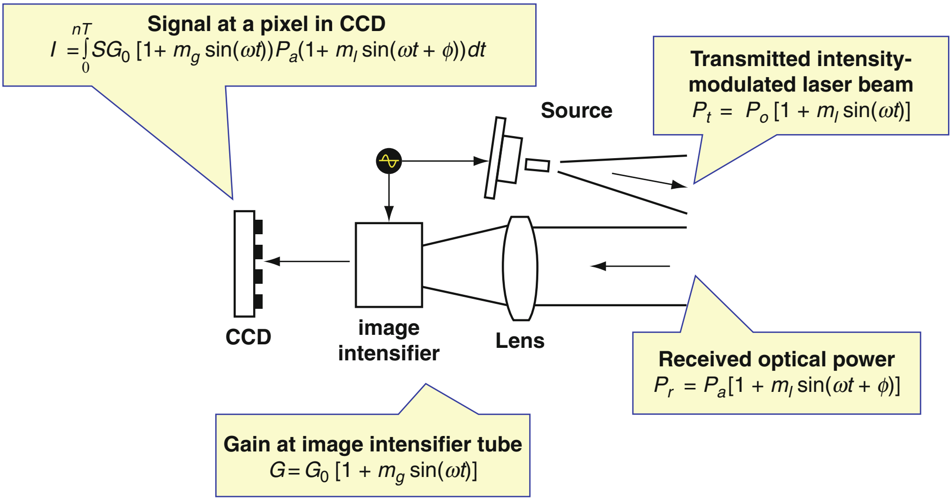
$$P_r = P_a[1 + m_l \sin(\omega t + \phi)] \tag{15.18}$$

$$G = G_0[1 + m_g \sin(\omega t)] \tag{15.19}$$

$$I = \int_0^{nT} SG_0(1 + m_g \sin(\omega t))P_a(1 + m_l \sin(\omega t + \phi))dt \tag{15.20}$$

and the output signal at the detector is

$$I = nTSG_0P_a(1 + \frac{1}{2}m_g m_l \cos(\phi)) \tag{15.21}$$



Signal at a pixel in CCD

15.2 Machine Vision Application Using 3-D Imaging

Machine vision is an important subject within the machine intelligence systems area. The goal of a computer vision system is to understand the given image data and use the extracted information for a high-level task. Typical application tasks include (1) the assembly or inspection of manufacturing parts, (2) the navigation of autonomous vehicles and (3) the analysis of microscopic images [1]. Identifying and locating a specified object in the scene is one of the most important goals within these tasks. The general problem of identifying the desired object is referred to as *object recognition*.

For an ideal computer vision system, the objects in the following cases should be located: (1) objects may have arbitrary and complicated shapes, (2) objects may be viewed from various directions and (3) objects may be partially occluded by other objects in a scene. Specially, in a manufacturing environment, such a machine vision system can be used in determining the location of grasp sites for a robot to manipulate for an object in the assembly or inspection of parts.

To realize such vision systems, system designers must resolve the following issues: (1) the type of sensor for data collection, (2) the methods of describing the collected data and the object and (3) the methods of matching the object descriptions obtained from the input data to the desired object model. The sensor determines the resolution and precision. More importantly, it determines whether the data provides 2-D or 3-D information of the scene. Object representations are used to describe the collected data and the desired object model. Also, the descriptions are used to calculate the various properties of objects in the scene during the matching stage. Matching strategies are performed for real-time online processes and must resolve many ambiguities between the input data and the model descriptions. Once the match has been established, the orientation and location information of the target object can be computed for further robot tasks.

In this section, the basic issues and corresponding methods in 3-D object recognition are discussed in detail. For an automated assembly application, a 3-D object pose estimation method is developed using range images as the input data. The local surface geometrical feature is described by a 3-D surface descriptor, Angle Distance Map (ADM). A triangular mesh model of the 3-D object surface is used for decreasing the cost of computing and storage of applying the ADM descriptions. The principal component analysis (PCA) method is applied on the original ADM description to extract the principal features for matching strategies. The pose information is computed according to the final 3-D feature points. The proposed approach is tested in an application for flexible robot assembly. The experimental results show that accurate pose estimation can be obtained for the 3-D computer vision applications.

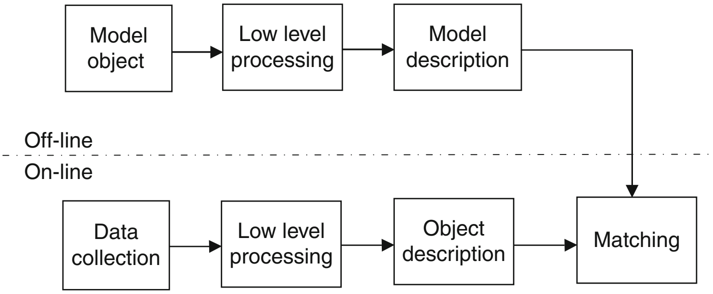
15.2.1 Computer Vision System

The basic issues involved in the design of a computer vision system are outlined in the introduction section. ➋ *Figure 15.9* shows a general paradigm of a computer vision system. The system includes online and offline processes. In an offline process, a description of a standard object is established as the model object. In an online process, the input data are represented by the same description method that is used in the offline process. The input object description and the model description are then compared in the matching stage. The located object and its pose information are used for further applications.

15.2.2 Low-Level Processes

For the specified high-level processes, the collected range images must be represented using symbolic descriptions. The first step is the partitioning of the input images based on the nature of the input data and the high-level processes. Also, since the ideal vision system must be able to recognize arbitrarily shaped objects from any view direction, the contour information for 3-D object recognition is very important. Segmentation and edge detection are the primary low-level processes in 3-D object recognition.

Range scanners sample points on the object surface. Therefore, the surface properties, such as surface normal and surface curvature, are used to obtain the segmentation and edge detection. Since the distance measurement made by the laser sensors is often inaccurate



■ **Fig. 15.9**
A general paradigm in computer vision

due to detection noise, quantization and calibration errors, the original range data should be smoothed. Most noise processes have been modelled as additive Gaussian stochastic processes independent of the scene. In range image processing, most researchers have adapted noise reduction methods developed from intensity images [5]. The methods of segmentation and edge detection for range images are discussed in this section.

Segmentation is an assignment of pixels into one of many disjoint sets such that the pixels in each set share a common property. Segmentation has been most often used in range image analysis and recognition as it helps partition an image array into low-level entities. In general, segmentation methods for range images are classified into two categories. One is based on region features, and the other is based on edge information.

In range image processing, unlike traditional 2-D intensity image processing, there are three primary types of edges in 3-D range images. These types of edges are step edge, which is discontinuous in depth value, roof edge, which is discontinuous in surface normals, and curvature edge that is discontinuous in a variety of surface normals. Since the roof and curvature edges do not correspond to depth discontinuity, the edge detection in range images is more complicated than in traditional intensity images.

There have been a number of research reports on edge detection in range images [11]. To extract all of the three types of edges in range images, the edge detection methods are divided into two classes. In the first class of methods, different operators or algorithms are applied to extract different types of edges. A merging process is then used to obtain final edge results.

15.2.3 3-D Object Description

Design of an appropriate surface representation scheme is a crucial factor for 3-D object recognition. Armen and Aggarwal [11] and Besl and Jain [12] made comprehensive surveys of 3-D object representation schemes and recognition strategies. Both locally and globally based representations, such as points or groups of points, straight line segmentations and polylines, planar and quadric surface patches, constructive surface geometry and superquadrics, have been proposed to describe a 3-D object surface.

Bolle and Vemuri utilized the Extended Gaussian Image (EGI) to describe 3-D objects in terms of their surface normal distributions on the unit sphere [13]. This type of global surface representation handles convex polyhedra efficiently, but for arbitrarily curved objects, they are either approximated by planar patches or divided into regions based on their Gaussian curvature. Besl and Jain proposed their representation method for quadric surfaces [14]. The Gaussian and Mean curvature information is used to classify the quadric surface types. These quadric surface–based representations may not adequately illustrate some objects with complicated surface forms. Superquadrics are an extension of the basic quadric surfaces and solids [15]. Several parameters of the superquadric function are used to determine the object's squareness, size, bending, tapering and twisting. Minimization techniques are used to recover the parameters from a set of data [16, 17]. 3-D objects with superquadric surfaces can be described accurately using the superquadric surface model. The occlusion problem can be solved using the model.

A free-form surface is defined to be a smooth surface, such that the surface normal is well defined and continuous almost everywhere, except at vertices, edges and cusps. It is not constrained to be polyhedral, piecewise quadric or superquadric. Most vision researchers have proposed both global and local structural descriptions based on local unconstrained geometrical features to represent free-form surfaces. Dorai and Jain proposed a representation scheme for free-form objects based on COSMOS (Curvedness-Orientation-Shape Map On Sphere) [18]. In their approach, an object is represented in terms of maximal surface patches of constant shape index. The maximal patches are mapped onto the unit sphere according to their orientations and shape spectral functions. This representation yields a meaningful and rich description for object recognition. A further analysis is needed for the object surfaces with rapidly changed shape indices. For the objects with some complex surface shapes, some comprehensive methods are also needed to analyse the angle features extracted by tripod operators. A 3-D surface descriptor, or a spin image, has been proposed by Johnson and Hebert [19]. A spin image is a data level descriptor used to match the surfaces which are represented by surface meshes. For a 3-D point on an object surface, the 3-D surface descriptor is generated by accumulating two projection distances between this point and its neighbourhood points. A robust performance is demonstrated in the presence of clutters and occlusions in a 3-D object recognition system.

15.2.4 Matching and Pose Estimation

Once the appropriate descriptions are derived from the range images, the 3-D computer vision system is able to match the two descriptions for completing the task of object recognition. This is performed in two steps. In the first step, a correspondence is established between the two sets of descriptions. For some partial occlusion cases, only partial descriptions of objects can be obtained. The matching strategy should be able to establish the correspondence between the partial description of the object and its full model description. The calculation of correlative coefficient is used to match the simple descriptions, such as feature vectors. For more complicated descriptions, such as symbolic geometrical features, some matching strategies, such as tree search, attributed graphs and triplet methods, are applied to match the two descriptions. In the second step, using the established correspondence, a geometrical transformation is derived. The 3-D orientation information of the object in the scene is then estimated according to the geometrical transformation.

Object pose estimation is an important application in 3-D object recognition. There are two primary approaches to obtain pose estimation. They are a feature-based approach and a model-parameter-based approach. In feature-based approaches, pose information is directly computed from the derived features corresponding to model features. The method by Sim and Dudek utilizes image-domain landmarks as the features for pose estimation [20]. Each landmark is detected as a local extremum of a measure of uniqueness and represented by an appearance-based encoding. Pose estimation is obtained through matching the observed landmarks to the learned prototypes. Burtnyk and Greenspan proposed a signature search method for 3-D pose refinement [21]. This approach generates a synthetic signature of what the camera would see if the object were in its currently assumed pose, and then proceeds to search for this signature in the actual data. It extracts a footprint signature from the model and performs a simple search through the data for the best match. The main difficulties in these feature-based approaches are feature extraction and correspondence specification for object pose estimation.

In model-parameter-based approaches, first a parametric object model is obtained from raw data. Pose information is computed from the model parameters. Stark and Fuchs defined a 3-D object model with six degrees of freedom in their pose estimation approach [22]. An active contour model utilizing Kalman filter is used to efficiently track the object silhouette.

The 3-D pose tracker uses the results of the contour tracker. The tracking results for polyhedral objects were presented. Although not based on geometry, a recent technique called parametric eigenspace has been proposed to project a large set of data of an object into the eigenspace using principal component analysis (PCA). Crowley and Schiele proposed a robot position estimation approach based on PCA of range data [23]. The structure of an environment is represented as a family of surfaces in the constructed eigenspace. Subsequent range data sets from the environment project as a point in this space. This representation converts the problem of associating range profiles to possible poses into a table lookup. Pose information is selected from the candidate poses using a Kalman filter.

In 3-D image processing, low-level processing, object description and matching methods are the most important tasks for 3-D object recognition. There have been a lot of approaches developed for these tasks. The selection of various methods is decided by the requirements of 3-D computer vision applications. The field knowledge of the applications is also applied in the three primary tasks to build the 3-D computer vision system.

15.3 Industry Application Example Using 3-D Imaging

In this section, a 3-D object pose estimation method is developed for guiding flexible robots on an automated assembly line. Accurate pose information, including the position and orientation of torque converters, is needed to guide a robot to grab a target torque converter. A laser camera is mounted on top of the working cell. ➲ *Figure 15.10* shows the work field and a grasping example of the automated assembly application.

➲ *Figure 15.11a, b* show, respectively, the intensity image and its corresponding range image. There are five torque converters laid in a bin, as shown in ➲ *Fig. 15.11*. In this assembly application, the objects, torque converters, are stacked in a bin of four layers. Using the range images, the developed 3-D object pose estimation method provides the orientation and position information of each torque converter. The framework includes two stages: (1) Segmenting each torque converter and locating the centre positions of torque converters, (2) Determining the orientation of the located torque converters. A diagram of the integrated 3-D pose estimation method is shown in ➲ *Fig. 15.12*.

15.3.1 Low-Level Processing

The goal of this 3-D computer vision system is to obtain the pose information for each torque converter in the stack. Therefore, the tasks in low-level processing are the localization of the stack area and each torque converter inside the stack area from the input workcell range image. As discussed earlier, edge detection and segmentation approaches are applied on the original range images.

As shown in *Fig. 15.11b*, there are only step edges between the stack area and the background. A normal intensity-based edge detection method is used to extract the edge. *Figure 15.13a* shows the edge detection result of *Fig. 15.11b*. The stack area is a large rectangle area in the range images. Using this application knowledge, a Hough transform is applied to the detected edge results. The Hough transform is a traditional image processing algorithm to extract some geometrical shapes, such as line and circle. After the stack area is extracted, nine subareas are equally segmented for each torque converter. These subareas are applied as input for the orientation and position estimation methods. *Figure 15.13* shows the edge detection and segmentation results.

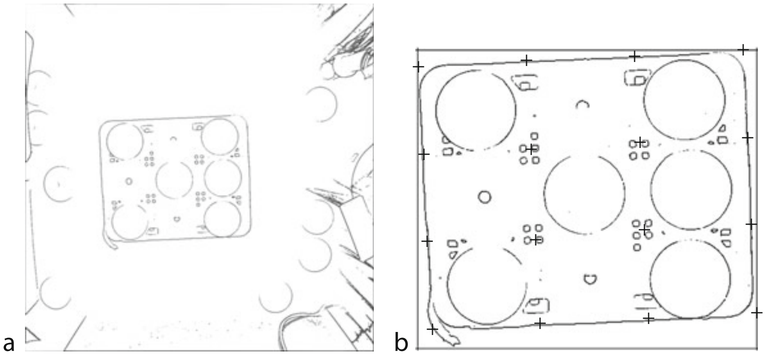

Fig. 15.13

Low-level processing of the 3-D computer vision system. (a) Edge detection result of the range image in Fig. 4b. (b) Extracted stack area and nine equally segmented subareas

15.3.2 3-D Surface Representation Using Angle Distance Map

In range images, surface shape is described by a dense collection of 3-D points. The 3-D points with their associated 3-D positions and surface normals are used as the fundamental components of our surface representation. An Angle Distance Map is a 3-D surface descriptor proposed to describe the local geometric features using global surface information. Using point *P* and neighbourhood point *Q*, as shown in *Fig. 15.14*, angle α between surface normals $\vec{n}_1$ and $\vec{n}_2$ of these two points and their 3-D distance *d* are the two parameters in the ADM descriptions (*Fig. 15.14*).

The ADM M_p of point *P* is defined as the function that projects its neighbourhood 3-D points to the 2-D coordinates corresponding to point *P*

$$M_P : R^3 \rightarrow R^2,\ M_P(Q) \rightarrow (\alpha,\ d) \tag{15.22}$$

If the coordinates of points *P* and *Q* are (x_1, y_1, z_1) and (x_2, y_2, z_2) and their surface normals are $(f_{x1}, f_{y1}, -1)$ and $(f_{x2}, f_{y2}, -1)$, angle parameter $\alpha$and distance parameter *d* are given by

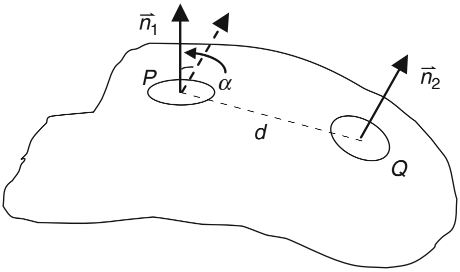

Fig. 15.14

A paradigm of angle and distance attributions used in ADM

$$\alpha = \arccos\left(\frac{f_{x1}f_{x2} + f_{y1}f_{y2} + 1}{\sqrt{f_{x1}^2 + f_{y1}^2 + 1}\sqrt{f_{x2}^2 + f_{y2}^2 + 1}}\right), \tag{15.23}$$

$$d = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2}. \tag{15.24}$$

In Angle Distance Map descriptions, the parameter α is an angle in degrees between 0 and 180. Parameter *d* is a 3-D distance in Cartesian coordinates. Normally the proposed ADM descriptions are square maps. The size of an ADM description is determined by the degree scale of parameter α. The distance area changes with different distance scales of parameter *d*.

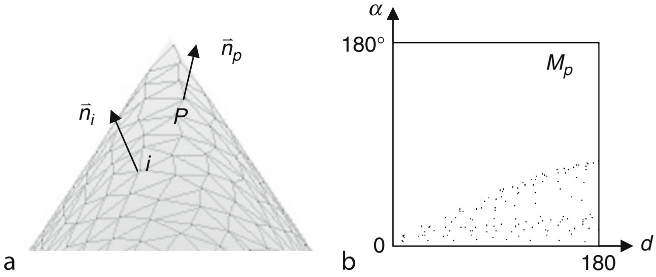
The ADM-based surface representation describes the geometric features of a 3-D point. For an object surface with dense collections of points, a triangular mesh model of the 3-D object is used to contain the computing complexity and the size of data representation of the ADM description. A triangular mesh is a piecewise linear surface, which consists of vertices, edges and faces. In this study, the vertices of the triangular meshes on an object surface are used to generate the ADM descriptions for the object surface representation.

➋ *Figure 15.15* shows an example of the ADM description of a point on a cone surface. As shown in ➋ *Fig. 15.15a*, for vertex *P* on the cone surface, ADM description M_p is obtained. The size of M_p is selected to be 180 × 180, and the scale of distance is selected to be one. The ADM description M_p is shown in ➋ *Fig. 15.15b*.

In the ADM-based surface description, each vertex has an ADM description. The surface geometric features are represented according to the distributions of ADM descriptions.

The ADM descriptions are compared using their correlation coefficients. Given two ADM descriptions M_p and M_q with a size of $N * N$, the linear correlation coefficient, $R\,(M_p, M_q)$, is given by

$$R(M_p,\ M_q) = \frac{N \times N \times \sum_i \sum_j p_{ij} q_{ij} - \sum_i \sum_j p_{ij} \sum_i \sum_j q_{ij}}{\sqrt{\left(N \times N \times \sum_i \sum_j p_{ij}^2 - \left(\sum_i \sum_j p_{ij}\right)^2\right)\left(N \times N \times \sum_i \sum_j q_{ij}^2 - \left(\sum_i \sum_j q_{ij}\right)^2\right)}} \tag{15.25}$$



■ **Fig. 15.15**
An ADM description example of a cone. (a) The range image and surface mesh of part of a cone; (b) the ADM description result of vertex *P*

Coefficient R is between -1 (anti-correlated) and 1 (completely correlated), and it provides a measure for comparing two ADM descriptions. The surface representation of ADM description is estimated through the correlation coefficient.

15.3.3 3-D Object Pose Estimation for Automated Assembly Application

In this automated assembly application, the 3-D orientation and position information of each torque converter is required for the robot system. The assembly application is illustrated in *Fig. 15.16* that shows the robot for pick and place operations and its test bed that is enclosed for eye safety issues. The red box on the top of the test bed is the range imaging device. *Figure 15.16b* shows the robot in action to move and angled-point to the object, a converter, to be picked and placed. From the top of the test bed, the range imaging device provides the vision function for the robot. The images, both intensity and range, are shown in *Fig. 15.16c*. The image processing in the vision system provides guidance data for the robot to move to a precise position and angled-aim to the tilted converter for picking and placing. In this 3-D object pose estimation method, the position and orientation information is computed using separate methods.

15.3.3.1 Centre Position Estimation

The contour of torque converters is a circle from the camera's view direction. The circle centre is used as the centre position of each torque converter. In the low-level processing, each torque converter is segmented within each sub-area. The Hough transform is applied to extract the circle shape within each sub-area. The centre position of the extracted circle is taken as the position of the torque converter. ➋ *Figure 15.17* shows the centre position results of ➋ *Fig. 15.13b*.

15.3.3.2 Orientation Estimation Using ADM Descriptions

The torque converters appear in different sizes and directions due to various levels and positions of stacks and the different orientations of torque converters themselves. ➋ *Figure 15.18* shows two examples. ➋ *Figure 15.18a, b* shows the intensity images with size of 130 × 130 and size of 105 × 106 pixels. The top circular region of a torque converter is a ring-shaped band, as illustrated in ➋ *Fig. 15.18a, b*. This ring-shaped band is an area identified as

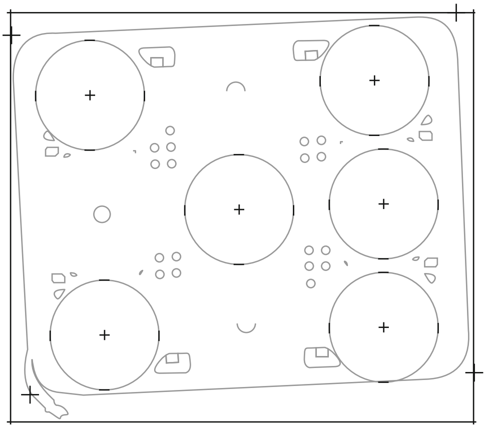

Fig. 15.17
Position estimation results of ➋ *Fig. 15.13b*

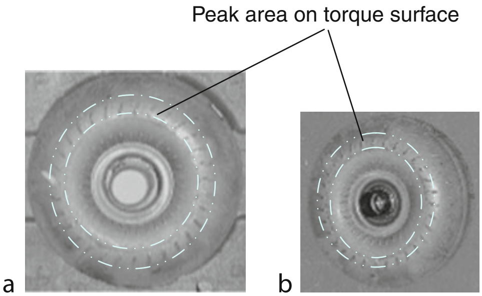

Fig. 15.18
Two torque examples and their peak areas. (a) Intensity image of example 1; (b) intensity image of example 2

a region that is most representative to the pose orientation of the object of interest. The surface normal direction of the tangent plane of the ring-shaped area is taken as the torque converter orientation.

In this orientation estimation approach, the proposed ADM descriptor is applied to represent the 3-D surface features. The correspondences between pairs of the features are obtained through the ADM descriptions. Since the ADM description is a local surface representation, the points belonging to the ring-shaped areas are extracted first. The tangent plane of the ring-shaped area is then generated through fitting the extracted feature points. Finally, pose information is estimated according to the surface normal of the extracted tangent plane.

For an efficient comparison between two original ADM descriptions, principle component analysis is applied to compress ADM descriptions. The PCA or the Karhunen-Loeve expansion provides a method to automatically determine a linear subspace with minimal number of dimensions. Such a representation is optimal in terms of the least-square error [13]. By using only the most important eigenvectors as defined by the corresponding eigenvalues, the dimension of the eigenspace is significantly reduced with a minimal loss in precision and reliability. This compression process greatly reduces computing complexity.

In this orientation estimation method, PCA is used to compress the original ADM descriptions consisting of all vertices on the object surface. Since the original ADM vectors are correlated, the Compressed ADM (CADM) descriptions are obtained through eliminating the eigenspace dimensions whose eigenvalues are relatively small. The projected CADM dimension, *s*, is determined according to the needed fidelity in reconstruction and the variance among ADM vectors.

The extracted subeigenspace constructed by *s* significant eigenvectors and the *s*-dimensional CADM vectors of model features is used to match the feature points in the pose estimation method.

As shown in *Fig. 15.19*, a general procedure of the 3-D object pose estimation is divided into two sections, the offline training and the online testing. In the offline training section, the feature points used to estimate orientation information are specified on the model object surface. The model object surface is first described in terms of the surface meshes. The ADM descriptions of mesh vertices are then obtained. The eigenspace of all ADM descriptions is constructed based

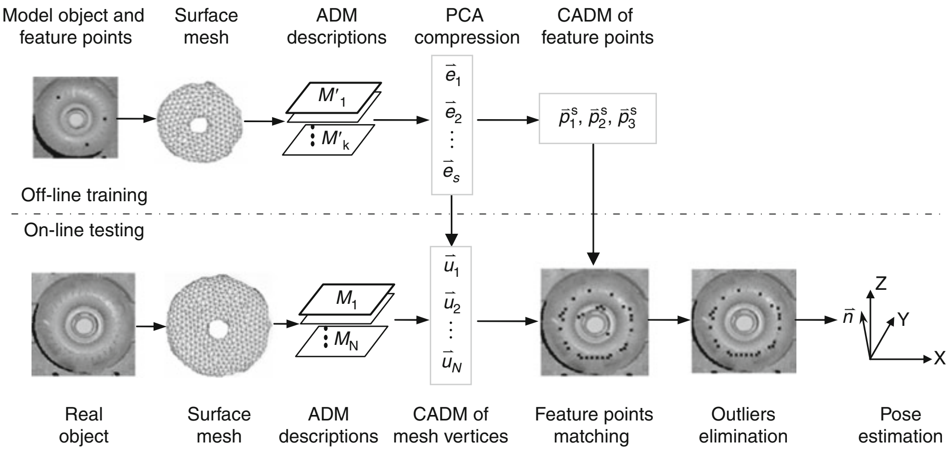

Fig. 15.19

A procedure of 3-D object pose estimation for an automated assembly application

on the PCA approach. According to the reconstruction accuracy and the variance among the ADM vectors, the CADM dimension s and corresponding s significant eigenvectors are generated. The CADM vectors of the specified feature points are then obtained by projecting the original ADM descriptions onto the subeigenspace constructed using the extracted s significant eigenvectors. The CADM vectors of the specified feature points and the s significant eigenvectors of the subeigenspace are the two components for the online testing process.

In the online testing section, the surface mesh representation for object surface is first generated. The ADM descriptions of the mesh vertices are then obtained. All ADM descriptions are projected into the subeigenspace using the s significant eigenvectors which are extracted during the offline training process. The projected CADM vectors are matched with the obtained CADM vectors of the specified feature points of the model object. The correspondences of the feature points are established by the maximal correlation coefficient between the training sampler and the testing objects.

Once the feature points are matched, the tangent plane of the ring-shaped area is estimated according to the least-square surface-fitting approach. Some points not belonging to the ring-shaped area are also extracted due to the sensor error or the difference between the model torque converter and the tested torque converter. Therefore, an iterative outlier elimination method is applied based on the 3-D projection distance between the points and the estimated tangent plane. For each elimination step, the point with the largest distance to the fitted tangent plane is found first. If the largest distance is also larger than a predefined threshold, the point is eliminated from the feature point set. This iterative process terminates only if no point is eliminated from the current feature point set. The tangent plane fitted by the final feature points is used to compute the orientation of torque converter.

15.3.4 Experiments and System

In this set of experiments, 45 torque converters placed in eight stacks with different positions and levels in a workcell are tested by the proposed orientation estimation approach. Ten torque converters with different positions and levels are used as model parts to obtain the pose information of all of the 45 torque converters. The orientation information of each torque converter is computed according to the Cartesian coordinates of range data. The errors between the computed accurate orientation and the estimated orientation of each torque converter are calculated to evaluate the accuracy of this approach. ➋ *Figure 15.20a* shows a one-level stack with five torque converters. A model torque converter with specified feature points is shown in ➋ *Fig. 15.20b*.

➋ *Figure 15.21* show the final matched feature points of the torque converters in ➋ *Fig. 15.21a* according to model part in ➋ *Fig. 15.21b*. The mean angle errors of these torque converters are shown in ➋ *Table 15.1*. The maximum mean angle error of these torque converters is 0.339°, and the minimum mean angle error is 0.020°.

For evaluating the proposed feature-based pose-determination approach, a general pose error E is defined to estimate the experimental results of all of the 45 torque converters obtained by 10 model torque converters. Let ε_{ij} represent the mean angle error of torque converter j obtained by model torque converter i. The estimation error E is computed by

$$E = \frac{1}{M \times N} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} \varepsilon_{ij}, \tag{15.26}$$

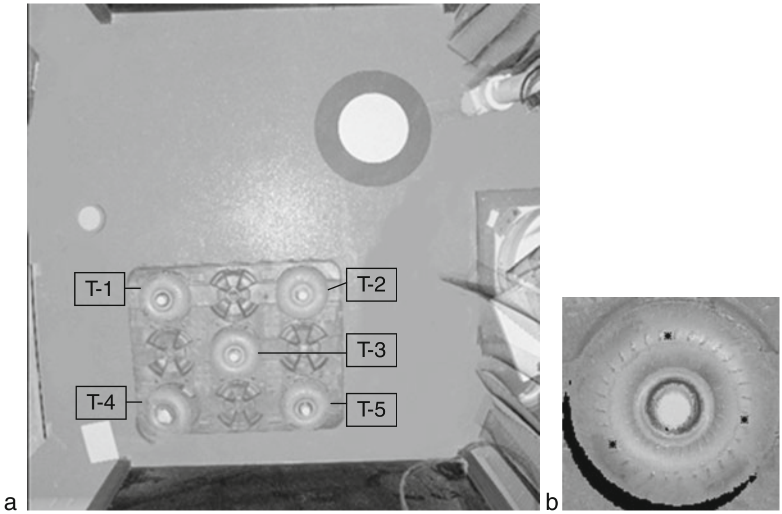

Fig. 15.20

Table 15.1

The mean angle errors (degree) of the torque converters in *Figure 15.21*

Torque converter	T2-1	T2-2	T2-3	T2-4	T2-5
Mean angle error (in degree)	0.020	0.339	0.245	0.297	0.078

where *M* and *N* are the number of model torque converters and test torque converters. In our experiments, the estimation error *E* is 0.263° for the 45 test torque converters and 10 model torque converters.

The experimental results show that 3-D surface features of a local point can be described well using the proposed ADM descriptions in range images. In this automated assembling application, the feature points used to determine the pose information are extracted according to the projected ADM descriptions. Accurate 3-D orientation information of automobile parts is obtained by fitting the feature plane based on the refined feature points.

Robots and machine vision systems are frequently an integral part of industrial automation. The combinations of industrial robots and machine vision systems are typically found in manufacturing process automation. The advent of robotic technology has warranted the strenuous requirement for pick-and-place operations, and they account for majority of repetitive manoeuvres in manufacturing processes. Combined robotic instrumentations with factory assembly controlling and monitoring are key to achieving high productivities in the industry that need less human interventions, such as semiconductor and electronics assembly. In manufacturing processes, particularly in the processes that need human intervention, the success rate is small. Such manufacturing processes can be found typically in automotive assembly lines. In these assembly processes, e.g., transmission parts assembly, the positions and orientations of the parts deviate, frequently, from the positions and orientations defined by the designed procedure. Therefore, an operation process without the control based on the real-time online feedback is not suitable. The real-time online process, such as a precision-feedback controlled and monitored process, requires the additional assistance from a vision system that provides not only two-dimensional grid feature cues, but also three-dimensional orientation cues. The method developed in this study represents a solution to the problems, such as heavy parts pick-and-place, in the assembly processes.

In 3-D image processing, the range data of the environment are collected and analysed for completing a specified vision task. Using the traditional image processing methods, the target parts are segmented from the original range images. The centre position is then computed through the circle Hough transform algorithm. For the 3-D orientation estimation, a 3-D free-form surface descriptor, Angle Distance Map, is introduced. The principal component analysis is applied to make the ADM representation efficient for a large model database. Feature points used to determine the object pose information are matched according to the compressed ADM descriptions by PCA. For accurate pose estimation, the original extracted feature points are refined by an outlier elimination approach. 3-D orientation information is estimated according to the extracted feature points. The experimental results show that accurate object pose is obtained according to the proposed 3-D object pose estimation method.

15.4 Techniques in Range Image Processing, Part 1: Edge Detection

There are numerous approaches in range image processing. The techniques in this aspect are many, and for every imaging attribute description, there are various approaches. We present two approaches: (1) edge detection and (2) region segmentation.

15.4.1 Edge Detection

In range image processing, the 3-D geometrical features of objects are extracted for high-level machine vision tasks. Edge feature is an important 3-D feature in range images. Unlike traditional 2-D intensity image processing, there are primarily three types of edges in range images, and they are step edge which is discontinuous in depth value, roof edge which is discontinuous in surface normals, and curvature edge which is discontinuous in a variety of surface normals. ➲ *Figure 15.22* shows the three types of edges.

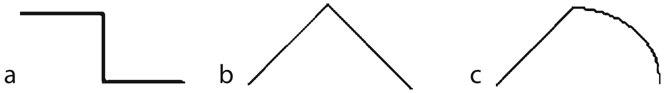

Fig. 15.22

Three types of edge in range images: (a) Discontinuities in depth; (b) discontinuities in surface normals; (c) discontinuities in the variety of neighbourhood surface normals

Surface normal is a first-order derivative feature. This type of local 3-D features is more robust to image noise than the features obtained using higher-order derivatives. The angle between neighbouring surface normals is one of the typical geometrical relationships used to extract 3-D surface feature. In this study, an angle attribute of neighbouring surface normals is defined. An edge detection method in range images is then developed for three different types of edges: step edge, roof edge and curvature edge. The test results on real range images show that our method correctly extracts all three types of edges simultaneously.

15.4.2 Angle Attribute of Neighbouring Surface Normals

In 3-D surface analysis, some geometrical features are obtained through the varieties of local surface normals. In many traditional approaches, such as 2-D intensity image processing, the gradients along X and Ydirections of a range image are used to extract the value discontinuities of surface normals. This approach does not distinguish the orientation variations of surface normals, while the orientation feature of surface normals is also important in 3-D surface analysis. Based on this point of view, an angle attribute of neighbourhood surface normals is proposed as a local surface geometrical feature. ➲ *Figure 15.2* shows a paradigm of some neighbourhood surface normals.

The proposed angle attribute is an angle vector used to describe the local surface feature on the central point. In ➲ *Fig. 15.23*, there are four pairs of surface normals with a centre to be the point of concern. The angle attribute $\vec{\theta}$ is defined as

$$\vec{\theta} = [\theta_0, \ \theta_1, \ \theta_2, \ \theta_3]^T, \tag{15.27}$$

where $\theta_i (i = 0, 1, 2, 3)$ is the angle value between the neighbourhood surface normals along the directions of 0°, 45°, 90° and 135°, as shown in ➲ *Fig. 15.2b*. The value of θ_i is computed by

$$\theta_i = \frac{(\mathrm{Angle}(\vec{n}, \ \vec{n}_i) + \mathrm{Angle}(\vec{n}, \ \vec{n}_{i+4}))}{2}, \ i = 0, \ 1, \ 2, \ 3, \tag{15.28}$$

where $\vec{n}$ is the surface normal of the central point in ➲ *Fig. 15.2a* and $\vec{n}_i$ is the surface normal of the neighbourhood points. Let (f_x, f_y) and (f_{xi}, f_{yi}) be the gradients of $\vec{n}$ and $\vec{n}_i$, and $\mathrm{Angle}(\vec{n}, \ \vec{n}_i)$ is then computed as

$$\mathrm{Angle}(\vec{n}, \ \vec{n}_i) = \arccos\left(\frac{f_x f_{xi} + f_y f_{yi} + 1}{\sqrt{f_x^2 + f_y^2 + 1}\sqrt{f_{xi}^2 + f_{yi}^2 + 1}}\right). \tag{15.29}$$

As shown in ➲ *Fig. 15.23b*, the specific parameter d is the coordinate distance value between the central point and its neighbourhood points. Analytic resolutions are adjusted using different values of parameter d. Obviously, angle features with small d result in a higher resolution for features. On the other hand, a lower resolution is obtained using large d in the

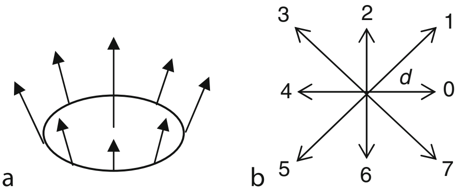

Fig. 15.23
(a) A paradigm of local surface normals; (b) a paradigm of computing the angle attribute of neighbourhood surface normals

angle feature. In normal cases, angle attributes with a larger *d* are more tolerant to noise in an image, and they are applied to extract roof edges that represent a smooth change between two regions of interest.

In this study, for the different types of edges in range images, an edge detection method based on the angle attribute is developed. According to the angle attribute, a Mean Angle Feature (MAF) $\bar{\theta}$ is defined as

$$\bar{\theta} = \frac{\sum_{i=0}^{3} \theta_i}{4}, \tag{15.30}$$

where θ_i, $i = 0, 1, 2, 3$ are computed using (15.28).

The Mean Angle Feature is applied to extract the three types of edges simultaneously in a typical range image: step edge, roof edge and curvature edge. For step edges, ideally there is no real surface normal at the step edge. In image processing, the value of the surface normal at this local area is still obtained by common approximation methods. Since the value of the approximated surface normal is random, the value of an MAF at this local area is also distinguishable. For roof edges, there is an orientation variation at the edges between two neighbourhood surface patches. The MAF describes the surface orientation variation along different directions. Therefore the orientation variation is extracted using an MAF operator. For curvature edges, the surface orientation varies not only within the neighbourhood patches but also at the curvature edge between the patches. Nevertheless, the characteristics of the orientation variation are consistent within one patch, and they are different from the adjacent patches. According to the differential values of the MAF, the curvature edges can be extracted through detecting the changes of the characteristics of the orientation variation. Based on the nature of edges in range images, an edge detection method is developed for extracting the three types of edges in range images simultaneously.

15.4.3 Edge Detection in Range Images

In this edge detection method, different types of discontinuities are detected based on the MAF of a local surface. According to (15.29), the angle values are computed using the gradients of surface normals. In traditional methods, the gradients are computed using the first-order partial derivative operators. For real range images, due to the effect of geometrical distortion, computed gradients do not represent the true geometry. Especially for the images with curved surfaces, the gradients cannot be correctly approximated using traditional gradient computing methods. In our edge detection method, a surface fitting algorithm is applied to obtain the accurate gradients in real range images. The estimated surface function $\widehat{f}(x,\ y)$ is described as

$$\widehat{f}(x,\ y) = a_{20}x^2 + a_{02}y^2 + a_{11}xy + a_{10}x + a_{01}y + a_{00}, \tag{15.31}$$

where a's are the parameters of a geometrical function. The subscript of a denotes the polynomial of that parameter. The gradient values are then given according to

$$f_x = a_{10},\quad f_y = a_{01}. \tag{15.32}$$

Prior to calculating the surface properties, a smoothing process is applied on the range images, which include detector noise, quantization and calibration errors. A Gaussian smoothing method is applied in this edge detection method. In a Gaussian smoothing, two-dimensional image data are convolved with the rotation-invariant Gaussian filter

$$g(x,y) = e^{-(x^2+y^2)/2\sigma^2} \tag{15.33}$$

where (x,y) is the coordinate of each point in the image and σ^2 is the variance. Alternatively, Gaussian smoothing is approximated through a convolution with a 3 × 3 operator

$$\begin{bmatrix} 1 & 2 & 1 \\ 2 & 12 & 2 \\ 1 & 2 & 1 \end{bmatrix}. \tag{15.34}$$

After the gradients are obtained, the MAF of each point in a range image is computed according to (2) and (4). The result of an MAF map of range images is then generated. An initial edge result based on the MAF map is generated according to

$$\Delta\bar{\theta} = \left|\frac{\partial\bar{\theta}}{\partial x}\right| + \left|\frac{\partial\bar{\theta}}{\partial y}\right|. \tag{15.35}$$

A binary edge map of range image is obtained based on the initial edge result. The different types of edges in a range image are detected simultaneously according to the edge map.

In the edge map, parameter d of the MAF operator causes a double-edge effect at step edges in range images. There is a thin gap in the middle of the extracted edge area. A common expansion and thinning process is applied to eliminate this gap. In a binary edge map, the gap area is filled by expanding the initially extracted edge points. In this edge detection approach, for a non-edge point and its adjacent area, typically 5 × 5, if the pixel number of edge point within the neighbourhood area is larger than a predefined threshold, the non-edge point is changed into an edge point in the binary edge map. After the expansion process for all pixels in the binary map, a thinning process is realized using a normal skeleton algorithm. A distance attribute of each edge point is defined at first. For each edge point, the nearest non-edge point from it in all directions is detected. The distance between the nearest non-edge point and the concerned edge point is defined as the distance attribute of the edge point. The edge points with the local maximum distance attribute are considered as skeleton points. The thinning process is realized by eliminating the non-skeleton points.

The edge detection method for range images consists of the following steps:

1. Apply a smooth operator in (➋ 15.34) on original range image.
2. According to (➋ 15.31) and (➋ 15.32), compute the gradients along X and Y directions for each point in range image.

3. Based on (➋ 15.28)–(➋ 15.30), extract the MAF for each point in range image and generate an MAF map for range image.
4. According to the MAF map, the initial edges are detected based on (➋ 15.35).
5. Apply the expansion and thinning process on the edge map to obtain the edge as the final result of the method.

15.4.4 Experimental Results and Analysis

The experimental range images in this study are acquired using a scanner-based infrared laser radar imager. Noise is apparent in the acquired range images. The smoothing process and surface fitting method are applied to obtain accurate surface normal. To extract smooth roof edges and obtain a fine edge resolution, the value range of parameter *d* in the MAF computation is selected from 3 to 5. Based on the ground truth rule, the extracted edges are matched against the original range images. The results show that the edges match well with the gradient changes in the original range data.

➋ *Figure 15.3* shows the experimental results of a polyhedral object. ➋ *Figure 15.24a* shows the original range image with a size of 404 × 122 pixels. The corresponding intensity image and

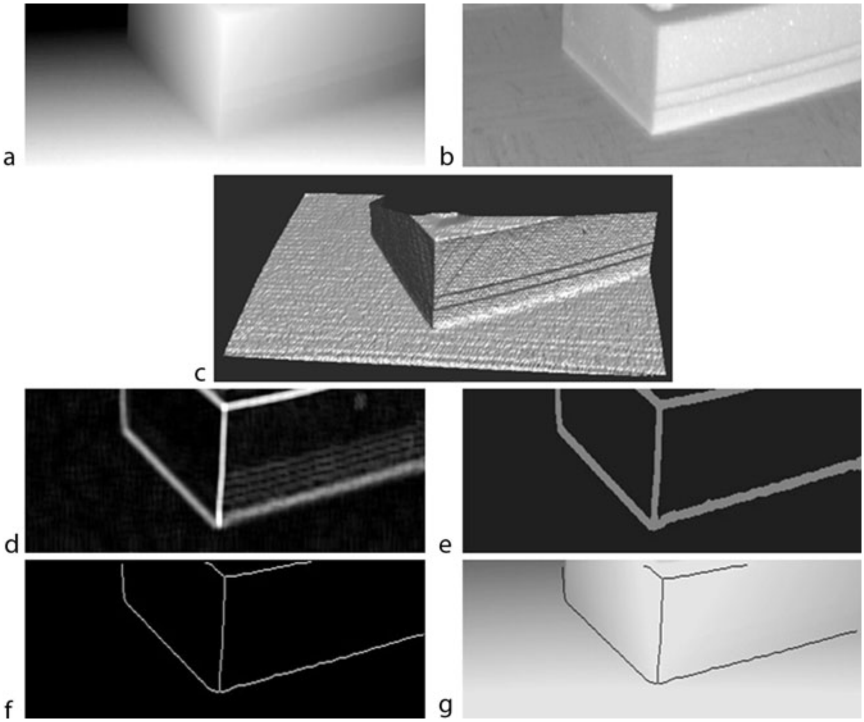

Fig. 15.24

(a) The original range image of a packaging part; (b) the corresponding intensity image; (c) the 3-D display for showing image noise; (d) the MAF map of (a); (e) initial edge result; (f) the final edge result after expansion and thinning processing of (e); (g) a superimposed image of (a) and (f) to show edge localization accuracy

a 3-D display using a light mode are shown in *Fig. 15.24b, c*. There are several types of edges in this range image, such as step edges and roof edges of concave and convex types. The MAF map is shown in *Fig. 15.24d*. The surface angle features can be seen in the MAF map. *Figure 15.24e* shows the initial edges extracted from the MAF map. After expansion and thinning processing, the one-pixel-width edges in range image are extracted and shown in *Fig. 15.24f*. To verify the localization of the edge points, the edge image in *Fig. 15.24f* is superimposed onto the original range image in *Fig. 15.24a* to produce an accuracy verification as shown in *Fig. 15.24g*. The edge points are checked based on the ground truth and they are found to be accurate.

Figure 15.25 shows the results from applying our method to a range image of a cylinder part. *Figure 15.25a, b* show the original range image and its corresponding intensity image with a size of 228 × 165 pixels. A 3-D display is shown in *Fig. 15.25c*. Noise in the image is apparent. There are step edges between the flat and curved surface in this image. *Figure 15.25d* shows the 3-D surface angle features extracted according to the MAF map. The initial edge map is shown in *Fig. 15.25e*. The double-edge effect is reflected in the initial edge result. *Figure 15.25f* shows the final edge result after the expansion and thinning process. *Figure 15.25g* shows the edge image being superimposed on the original range image. Although some image processes, e.g., smoothing process and expansion and thinning process are applied in this edge detection method, edge localization is found accurate for all three types of edges.

The result of detecting edges from a curved industrial part is shown in *Fig. 15.26*. The original range and intensity images with a size of 209 × 173 pixels are shown in *Fig. 15.26a, b*, respectively. *Figure 15.26c* shows the same mode 3-D display. In this range image, there are three types of edges: step edge, roof edge and the edge between the surfaces with different curvatures. The 3-D surface features are described according to the MAF map as shown in *Fig. 15.26d*. *Figure 15.26e* shows the initial edge map detected from the MAF map. The double-edge effect can also be seen in the initial edge result. The final result with different types of edges is shown in *Fig. 15.26f*. *Figure 15.26g* shows the superimposed image of the edges and the original. The experimental results show that the three types of edges in a range image are correctly detected simultaneously using the MAF of neighbouring surface normals.

In correspondence, an angle attribute of neighbourhood surface normals is proposed for extracting the 3-D geometrical surface features. Based on the geometrical features of this angle attribute, an edge detection method is developed for extracting the three types of edges in range images. Using the MAF map of an original range image, the different types of edges are distinguished and detected simultaneously. To eliminate the effect of noise in the real range images, some image processes are applied to extract the final edge results. The experimental results show that the proposed method produces the edges matched to ground truth verification.

15.5 Techniques in Range Image Processing, Part 2: Region Segmentation

Segmentation is an assignment of pixels into one of many disjoint sets such that the pixels in each set share a common property. Currently, many machine vision techniques use range images to obtain useful descriptions of 3-D scenes. Segmentation has been most often used in range image analysis and recognition as it helps partition an image array into low-level entities. In general, segmentation methods for range images are classified into two categories. One is based on region features, and the other is based on edge information.

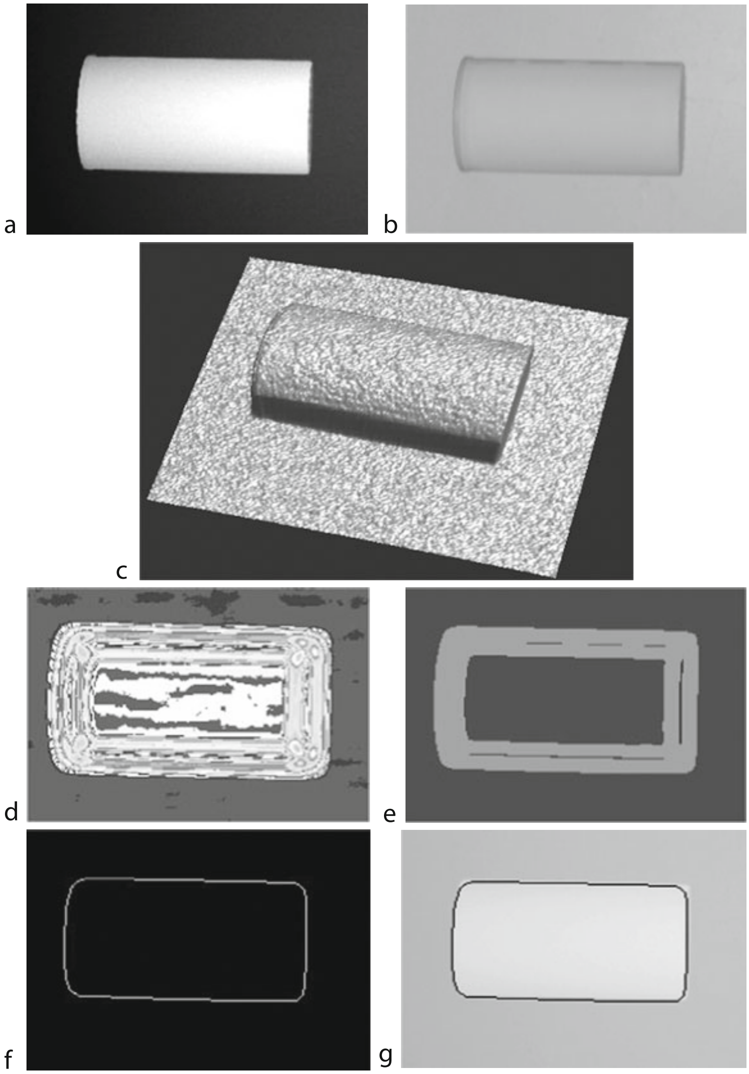

Fig. 15.25
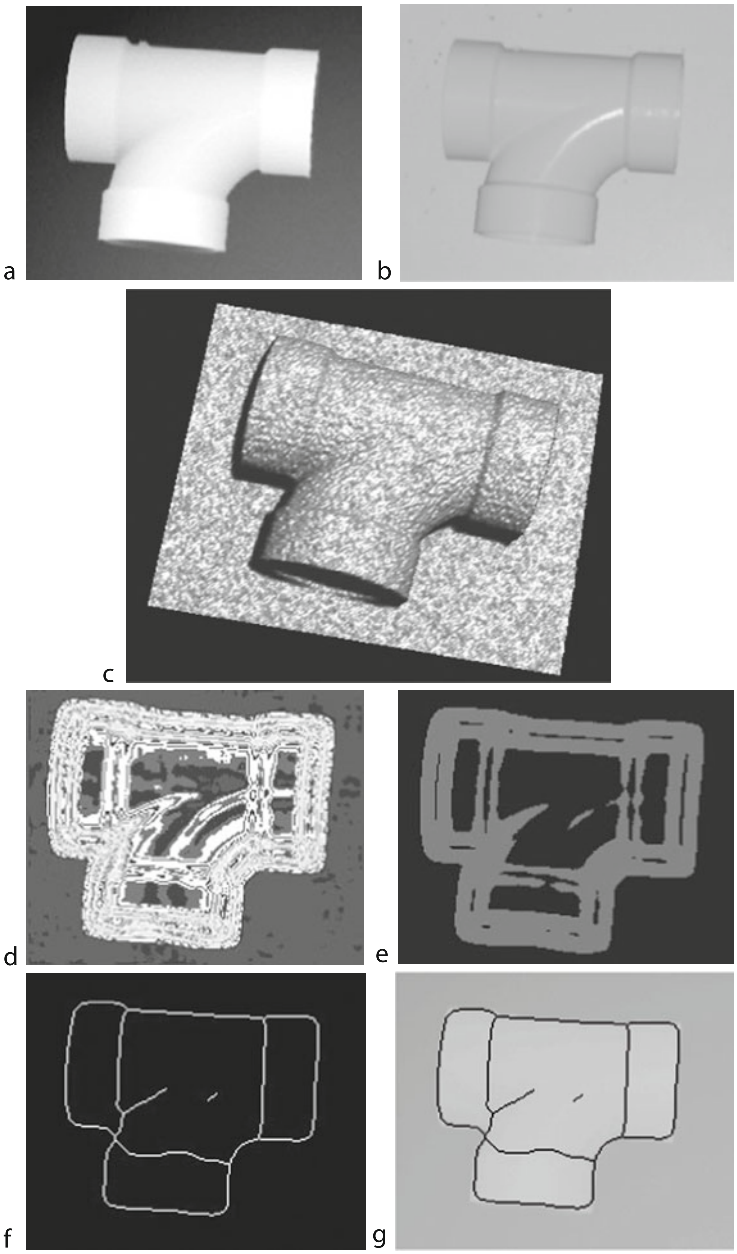
(a) The original range image of a cylinder part; (b) the corresponding intensity image; (c) the 3-D display for showing image noise; (d) the MAF map of (a); (e) initial edge result; (f) the final edge result after expansion and thinning processing of (e); (g) a superimposed image of (a) and (f) to show edge localization accuracy

In region-based segmentation methods, the pixels having similar properties are grouped together. The techniques of surface fitting and feature clustering are two commonly applied to analyse the region properties for range image segmentation. Region growing techniques select a set of seed regions first and grow the seed regions by iterative merging of adjacent regions with similar properties.



■ **Fig. 15.26**

In this section, a segmentation approach based on two-dimensional gradient histogram is proposed and the images are taken from a range sensor. The gradients along directions of x and y coordinates are applied in the segmentation method. According to the distribution of the gradients histogram, a four-neighbourhood region growing algorithm is developed to achieve the preliminary planar patch segmentation based on a proposed grouping criterion. The gradient features are derived from the first-order derivatives. Compared with the second-order derivative, typically used in some methods, the first-order derivatives are insensitive to noise and easy to compute. Since some pixels may not be grouped into correct regions due to noise effect, a merge process is applied on the first-round segmentation results. The selection of the segmentation parameters is also discussed in this study. The tests show that this algorithm can be used to segment polyhedral objects in range images and it is less sensitive to noise and computationally efficient.

15.5.1 Gradient Based Region Growing

It is well known that the higher-order derivative features are more sensitive to noise than lower-order derivative features. To real range images, the results usually do not meet the expectation from theoretical aspects because of noise effects and quantization errors. Therefore, the first-order derivatives are used for the segmentation in this study. The segmentation features are one-dimensional slice gradients in two coordinate directions. For a given surface $\vec{r} = (x,\ y,\ f(x,\ y)),\ f(x,\ y) : (x,\ y) \in Z \times Z \rightarrow \Re$, according to the theory of differential geometry, the unit surface normal $\vec{n}$ of a point on a patch is given by

$$\vec{n} = \frac{1}{\sqrt{r_x^2 + r_y^2 + 1}} (-r_x, -r_y,\ 1) \tag{15.36}$$

where r_x and r_y are the partial derivatives of $\vec{r}$ with respect to x and y. The surface normal is uniquely determined by the two gradients along the two perpendicular axes.

In this gradient-based method, a gradient histogram is defined in a 3-D parameter space for the polyhedral segmentation. As shown in ➲ *Fig. 15.1*, x-axis represents f_x, y-axis represents f_y and z-axis represents the number of the pixels with the same f_x and f_y. For a given surface planar patch of a range image, it is assumed that the noise is uniform and Gaussian. Thus, the distribution of pixel numbers with respect to the two range gradients f_x and f_y is Gaussian. In the feature space, each peak corresponds to a group of regions with the same surface normal and the top of each peak corresponds to the mean gradient values of each region. A segmentation of planar surfaces is obtained by partitioning peaks in the gradient histogram space (➲ *Fig. 15.27*).

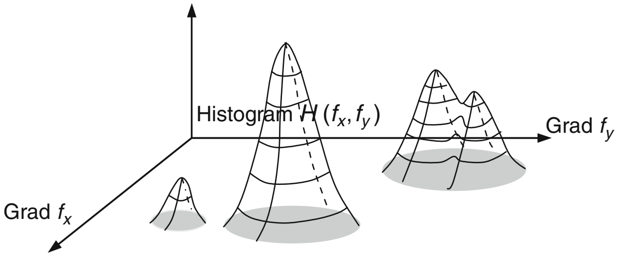

Fig. 15.27
The gradient histogram space

In the proposed region growing algorithm, two neighbouring pixels are grouped into the same patch if their surface properties, f_x and f_y, belong to the same Gaussian distribution in the gradient histogram space. A peak point searching algorithm is developed through iteratively searching the local maxima in the gradient histogram space.

For two neighbourhood points P_1 and P_2, with gradients (f_{x1}, f_{y1}) and (f_{x2}, f_{y2}), their corresponding histogram points, $H\ (f_{x1}, f_{y1})$ and $H\ (f_{x2}, f_{y2})$, are shown in *Fig. 15.28*. A grouping criterion is used: if $H\ (f_{x1}, f_{y1})$ and $H\ (f_{x2}, f_{y2})$ share the same peak area in the feature space, P_1 and P_2 are grouped into the same region; otherwise P_1 and P_2 belong to different regions.

A coarse segmentation result is obtained by applying a four-neighbourhood expanding grouping algorithm based on the grouping criterion. The four-neighbourhood expanding algorithm is an iterative grouping method beginning from a seed pixel. The seed pixels are the ungrouped pixels in range image scanned one by one. For each area grouping operation, the grouping algorithm expands in four directions from a seed pixel of this region. The ungrouped pixel in each direction is compared with the seed pixel according to the grouping criterion. The new grouped pixels are added to this region, and saved as new seed pixels for the future grouping operations. This iterative grouping algorithm terminates when there is no new seed pixel grouped into this region.

During grouping process, some points may be grouped into incorrect regions due to noise or other geometrical distortion. In this region growing approach, if the total pixel number of a grouped region is smaller than the threshold R_{Num}, then that region is considered as dominated by noise or geometrical distortion. For incorrect coarse segmentation results, a merge process between a noise region and its right neighbour regions is developed. For two adjacent regions R_1 and R_2, while the pixel number of region R_1 is smaller than R_{Num}, and the pixel number of region R_2 is larger than R_{Num}, a merge criterion is proposed: if $\left|\bar{f}_{x1} - \bar{f}_{x2}\right| + \left|\bar{f}_{y1} - \bar{f}_{y2}\right| < D$, R_1 and R_2 are merged into one region; otherwise R_1 and R_2 cannot be merged into one region. The variables $\bar{f}_{x1}$, $\bar{f}_{x2}$, $\bar{f}_{y1}$ and $\bar{f}_{y2}$ are the mean gradients of each region, and D is a threshold to gradient values. The selection of thresholds R_{Num} and D is discussed in Sect. 15.5.3.

Prior to calculating the surface properties, a smoothing process is applied on real range images, which include detector noise, quantization and calibration errors. A Gaussian smoothing method by Brady and Ronce [24] is applied in this segmentation method. In a Gaussian smoothing, two-dimensional image data are convolved with the rotation-invariant Gaussian filter

$$g(x, y) = e^{-(x^2+y^2)/2\sigma^2} \tag{15.37}$$

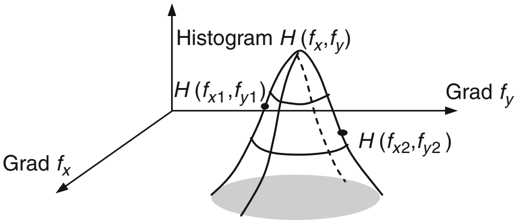

Fig. 15.28
A paradigm for grouping criterion

where (x, y) is the coordinate of each point in the image and σ^2 is the variance. Alternatively, Gaussian smoothing is approximated through a convolution with a 3 × 3 operator

$$\begin{bmatrix} 1 & 2 & 1 \\ 2 & 12 & 2 \\ 1 & 2 & 1 \end{bmatrix}. \tag{15.38}$$

The gradients of each pixel are computed, and the histogram is then obtained according to the gradients. A coarse segmentation result is obtained using a four-neighbourhood iterative expanding algorithm according to the grouping criterion. For those grouped regions dominated by noise or geometrical distortion, a merge process is applied based on the merge criterion. In this region growing approach, the cluster region number is not required a priori. The procedure is described by the following steps:

1. The original range image is smoothed using the Gaussian mask shown in (15.38). The gradients of each pixel in the smoothed range image are computed, and the gradient histogram is obtained.
2. The segmentation result map Q is initialized by setting each point with a non-processing value -1, also setting the current region label as 0, and setting the current scanning position in Q as $i = 0$ and $j = 0$.
3. Scanning and checking the map pixels $\{(i, j)\}$ one by one.
4. If $Q(i, j) \neq -1$ go to Step 6.
5. The pixel (i, j) is taken as a seed of a new region. The current region label adds one. According to the gradients of this point in the range image, this seed grows along its four neighbouring directions based on the grouping criterion. The grouped points are taken as new growing point candidates. This four neighbouring expansion process is iterated until no new point is grouped into this region. At each grouping process, the value of the grouped pixel in the segmentation map Q is set as the current region label. The attributes of this region, such as region pixel number and mean gradient $\bar{f}$, are also modified.
6. If the scanning process is not over, go to Step 3.
7. The regions with its pixel number smaller than threshold R_{Num} are processed according to the merge criterion.

15.5.2 Threshold Selection

There are two thresholds, R_{Num} and D, used in this gradient-based region growing method. *Figure 15.29* shows a paradigm of selecting threshold R_{Num}. In this gradient histogram, the pixels whose gradient histogram values are larger than the R_{Num} are taken as effective region points; otherwise they are taken as noise points. When R_{Num} is selected to be smaller than a representative value for target regions, some pixels due to noise and some small blocks due to distortion are then taken as valid regions, thus causing under-thresholding. When R_{Num} is larger than necessary, some small but valid regions are treated as noise, thus causing over-thresholding. In this study, an area ratio of the noise points to the whole points in a range image is applied to decide the threshold R_{Num}. Normally the area ratio value depends on the areas

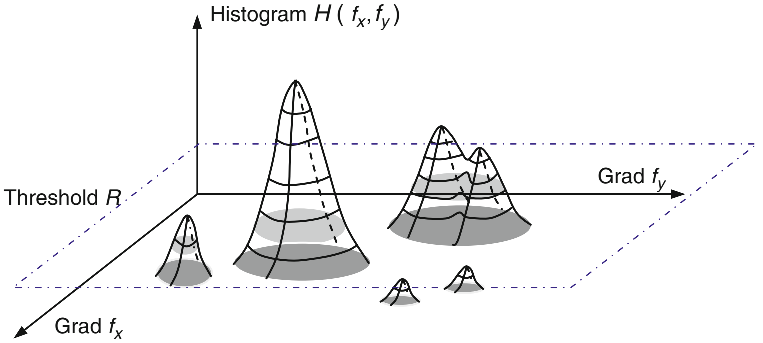

Fig. 15.29
A paradigm for selecting threshold R_{Num}

such as noise area, geometrical distortion area and jump edges. According to a candidate threshold R, the area ratio value, $f(R)$, is given by

$$f(R) = \frac{1}{Total}\sum_{f_x}\sum_{f_y} H(f_x, f_y), \quad H(f_x, f_y) < R, \tag{15.39}$$

where R is a candidate threshold value in the gradient feature space, and *Total* is the total pixel number of the processed range image. For a predefined area ratio value p, threshold R_{Num} applied in this segmentation method is derived by

$$f(R_{\text{Num}}) = p. \tag{15.40}$$

Figure 15.29 shows a paradigm of selecting threshold R_{Num}. The threshold R_{Num} is obtained by applying an iterative searching algorithm. The candidate threshold R is increased one by one from zero. For each candidate threshold R, the area ratio value is computed according to (15.39). If (15.40) is satisfied, the candidate R is taken as the threshold R_{Num}. The area ratio value p in (15.40) is a predefined parameter. The selection of value p depends on the contents of range images. If range images contain a lot of noise, distortion and edge areas, the noise ratio is large. Therefore, parameter p is selected as a large value. Otherwise, parameter p is selected as a small value. For normal-range images, parameter p is selected as 5% for the noise area inside the images.

Threshold D is another parameter in the merge process. After the coarse segmentation, for those regions whose region pixel number is smaller than threshold R_{Num}, a merge process is applied between the small regions and their adjacent larger regions whose region pixel number is larger than threshold R_{Num}. As defined in merge criterion, two adjacent regions are merged if the difference between their mean gradients is smaller than threshold D. The merge process is executed region by region. For two adjacent regions, the value of threshold D is decided by the gradient variation of the larger region within the pair of merging regions. Parameter σ_f is defined as the mean difference of gradients of the larger region, and is computed by

$$\sigma_f = \frac{1}{N}\sum_{i=0}^{N}\left[|f_{xi} - \bar{f}_x| + |f_{yi} - \bar{f}_y|\right], \tag{15.41}$$

where $\bar{f}_x, \bar{f}_y$ are the mean gradient values of the region, and N is the pixel number of this region, and f_{xi} and f_{yi} are the gradients on x-axis and y-axis, respectively, of pixel i. Based on the gradient difference parameter σ_f, threshold D is given by

$$D = 2\sigma_f. \tag{15.42}$$

15.5.3 Analysis

The range images used in this study are acquired using a laser range imager. There is noise in the images. A Gaussian smoothing process, defined in (➋ 15.37) and (➋ 15.38), is applied to obtain accurate gradient properties. The area ratio value of parameter p depends on the areas, such as geometrical distortion area and jump edges. In these experiments, parameter p is selected as 5%. Based on the ground truth rule, the extracted segmentation results are matched against the original range images. The experiments show that this gradient-based segmentation method generates good results for understanding 3-D polyhedral objects.

➋ *Figure 15.30a* is an original intensity image of wall and ground. Its size is 166 × 143 pixels. ➋ *Figure 15.30b* is the corresponding range image. Image noise is apparent in a 3-D display mode as shown in ➋ *Fig. 15.30c*. ➋ *Figure 15.30d* shows the gradient histogram of the smoothed range image. There are two major peaks corresponding to the directions of the wall and the ground regions. Some areas with small histogram values represent noise effect and geometry distortion. Through our region grouping approach, the neighbourhood pixels within the vicinity of the same gradient peak are grouped together. The region grouping result without the merge process is shown in ➋ *Fig. 15.30e*. Most of the pixels are grouped correctly. However, three small patches are grouped incorrectly because of noise or geometry distortion. ➋ *Figure 15.30f* shows the final result of applying the merge process.

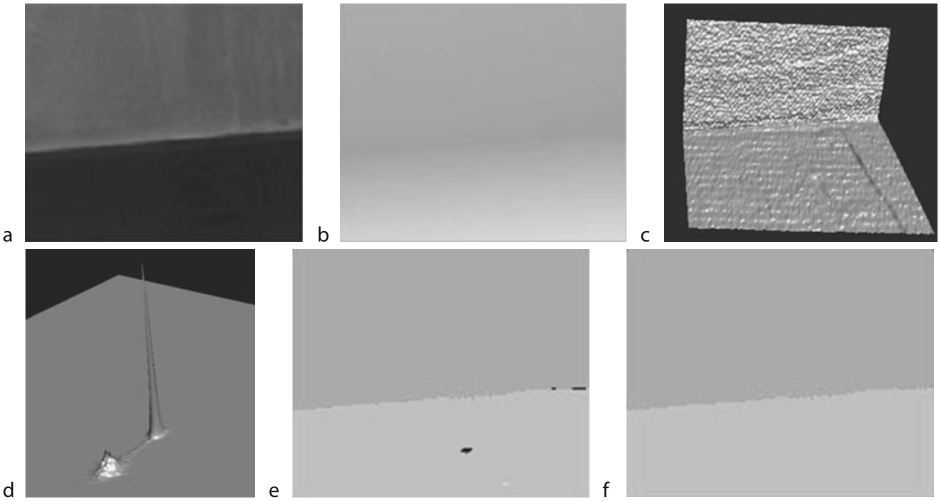

Fig. 15.30
A segmentation sample of wall and ground. (a) Original intensity image; (b) correspondent range image of (a); (c) 3-D display for showing image noise; (d) gradient feature space; (e) the result of initial region grouping; (f) the final segmentation result of applying the merge process

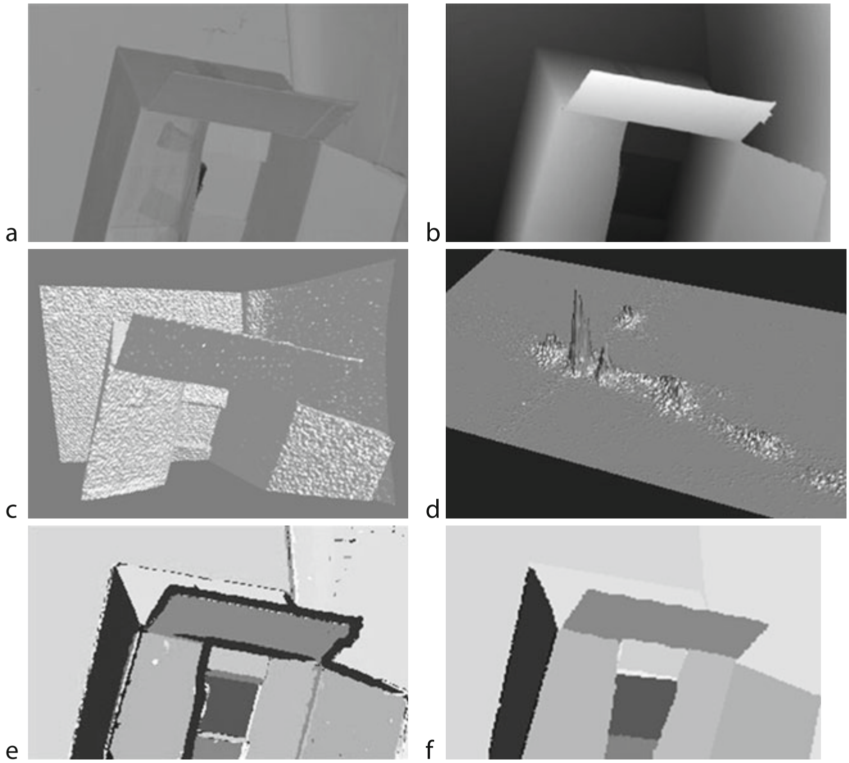

Fig. 15.31

A segmentation sample of a box. (a) original intensity image; (b) correspondent range image of (a); (c) 3-D display for showing image noise; (d) gradient feature space; (e) the result of initial region grouping; (f) the final segmentation result of applying the merge process

Figure 15.31 shows another segmentation process. *Figure 15.31a, b* shows the original intensity and range images of a box. The image size is 298 × 187 pixels. A 3-D display mode shows the range image in *Fig. 15.31c*. Image noise can be seen clearly. *Figure 15.31d* shows the gradient histogram. The main peak areas and some random distribution areas due to the image noise and jump edges can be seen. The initial region grouping result is shown in *Fig. 15.31e*. Some small patches and jump edges are grouped incorrectly. These regions are merged into their neighbourhood regions using the merge process. *Figure 15.31f* shows the final segmentation result.

Figure 15.32a shows an original intensity image of a packaging box. The image size is 364 × 248 pixels. *Figure 15.32b* shows the corresponding range image. A 3-D display mode is shown in *Fig. 15.32c*. *Figure 15.32d* shows the feature space of the range image. Three major peaks corresponding to the three directions of the planar regions. The region grouping result of the coarse segmentation is shown in *Fig. 15.32e*. *Figure 15.32f* shows the final segmentation result after applying the merge process. The noise area and jump edges in range images have been correctly grouped through the proposed gradient-based region grouping method.

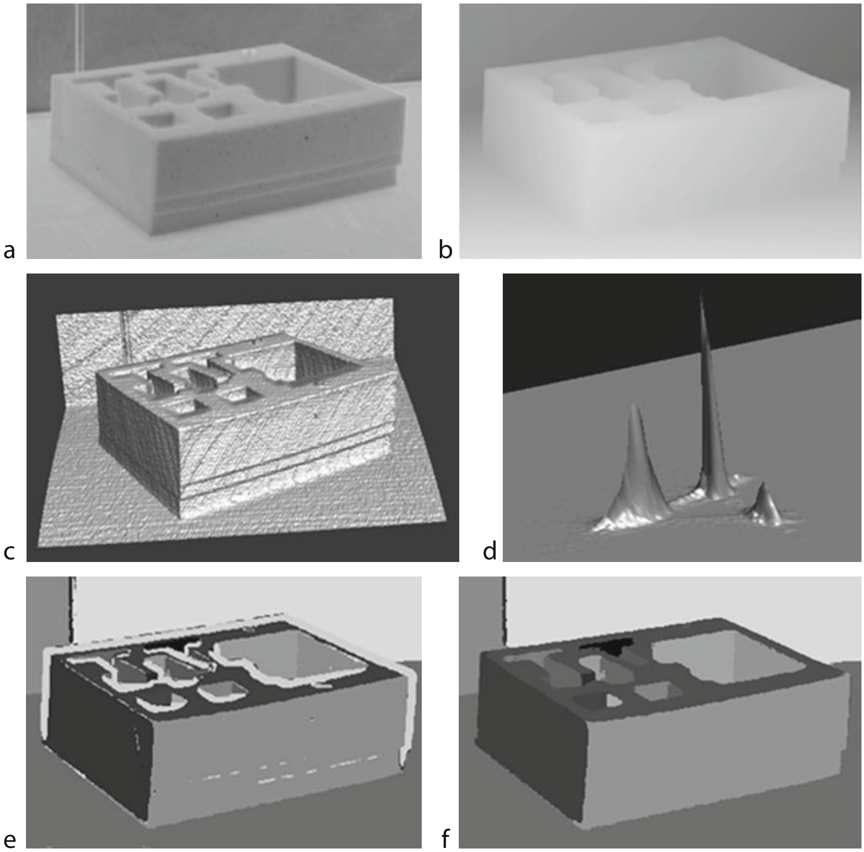

Fig. 15.32

A segmentation sample of a part. (a) original intensity image; (b) correspondent range image of (a); (c) 3-D display for showing image noise; (d) gradient feature space; (e) the result of initial region grouping; (f) the final segmentation result of applying the merge process

In this approach, two thresholds used in the merge process are derived from (15.39) to (15.42). The experimental results show that the thresholds have been selected properly. *Figure 15.33* shows some segmentation results of the object in *Fig. 15.32b*, with different threshold values. It is known that if R_{Num} is set too small, some small noise regions are taken as real separate regions and then lead to an incorrect segmentation as shown in *Fig. 15.33a*. If R_{Num} is set too large, some valid regions whose region pixel number is smaller than R_{Num} are taken as noise regions. If these small regions and their adjacent large regions satisfy the merge criterion, these valid regions are merged incorrectly into the adjacent large regions. As shown in *Fig. 15.33b*, two planes of the hole of the lower-left corner of the box surface are merged into one region. The different values of the threshold D also affect the final segmentation result. If D is selected too large, some real separate neighbouring regions with smaller gradient difference will be merged together. There is no such instance in this image. If D is selected too small, some small regions cannot be grouped correctly into their neighbourhood because of their larger

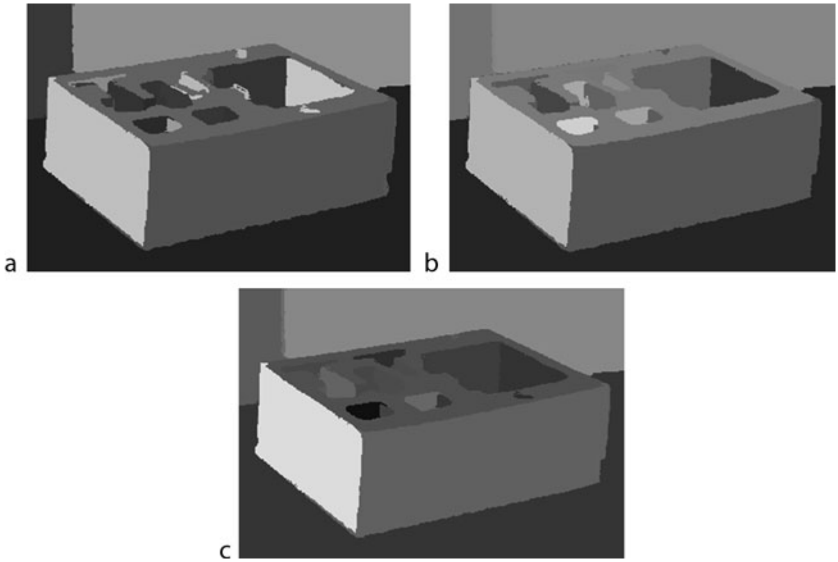

Fig. 15.33
Some incorrect segmentation results with different threshold selections: (a) the segmentation result with a smaller RNum; (b) the segmentation result with a larger RNum; and (c) the segmentation result with a smaller D

gradient difference. As shown in *Fig. 15.33c*, compared with the correct segmentation results shown in *Fig. 15.32f*, there is an incorrectly merged region on the top surface of the box.

Compared with other popular segmentation methods, the above discussed approach is much simpler and more robust because only the first-order features are used. The gradients along *x* and *y* directions and their histogram are applied as the segmentation features. The problem of surface segmentation becomes a problem of points clustering in a feature space. A grouping criterion is proposed for the region growing based on the gradient histogram. A four-neighbourhood iterative expanding algorithm is developed in region grouping. The regions with arbitrary shape can be grown in one expanding process. For a certain type of regions in range images, such as noise, geometrical distortion area and jump edges, a merge process is applied to the initial region growing results according to a proposed merge criterion. The experiments show that the proposed algorithm generates good results for understanding polyhedral objects in range images.

16 Colour Recognition

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_16,

Abstract: Colour is an important feature of many industrial artefacts. Moreover, a very large proportion of packaging materials are coloured. The inspection of coloured objects is therefore of considerable importance. In addition, natural products and raw materials are often inspected, graded or sorted on the basis of their colours. As so often happens in Machine Vision, the prime requirement is for verification rather than unassisted recognition. Sometimes the range of allowed colours can be specified quite precisely. On other occasions, it has to be learned from carefully selected samples. Our scope for flexibility is limited by the need to use commercially available image sensors. These almost invariably provide RGB output signals. We shall therefore concentrate primarily on pixel-by-pixel recognition of colours based on RGB data. Several techniques exist, including "brute force" methods that rely on standard Pattern Recognition algorithms, while others are based more firmly on Colour Science. Multispectral data allows a more refined approach to colour recognition than is possible with RGB. It requires more sophisticated image acquisition methods but can use well-established Pattern Recognition algorithms. Our goal is to provide image segmentation techniques that can be used to identify regions according to "standard" colours ("red," "yellow," "green," etc.) and colours that are specific to one particular situation (i.e., product or factory). A colour recognition program generates one or more binary images that can then be measured using the techniques described in ➋ Chaps. 14 and ➋ 18–20. In this sense, colour recognition serves simply as a means of segmenting an image.

16.1 Why We Need to Recognise Colours

Colour recognition is just one step in the bigger process of product inspection. To begin, let us consider a typical and surprisingly important task: inspecting a simple package. Most low-value products and many high-values ones too are packaged with labels printed in a few block colours. (That is, large areas of constant colour with no significant amount of blending between them. An example is shown in ➋ *Fig. 16.1*) A colour recognition system must partition the image, so that each colour imprint can be analysed separately. Once the segmentation has been completed, we can rely on standard binary image processing operators to measure them individually and thereby complete the inspection process. In some applications, colour separation can be performed very effectively using optical filtering (➋ Chaps. 4 and ➋ 5) and this should never be forgotten as an alternative to the software-based techniques that we shall discuss in this chapter. Optical colour-separation techniques are robust, fast and cheap but unfortunately are inflexible compared to software methods. (Fig. 4.11) Our theme throughout the remainder of this chapter is the use of colour recognition algorithms for image segmentation. Some of these are grounded in Colour Science, while others use a standard Pattern Recognition methodology, with spectral decomposition being performed optically by a bank of narrow band-pass filters.

Colour recognition algorithms have been devised around RGB, HSI and YUV tristimulus models. The question therefore arises as to which is best. It is reasonable to expect that the answer to such a question would be based on the large body of research that is encompassed by the term *Colour Theory.* However, practical considerations must prevail, as in any other branch of engineering. Video cameras separate the spectral components by optical filtering, thereby generating RGB signals first. If we were to base colour recognition algorithms on other tristimulus models, we would need to transform the signals first. (Some cameras contain internal circuitry for doing this but we should not suppose that cameras can measure

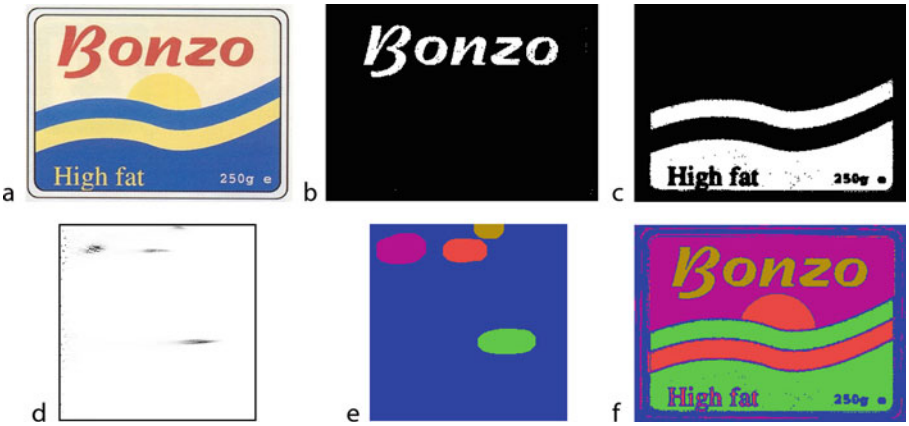

Fig. 16.1

Segmenting an image using colour. Note: parts (d)–(f) illustrate points explained later this but are not meaningful at this point in the chapter. (a) Original image: simulation of a container for a butter substitute, printed in block colours. (b) Output of a programmable colour filter (PCF, Sect. 16.3.1) designed to recognise "red". (c) Output of a PCF designed to recognise "blue". (d) HS scattergram, negated for clarity. (e) Clusters were identified by filtering and thresholding to form grey-scale blobs. The map image is displayed in pseudo-colour for clarity of illustration. (f) Programmable colour filter programmed using the map image in (e). Notice that the pseudo-colours have no direct relationship to the true colours in the original image; it is important point to understand that the original image has been segmented is a way that is subjectively judged to be reasonable

HSI or YUV directly.) Conversion formulae between RGB and other colour models are given in [3]. If we can separate two colour classes in, say, HSI space, we can also do so in RGB space. The partitioning surface may be much more complicated in one space than the other but the two classes can nevertheless be separated perfectly in both. The reason is that the RGB-to-HSI transformation is reversible.

16.2 Applying Pattern Recognition Methods in RGB Space

The reader is referred to the Sect. 16.5 of this chapter, where the Pattern Recognition Techniques mentioned here are described in more detail.

One way to recognise colours in a machine is to employ a standard pattern classifier to partition RGB space. This is effective for discriminating between block colours, since large areas of nearly constant colour generate dense compact clusters, with very points lying between them. It is often instructive to analyse the structure and relationship between clusters using interactive software. For example, MATLAB [4] enables users to "fly around" clusters in a 3D space. Users can view the clusters from different directions and thereby gain a better understanding of the nature and difficulty of the discrimination task (*Fig. 16.2*).

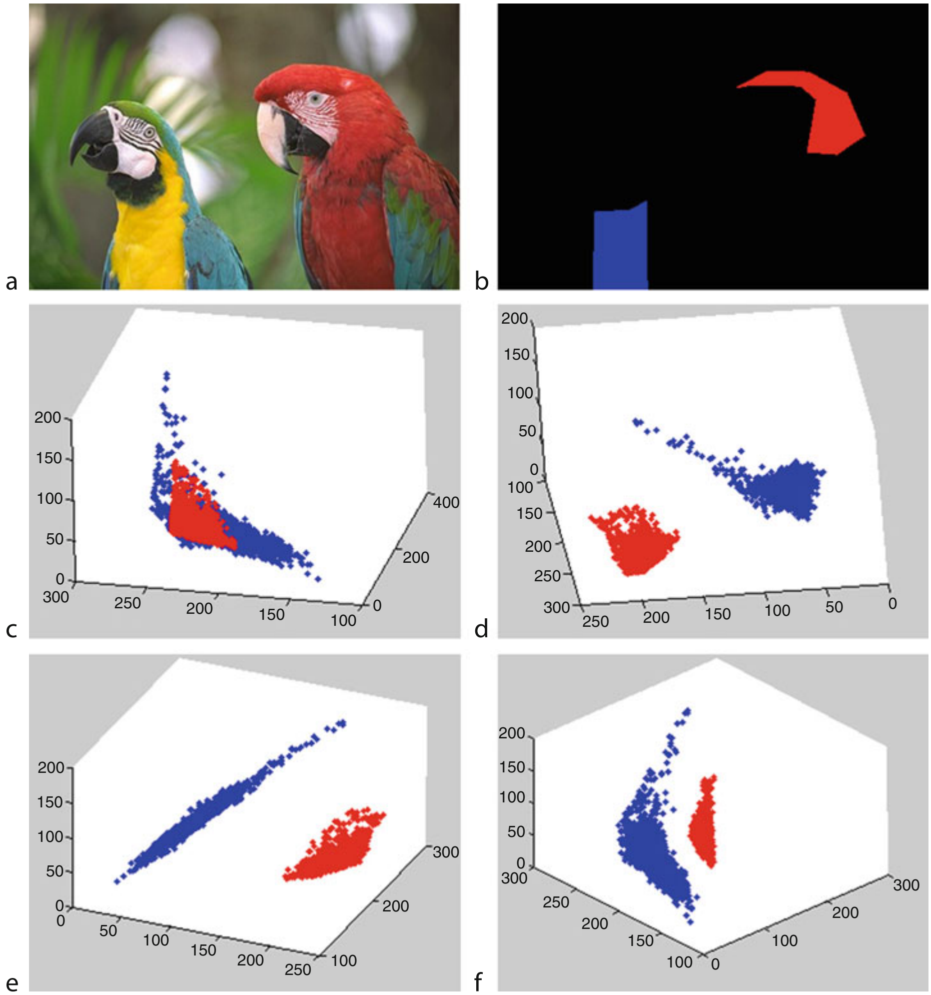

Fig. 16.2

Interactive analysis of clusters formed in RGB space by two regions of nearly constant colour. (a) Original colour image. (b) "Yellow" and "red" mask regions, selected by the author. (c)–(f) Screen-shots captured during an interactive MATLAB session, as the author "flew around" RGB space. (Points in RGB space corresponding to yellow are displayed in blue here, for clarity.) Notice that the clusters are well separated, although they appear to overlap in (c). It would be a trivial exercise to design a colour recognition system that distinguishes between these particular samples of "yellow" and "red"; a linear classifier, Compound Classifier or Nearest Neighbour Classifier, or Neural Network would all do this, with ease. (These are all discussed later and in Chap. 24.)

Standard Pattern Recognition methods can be used to partition RGB space so that "universal" and application-specific "named" colours can be identified automatically. Both supervised and unsupervised learning algorithms can be applied. The low dimensionality (3 for RGB space) makes it possible to use human intuition, guided by interactive data-visualisation software, to guide the choice/design of a suitable classifier. The following pattern classifiers are described in the Sect. 16.5 to this chapter. Also see [1].

(a) Compound Classifier (CC)
(b) Nearest neighbour classifier (NNC)

These classifiers are both capable of forming decision surfaces of unlimited complexity and effective learning rules have been devised. For both of these classifiers, there is a clear and easily understandable relationship between the values of the stored parameter and the position of the decision surface. This advantage is not enjoyed by some other classifiers. This is particularly valuable as human beings are able to visualise the clustering of data points in low-dimensionality spaces, such as RGB and HSI spaces. As a result, a vision engineer is able to develop an intuitive "feel" during the classifier design process and can assist the learning algorithms in adjusting the placement of the decision surface. It is manifestly obvious from visual examination of the clustering in RGB space that linear discrimination methods are not adequate for all but the simplest colour recognition tasks. (*Fig. 16.2* shows an extremely simple distribution of data points.) Separating one compact class (e.g., *torquoise*) from its complement (i.e., *not torquoise*) obviously requires a more sophisticated approach that either the CC or NNC can fulfil but a linear classifier cannot (*Fig. 16.3*). In *Fig.16.4*, results are shown for a Compound Classifier that was designed to recognise a single ill-defined class: *apple red-yellow*. (This involves *colour recognition*, not *colour discrimination*.) The author intervened in this design process only to define a polygonal region to represent this class. In practice, a person might be able to improve recognition accuracy and computational efficiency.

Multi-layer neural networks provide an alternative solution, as they are also able to implement complex decision surfaces. The author has not needed to employ neural networks for colour recognition, since they do not confer any obvious advantages over the CC and NNC, which more easily allow the vision engineer to retain an intuitive involvement in the classifier design process.

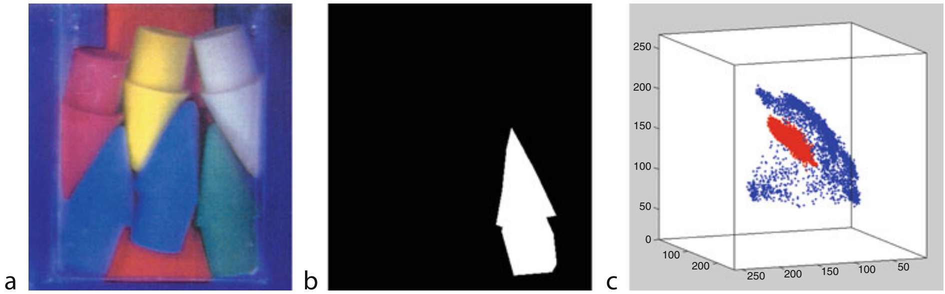

Fig. 16.3

Showing a compact colour class ("torquoise") and its complement ("not torquoise") (a) Original image. (Packet of rubber pencil erasers.) (b) Binary mask, drawn by the author. This defines the "torquoise" class. After dilation, its logical inverse defines the "not torquoise" class. (c) HSI plot for points in the two classes: "torquoise" (red points) and "not torquoise" (blue points). Interactive exploration of this space shows that the "torquoise" class lies inside a hollow shell (i.e., the class "torquoise")

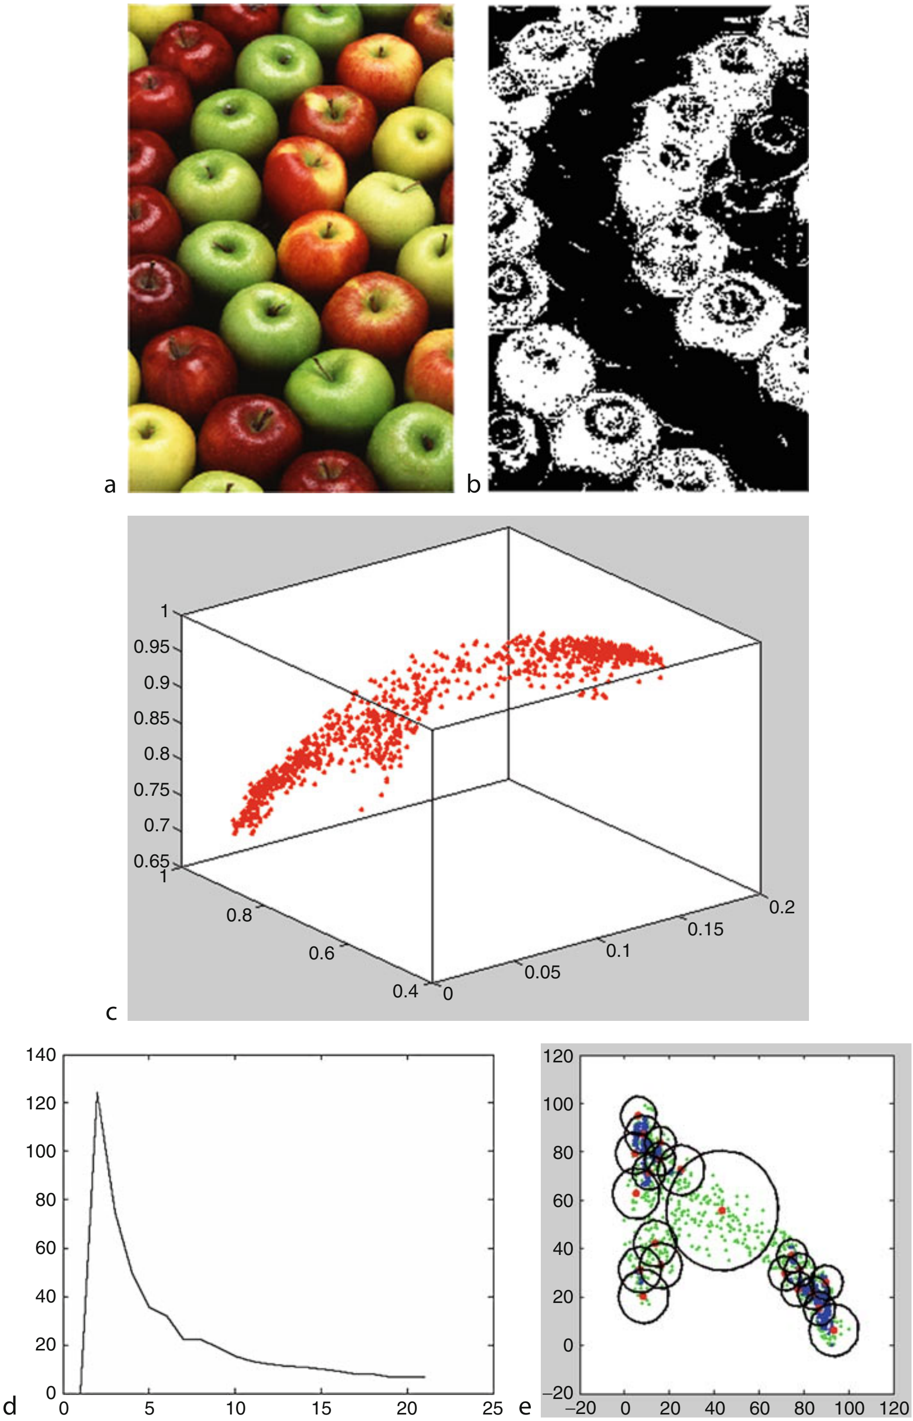

Fig. 16.4 (Continued)

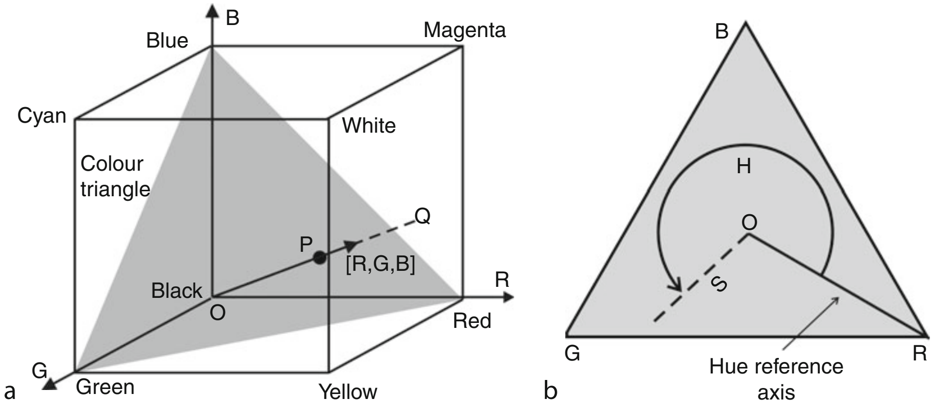
16.3 Colour Triangle

In this section, we move towards an alternative approach to colour recognition. This is described first in terms of RGB space but is, in reality based on an HSI model.

Consider ➋ *Fig.16.5*, which shows a diagram representing RGB space. The cube defined by the inequality

$$0 \leq R, G, B, \leq W$$

is called the *Colour Cube.* (W is a positive constant.) The Colour Cube shows the allowed range of variation of the point [*R,G,B*]. The *Colour Triangle,* also called the *Maxwell triangle,* is defined as the intersection of that plane which passes through the points [*W,0,0*], [*0,W,0*] and [*0,0,W*], with the Colour Cube. Now, the orientation of the line joining the point [*R,G,B*] to the



■ **Fig. 16.5**
RGB Colour space. (a) Relating the Colour Triangle to the Colour Cube. (b) Hue (H) and saturation (S) use polar coordinates to define a point in the Colour Triangle. Q is the point at which the line OP extended crosses one of the faces of the Colour Cube

■ **Fig. 16.4**
Using a Compound Classifier to recognise "apple red-yellow". (a) Original image. A small region of this image (about the same size as one apple) was selected by the author to generate the training data. (b) Result of applying the Compound Classifier to each pixel in the input image (i.e., including but not limited to the training set). (c) The distribution of points in HSI space. (d) Outliers were removed and Maximindist was then applied. (See ➋ Sect. 16.5 to this chapter.) This is a plot of the maximin distance versus the number of stored points. (e) HS space. Green points belong to the original training set. Outliers were then removed (blue points). Maximindist was then applied to the blue points. This generates the starting positions used by the one-class learning rules for the Compound Classifier. The circles form the decision surface of the Compound Classifier after learning. Notice that the large circle in the centre could be replaced by a two, or more, smaller circles. This would improve the performance of the classifier

origin could be specified uniquely by two angles (not shown). An alternative, and much more convenient way to do this is to define the orientation of this line, by specifying where the vector [R,G,B] intersects the Colour Triangle (P in ➋ *Fig. 16.5*) The vector [R,G,B] is extended if necessary. Then, by specifying two parameters (i.e., defining the position of point P in the Colour Triangle), the orientation of the [R,G,B] vector can be defined. All points lying along the line OPQ are associated with the same sensation of colour in a human being. (Very close to the origin there is a loss of colour perception but, for simplicity, we shall ignore this.) Hence, all RGB vectors which project onto the same point in the Colour Triangle are associated with the same colour name. For the purpose of setting the PCF's look-up table, colour names are assigned by an authority, called the *teacher*, under controlled lighting conditions. The following points should be noted:

(a) Points in the Colour Triangle that are very close together are very likely to be associated with the same colour name.

(b) The quantity ($R + G + B$) is a useful estimate of the intensity perceived by a human being when he/she views the same scene as the camera. This is a demonstration of *Grassman's Law* [2]. (The length of the RGB vector, measured by Euclidean distance between its ends, is not nearly so useful as a predictor of human perception of intensity.)

(c) The position of the point P defines the *chromaticity*. This is the perceptual quality of a colour, independently of its intensity. Chromaticity requires the specification of two parameters. In the HSI model, these are hue and saturation.

(d) The Colour Triangle allows us to use a graphical representation of the distribution of colours, expressing them in terms of the spatial distribution of blobs in a monochrome image. This is a particularly valuable aid to our understanding the nature and interrelationship between colours. It also permits us to use standard image processing software, to perform such operations as generalising colours, interpolating between colours, merging colours, performing fine discrimination between similar colours and simplifying the boundaries defining the recognition limits of specific colours.

(e) Since the colours perceived by a human being can be related to the orientation of the [R,G,B] vector, a narrow cone, with its apex at the origin, can be drawn to define the limits of a given "named" colour. The intersection of the cone with the Colour Triangle generates a blob-like figure.

(f) Not all colours can be represented adequately in the Colour Triangle. The Tristimulus model provides a useful working hypothesis, but it does not guarantee that perfect colour recognition is possible using just the RGB primaries. For example, "gold" and "yellow" are mapped to the same region of the Colour Triangle. Vivid purple is mapped to magenta, while vivid cyan is mapped to a paler (i.e., less saturated) tone. In relative terms, these are minor difficulties, and the Colour Triangle remains a very useful concept for colour vision. If the reader still doubts this, remember the satisfaction that numerous people have with the rendering of colours on television, which is, of course, based on RGB sensing.

(g) Fully saturated mixtures of two primary colours are found on the outer edges of the Colour Triangle, whereas the centre of the triangle, where all three primary components are balanced, represents white. We shall refer to the centre of the Colour Triangle as the *white point*, since it represents achromatic (*neutral*) tones. Other, unsaturated colours are represented by nearby points within the triangle. Hue (H) is represented as the angular position of a point relative to the centre of the Colour Triangle, while the degree of saturation (S) is measured by the distance from the centre (➋ *Fig. 16.5b*).

(h) In order to calculate hue and saturation from the RGB variables, we use the following transformations:

$$H = \cos^{-1}\left((2R - G - B) \Big/ \left(2\sqrt{((R - G)^2 + (R - B)(G - B))}\right)\right) \qquad (1)$$

$$S = 1 - 3\mathrm{MIN}(R, G, B)/(R + G + B) \qquad (2)$$

$$I = (R + G + B)/3 \qquad (3)$$

16.3.1 Programmable Colour Filter

The Programmable Colour Filter (PCF) provides an electronic/software method of recognising colours. It does not require the use of any optical devices, except those built into a standard RGB camera. A PCF operates under software control and hence is more versatile than optical filters, which have a fixed spectral response. We shall develop the theoretical basis for the PCF later but first we describe how it may be implemented in low-cost electronic hardware. The system outlined in *Fig. 16.6* is capable of recognising colours based on an RGB video signal in real-time. It is able to recognise 65,536 (= 2^{16}) colours. Notice that the memory required is modest: 32 MB per look-up table (LUT). (The memory requirement is halved if we limit ourselves to working with not more than 256 colour classes.) Since several LUTs can be stored in a single high-capacity memory chip, such a system is capable of rapid switching from one colour recognition function to another, simply by altering the *LUT selection* inputs.

As evidence that this seemingly naive approach actually works (see *Figs. 16.7* and *16.8*).

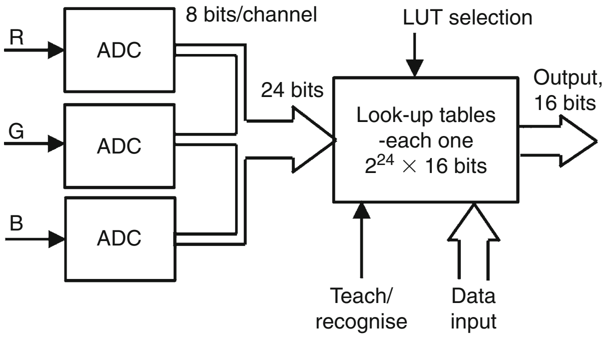


Fig. 16.6
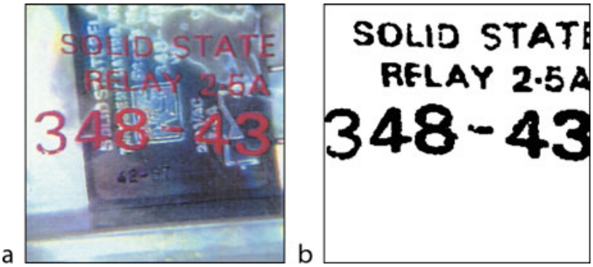
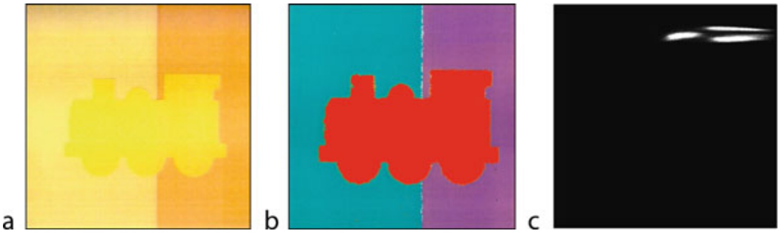
Programmable Colour Filter (PCF). The inputs are the RGB video channels (analogue). The output effectively defines the intensity in a monochrome image and hence can be manipulated using standard grey-scale image processing functions [4]



■ Fig. 16.7
Colour recognition. (a) Original image. Black electronics component with shiny silver printing. It is in a transparent plastic bag with red printing. The background is white. (b) Output of the PCF



■ Fig. 16.8
Another example of colour recognition. (a) Original image. The original artwork showed lower contrast than is evident here; the three shades of yellow are just distinguishable by eye. (b) Output of the PCF, displayed in pseudo-colour. (The PCF output has only four different levels.) (c) HS scattergram, no processing. The significance of this will be become clear later

16.3.2 Programming the PCF

We have not yet explained how the contents of the PCF look-up table are established. This may be a very slow process but need only be performed once. Thereafter, the PCF is very fast. The colour filter is normally "programmed" interactively (➲ Fig. 16.9). First, a sample colour image is displayed and the user draws a mask around a region of interest. Colours in this region are then analysed and a colour scattergram is generated in the Colour Triangle. To understand this, let us assume that each point $[i,j]$ in the region of interest yields a colour vector $[R_{i,j},G_{i,j},B_{i,j}]$. Furthermore, this vector, or its projection, will be assumed to intersect the Colour Triangle at that point defined by the polar co-ordinates $[H_{i,j},S_{i,j}]$ (P in ➲ Fig. 16.5). These hue and saturation values can be calculated using the equations just given. The point to note is that, each address $[i,j]$ in the region of interest defines a point in the Colour Triangle. The *Colour Scattergram* is generated thus

Rule 1: Clear the working image, I_{work}.
Rule 2: Select a point $[i,j]$ in the region of interest within the colour image.
Rule 3: Compute values for the hue and saturation, $[H_{i,j}, S_{i,j}]$. These are polar co-ordinates.
Rule 4: Add 1 to the intensity stored at that point defined by $[H_{i,j}, S_{i,j}]$ in image I_{work}. (Hard limiting occurs if we try to increase the intensity beyond the white level, 255.)
Rule 5: Repeat Rules 2–4 for all $[i,j]$ in the region of interest.

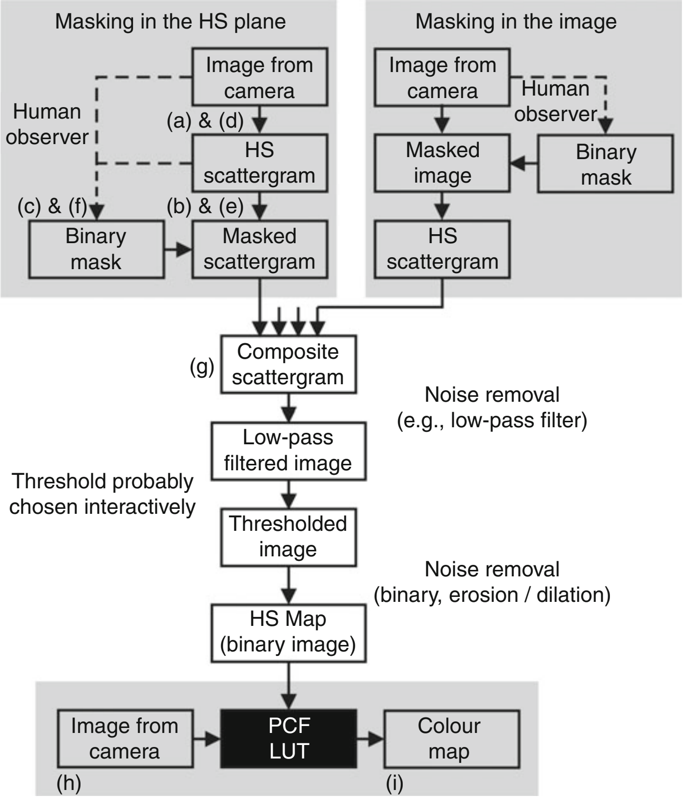


Fig. 16.9
Programming a colour filter and using it for colour recognition

Dense clusters in the colour scattergram are associated with large regions of nearly constant colour. A large diffuse cluster usually signifies the fact there is a wide variation of colours in the scene being viewed, often with colours blending into one another. On the other hand, a printed sheet containing only block colours (i.e., regions of constant colour with step-wise colour changes) generates a series of small dense clusters that are distinct from one another. The colour scattergram is a very useful method of characterising colour images and hence has a central role in programming the colour filters described below. As we shall see later, it is a valuable aid to understanding and communicating ideas about colour to another person, or to a computer.

Programming the PCF proceeds in one of two ways:

(a) The user defines a set of colours to be recognised, by interactively drawing a closed contour, usually around the main cluster in the colour scattergram. Other clusters and outlier points are normally ignored (see ➋ *Fig. 16.4*). The result is a binary image containing a single blob.

(b) The colour scattergram is processed using a (grey-scale) image processor, such as QT (➋ Chap. 21). Processing will probably involve

- Grey-scale filtering (This is usually needed to smooth the scattergram).
- Thresholding.

- Binary noise reduction.
- Selection of the blob(s) to be retained.
- Binary morphology, to enlarge the blob(s). (Needed for generalising colour recognition).
- Blob labelling. (QT function *ndo*) Each blob is assigned a different intensity value. The result is a multi-level image containing one or more blobs.

The next step is common to both manual or automated definitions of blobs in the Colour Triangle. It is called *Back-projection*, since it involves defining values for a set of points in the Colour Cube from those that were previously projected into the Colour Triangle. Consider ➲ *Fig. 16.10*. The position of a point in the Colour Triangle can be specified by two Cartesian coordinates *U* and *V*, where:

$$U = (R - G)\Big/\Big[\sqrt{2}(R{+}G + B)\Big]$$

and

$$V = (2B - R - G)/[\sqrt{6}(R + G + B)]$$

(It is easier to use Cartesian Coordinates ([*U,V*], here instead of hue and saturation [*H,S*], although one pair of values uniquely defines the other.) The set of points within the Colour Cube that give a constant value for *U* and *V* lies along a straight line and will be denoted by *Φ([U,V]* (➲ *Fig. 16.11*). All members of *Φ*([*U,V*]) are perceived as being the same colour as one another and map onto the same point in the Colour Triangle. Let *θ* be a set of connected points in the Colour Triangle (i.e., forming a blob)

$$\theta = \{[U_1, V_1], [U_2, V_2], [U_3, V], \ldots\}$$

If all members of *θ* are associated with the same colour name (ω), then all points in the set

$$\psi = \{\Phi(\mathbf{X})|\mathbf{X} \in \theta\}$$

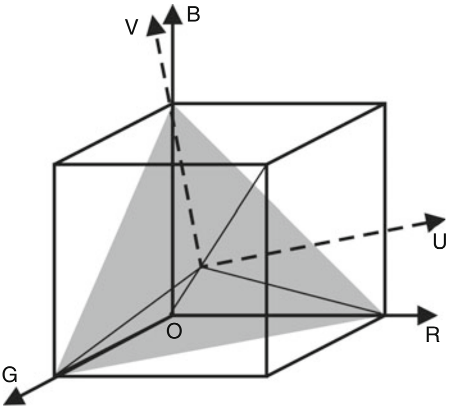

Fig. 16.10
Defining Cartesian axes U and V in the Colour Triangle

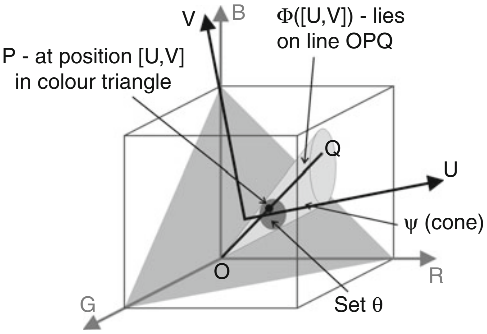

Fig. 16.11
Calculating the PCF look-up table (LUT) values by back-projection. The point at position [U,V] in the Colour Triangle is a member of the blob (i.e., connected set) θ. All points in the set Φ([U,V]) are perceived by an observer as being of the same colour as each other and lie on the line OPQ. The cone ψ has its apex at O and has cross-section θ in the Colour Triangle. All points in ψ are therefore associated with colour name ω. This partially determines the values for the PCF LUT. Other blobs in the Colour Triangle are treated in the same way. Points in the Colour Triangle that have not been specifically associated with a name are assigned to the class "colour not recognised"

should also be assigned to that same colour class. Notice that ψ is a cone with its apex at the origin of the colour space. The intersection of that cone with the Colour Triangle is the set θ. Back-projection is the process of setting all cells in the PCF look-up table that have addresses in ψ to the value ω.

We have just described the rationale for the back-projection procedure, not the computational details. In fact, the same operation is performed for all points in the Colour Triangle. This is necessary, so that we can define values of all points in the Colour Cube and hence all entries in the PCF's look-up table. There may be several blobs, with different values of ω, in the Colour Triangle, so the PCF will, in future, be able to recognise several classes. Points that are not within one of the blobs in the Colour Triangle are treated in the same way. In this case, the value for ω is a number representing *"colour not recognised".*

To distinguish this from the method described in the following section, we shall refer to this as *PCF1*. Note that it is based on the UV plane. Practical results based on this approach will be presented later

16.3.3 Programmable Colour Filter in the HS Plane

The previous section described colour recognition techniques based on RGB colour space and coordinates, $[U,V]$, to define points in the Colour Triangle. We shall now discuss methods based on a different but closely related form of scattergram: hue and saturation are plotted using Cartesian coordinates (see *Fig. 16.5b*). In order to calculate *HSI* from *RGB* variables, we use Eqs. 16.1 –16.3. Once again, we assume that we can safely discard intensity and that look-up tables could be used to improve the time to "calculate" *H* and *S*. Once we have derived

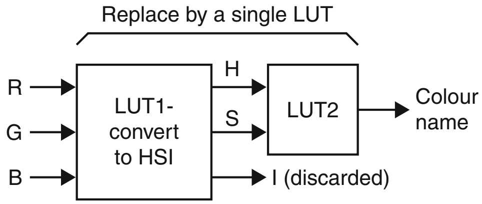

Fig. 16.12
Colour recognition based on [H,S] uses RGB inputs

a method for recognising colours based on HS values, it is possible to use another LUT for colour recognition. We then have two LUTs in tandem:

- LUT1 converts from RGB to HSI representation (LUT1 output defines the inputs to LUT2).
- LUT2 performs the colour recognition based on [*H*,*S*].

(*Figure 16.12*) These can be replaced by a single LUT. It is justified conceptually on an HS model but in reality it uses RGB inputs. The system shown in *Fig. 16.12* is also capable of performing real-time colour recognition, whether we use one or two separate LUTs.

We begin by calculating a colour scattergram in HS space. This is very similar to the process described in the previous section. The result is again a grey-scale image in which intensity indicates how many pixels have those particular values of [*H*,*S*] (see, for example, *Fig. 16.13b*). The scattergram can then be processed in a very similar way to that described in the previous section; thresholding, filtering and blob analysis (to eliminate the effects of minor peaks in the scattergram) are appropriate (*Fig. 16.9*). The HS scattergram can be calculated by the QT function *shs* and the recognition is performed using *pcf* (see Chap. 21). To distinguish this from the method described in Sect. 16.3.2, we shall refer to this as *PCF2* and refer to the fact that it is based on the HS plane.

16.3.4 Incorporating Human Intuition

The PCF1 and PCF2 procedures described so far work reasonably well but do not always produce sufficiently accurate colour discrimination. Matters can often be greatly improved, by allowing a vision engineer to adjust the blobs in the [*U*,*V*]/[*H*,*S*] plane interactively. For both the PCF1 and PCF2 colour recognition procedures, we have simplified the task of designing a filter, by creating a simple visual representation that a person can readily understand and adjust. We shall call this the *map image*. By inspecting the blobs in the map image, an experienced engineer can predict the behaviour of the PCF that will result from it. For example, when a blob representing a colour class (*C*) is enlarged, the set of colours that the PCF will associate with C also becomeṣ larger. This leads us to the concept of *colour generalisation*. We shall describe it and other procedures that an engineer can employ to adjust the behaviour of the PCF later. These all rely on manipulating a collection of blobs in the map image.

16.3.5 Colour Generalisation

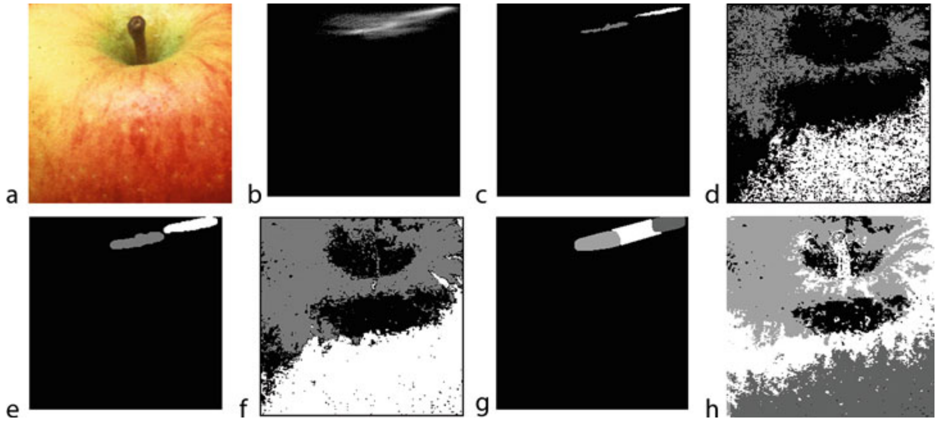
For the sake of simplicity, let us consider just one blob (Z) in the map image. When we use Z to define the LUT contents, a certain set (S) of colours will be recognised. When Z is enlarged, say by binary dilation, S and a set of "similar" colours will be recognised. By changing the amount of dilation, the degree of generalisation can be varied. In the case of the PCF2 procedure, dilation can be applied in different amounts along the H and S axes, by using a rectangular, rather than square structuring element.

We can extend this idea, so that the blobs become very large indeed, but we cannot, of course, allow them to overlap. Suppose that there are several separate blobs in the map image, representing a number of distinct colour classes. In some applications, it may be important to distinguish between colour classes, rather than identify the precise limits of any one of them. For example, a widget may have only achromatic, yellow and red features. The map image would then have three blobs. By dividing the plane on a nearest neighbour basis, all colours can be attributed to the "achromatic," "red" or "yellow" class. "Orange" would be divided between "red" and "yellow," while "green" would be assigned to "yellow." (It is more similar to "yellow" than it is to "red" [➔ *Fig. 16.13*].) To partition the $[U,V]/[H,S]$ plane, we can use the watershed function (➔ *Fig. 16.14*). The following operations are required. (QT commands are set in brackets. See ➔ Chap. 21)

```
Watershed function (wsh)
Negate (neg)
Label blobs. Shade each blob so that it has a unique intensity. (ndo)
Dilate. Apply a small amount of dilation, to fill the gaps between blobs. (dil)
```

16.3.6 Colour Interpolation

Suppose there are two small separate blobs (sets of points, S_r and S_y) close together in the map image, representing "red" and "yellow". Then, we can reasonably expect the points within the



■ **Fig. 16.13**

Colour generalisation and interpolation. (a) Original image. Natural products, such as apples, often have colours blending into one another. (This tends to produce indistinct clusters in the colour scattergram.) (b) Hue-saturation (HS) scattergram. (c) HS scattergram thresholded. (d) PCF based on map image (c). (e) Binary dilation applied to (c). (f) PCF based on (e). (g) Mask image, contrived to show colour interpolation. The two grey blobs are derived from (c). The white region was obtained from their convex deficiency. (h) PCF based on (g)

convex hull of the combined set $S_r \cup S_y$ but not in either of them to be called "orange." (*Fig. 16.13*). Here is the algorithm expressed in pseudo-code for an image processor. (Again, QT commands are given in brackets.)

```
Convex hull (chu_all)
Exclusive OR (Find points in the convex hull but not originally in the [U,V]/
[H,S] plane. (exr)
```

16.3.7 Logical Operations on Colour

Suppose that we have analysed five images, containing samples of "butter," "canary," "sulphur," "banana" and "lemon" and that this has produced five separate binary map images; there is one blob in each map image, representing a different subset of "yellow." In order to obtain a PCF that can recognise the more general class "yellow," we can combine these images by forming their logical union. The result is a map image containing a single blob that we can then use to build PCF1, or PCF2, so that it will recognise the general colour class called "yellow." In this way, we are able to form the logical union of two, or more colour sets. However, we can perform fuzzy logic on colour sets, by combining grey-scale map images. This is implicit in the flow chart for building a PCF shown in *Fig. 16.9*. Colour union is particularly useful for combining colours derived from natural products; since they are highly variable. For example, we might want to program a PCF to recognise the colour *leaf green*. This will require us to combine results from many different samples of foliage (*Fig. 16.15*). This is simply an extension of the principle outlined in *Fig. 16.9*. (Notice the multiple inputs to the box labelled *Composite scattergram*.) This diagram also shows a binary mask, drawn by a vision engineer, ANDed with a (grey-scale) map image, to suppress "unwanted" colours. "Red" and "orange-yellow" are eliminated in *Fig. 16.15*.

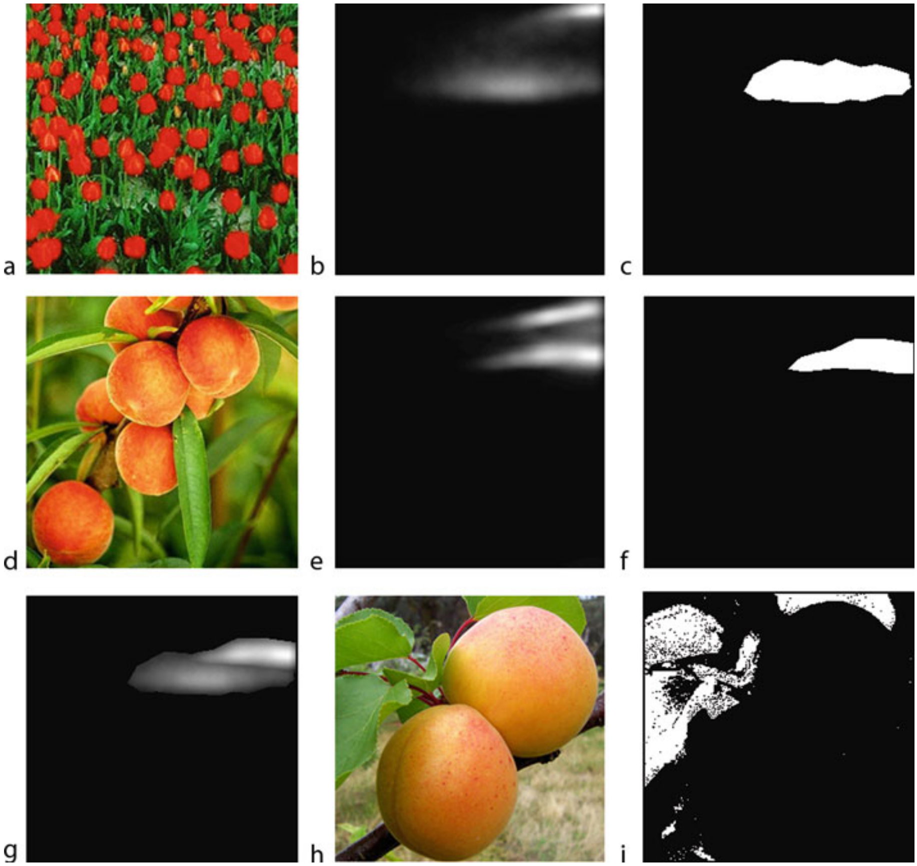

Fig. 16.15
Building a general concept of “green” using fuzzy logic operations in HS space. In practice, many more than two clusters should be merged to build a PCF that will have a sufficiently general concept of “green”. (a) Original image I_1. (b) HS scattergram of I_1. (S_1) The upper cluster is generated by the red flowers; the lower cluster is created by the green leaves. (c) Binary mask, M_1. (Drawn by the author; encloses the “green” cluster and nothing else.) (d) Original image I_2. (e) HS scattergram of I_2. (S_s) The lower cluster is created by the green leaves; the yellow-orange fruit generates the upper cluster. (f) Mask M_2 was drawn by the author to enclose the “green” cluster in S_2. (g) Merging the two “green” clusters. First, M_1 and M_2 were used to mask S_1 and S_s respectively. The resulting images were then merged, using pixel-by-pixel addition. The result (S_g) shown here, is a more general concept of “green” than is represented in either I_1 or I_2. (h) Original image I_3. (i) The PCF was programmed using a thresholded version of image S_g and was then applied to I_3. Applying suitable noise-removal operations and colour generalisation, much better results could be obtained for a PCF that recognises “green”

16.3.8 Interaction and Human Intuition

A useful trick when designing a PCF is to use a cursor to select blobs one at a time from a binary map image. In this way, the contribution of each blob to the total behaviour of the PCF can be understood. Individual blobs can then be dilated/eroded, separately, to improve the desired colour recognition accuracy. Drawing around an individual intensity peak (cluster in the scattergram) in a grey-scale map image produces a polygonal mask that can achieve a similar result. This is illustrated in ➲ *Fig. 16.15*. Interactive analysis like this can be particularly useful in identifying diffuse low-intensity clusters in the colour scattergram that might otherwise go unnoticed. Some of these can make a significant contribution to the performance of a PCF, yet be difficult to "capture" successfully by an automated process.

While ➲ *Fig. 16.9* summarises the likely sequence of steps involved in designing a PCF, it should not be taken as the only possible way to proceed. An engineer may need to experiment for some considerable time before he/she is fully satisfied with the results. Once the PCF design phase has been completed, the colour recognition process is automatic and needs no further human intervention. An engineer should never apologise for using human intuition in the design process, provided the results are verified properly later. In this chapter, the author has tried to present a logical case for each step in the design of a PCF but human experience and low cunning are far more powerful than prescriptive rules in situations like this.

16.3.9 Colour Similarity and Special Effects Filters

The PCF software devised by the author (*pcf* in QT, ➲ Chap. 21) can use, as its input (i.e., the map image), any binary or grey-scale image, provided it is of the correct size. We can, for example, generate the map image using a graphics program, in order to create special effects. Four examples are illustrated in ➲ *Figs. 16.16–16.19*.

16.3.10 Relating Physical, Graphical and Symbolic Representations of Colour

We are close to defining an hierarchy of different representations for colour. Most but not all of its elements have been described but two remain unexplained. The first is the approximation of each blob in the $[U,V]/[H,S]$ plane by a set of overlapping discs. (Squares or rectangles could be used instead.) These can be fitted manually, or algorithmically, perhaps by the rules defined in the ➲ Sect. 16.5 to this chapter). For the sake of argument, let us assume that we have already fitted a set of discs thereby approximating the blob (Z) that represents a certain colour, *C*. These circles can be defined by a set of data triples of the form:

$$S = \{[X_1, Y_1, R_1], [X_2, Y_2, R_2], [X_3, Y_3, R_3], \ldots\}$$

$[X_i, Y_i]$ is the centre of the *i*th disc and R_i is its radius. Of course, we need to modify the PCF slightly, so that it accepts as input a set of data values (S), rather than the map image containing the blob Z. This is convenient because S requires far less data storage than Z. Notice that we can apply generalisation easily, by increasing all of the circle radii ($\mathrm{R_i}$).

The last element that we need to build the hierarchy is symbolic programming (➲ Chap. 23). A Prolog program can readily associate symbolic colour names (e.g., *carpet blue* or *cola can red*) with a list of circle parameters (S); only a simple Prolog fact of the following form is needed:

$$colour(Name, [[X1, Y1, R1], X2, Y2, R2], \ldots])$$

We can now introduce the hierarchy of colour representations (➲ *Fig. 16.20*). Beginning with a pattern of light, we progress through the PCF design phase, to create symbolic references

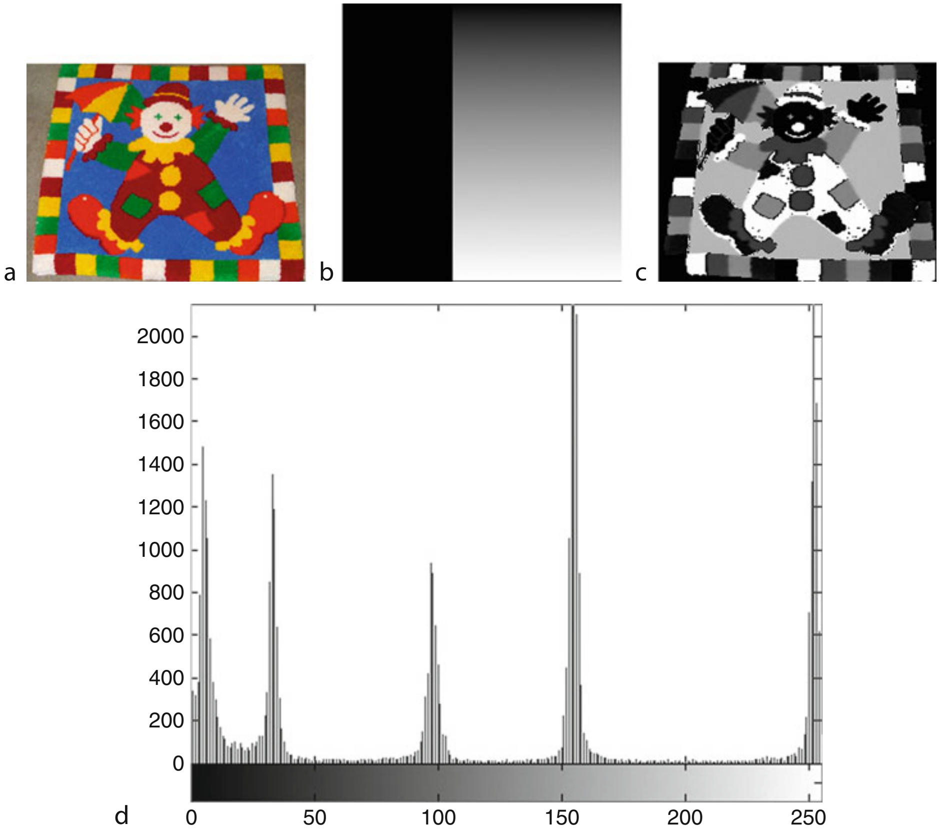

Fig. 16.16
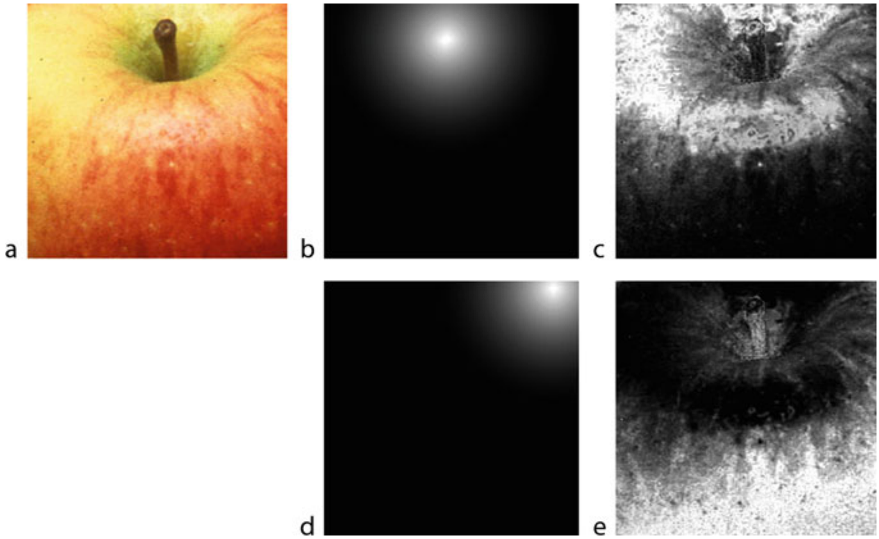
Using a PCF to measure hue, subject to the condition that saturation is above a given limit. (a) Original image. (b) Map image. (c) Output of the PCF based on (b). (d) Intensity histogram of (c). The sharp peaks indicate that there are large regions of nearly constant hue that can be separated by simple thresholding

to colour that can be incorporated into a Prolog program. Thereafter, it is possible to identify regions containing colours that have previously been learned, in a straightforward way.

16.3.11 Prolog Programming with Colour

We now have the ability to discuss colour in Prolog, which is an AI language that is well suited to logical reasoning. We can express relationships between colours in a simple way. For example, suppose that we have four PCFs that identify "butter yellow," "canary yellow," "lemon yellow" and "saffron yellow" and that these have been associated with the following disc-parameter lists

```
List_butter
List_canary
List_lemon
List_saffron
```



■ Fig. 16.17
Programmable colour filter used to determine colour similarity. Similarity is referred to a single point, defined by given pair of HS values. (**a**) Original image. (**b**) Map image. The peak intensity corresponds to a local maximum in the ''yellow'' region of the colour scattergram (➜ *Fig. 16.13*). (**c**) Output of the PCF based on (**b**). (**d**) Another map image. The peak intensity corresponds to a local maximum in the ''red'' region of the colour scattergram. (**e**) Output of the PCF based on (**d**)

Symbolic
Associate colour name with parameter list
Prolog database:
colour (name,[[[X1,Y1,R1],[X2,Y2,R2],...])

Fig. 16.20
Various representations of colour are made possible by the PCF

as explained above. Then, "yellow" might be expressed as the logical union of these colour sets, using four very simple Prolog rules:

```
colour(X,yellow) :- colour(X, List_butter).
colour(X,yellow) :- colour(X, List_canary).
colour(X,yellow) :- colour(X, List_lemon).
colour(X,yellow) :- colour(X, List_saffron).
```

We can express colour set intersection in an equally simple way:

```
colour(X,List_lemon) :-
      colour(X,List_orange_and_lemon),% Obvious meaning
      not(colour(X,orange)).          % Recognises the set ''not orange''
```

Of greater importance is Prolog's ability to accept declarative statements (➜ Chap. 23). A simple program is listed below. (Recall that a Prolog consists of a series of tests, not instructions.)

```
object(X,banana) :-
         colour(X,yellow),      % X is yellow - this relies on the PCF to
                                  identify ''yellow'' objects
         curved(X),             % X is curved
         length(X,L),           % Length of X is L mm
         L > 100,               % Simple arithmetic test
         L < 250,               % Simple arithmetic test
         width(X,W),            % Width of X is W mm
         W > 20,                % Simple arithmetic test
         W < 50,                % Simple arithmetic test
```

16.4 Multi-spectral Image Data

Conventional colour cameras generate just three output channels (RGB), although there is no fundamental reason why more channels cannot be provided in a solid-state camera. The present limitations are due to commercial rather than technical factors. One manufacturer has recently produced a camera with a fourth VIS channel ("emerald green"). Earth resources satellites have multi-channel scanners, with sensors for visible and infrared radiation. It is possible to build a multi-channel sensor incorporating one of the following.

- Automated monochromator relying on the physical movement of a narrow slit
- As above, but using an LCD optical modulator
- Switched LED arrays providing illumination over multiple narrow wavebands
- Multiple narrow band filters mounted on a rotating wheel
- Digital micro-mirror devices

Many multi-spectral imagers are slow, requiring several video frame periods to complete a multiband scan. It is worth mentioning that data projectors change the spectrum of the light they emit in a rather limited way, by altering the proportions of three primary colours. They do not ever generate "orange" light but only a mixture of red, green and (very little) blue. For this reason, they may be unsuitable for multi-spectral imaging.

Each pixel in a multi-spectral image, covering N distinct wave-bands, may be represented by a point in N-dimensional space. Colour recognition then becomes a standard Pattern Recognition problem and is concerned with partitioning this space. We can employ well-established classification techniques, such as Neural Networks (➜ Chap. 24), Nearest Neighbour and Compound Classifiers (➜ Sect. 16.5 to this chapter). The same mathematical

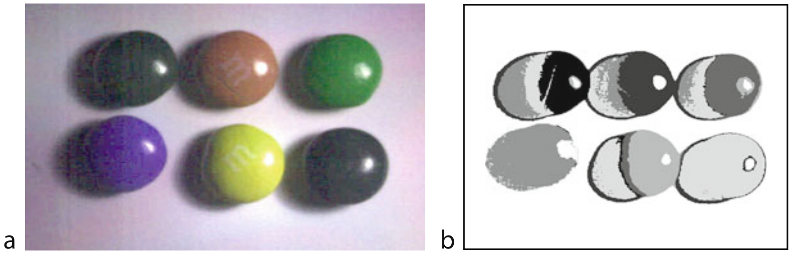

Fig. 16.21
Colour recognition of M&M candies using an NNC, operating in 13-dimensional space. (a) The scene was lit using an intense "point" source placed to the right. (This produces one small highlight on each object). Intensity values from 13 images (obtained by sampling at wavelengths of 460, 480, 500, ..., 700 nm) were combined to give a 13-element vector description of the optical spectrum of each point in the scene. One locate was defined manually on the well-lit side (right-hand side) of each object. Hence, there was only one locate representing each of the six colour classes. This simple method of designing an NNC gives good results in the well-lit areas but does less well where the intensity is low. (The camera is overloaded by the highlights, which therefore create classification errors.) To improve recognition accuracy, it would be necessary to add extra locates, by sampling in the darker areas, as well.

decision making techniques can be used with a mixture of any of the following sensory data and might reasonably be included in the term "multi-spectral":

- Visible light (VIS)
- Ultra-violet illumination and UV sensing
- Fluorescence (This might be UV lighting and VIS viewing, VIS lighting and VIS viewing)
- Phosphorescence
- Infra-red, including but not restricted to thermal imaging
- X-ray
- Range sensing
- Microwave
- Magnetic-field mapping

A simple experiment using a Nearest Neighbour Classifier to recognise colours based on a 13-element representation of colour is shown in ➲ *Fig. 16.21*.

16.5 Supplement

16.5.1 Compound Classifier

This classifier makes a binary decision M = ±1, according to the following rules:

- **X** is a Q-dimensional vector describing the colour at a single point in the input image. It is called the *test vector*. For an RGB image, Q = 3 and
$$\mathbf{X} = [\mathrm{R}, \mathrm{G}, \mathrm{B}]$$
- $\mathbf{X}_i$ ($i \in [1,N]$) is a Q-dimensional reference vector.
- $D(\mathbf{X},\mathbf{X}_i)$ is the Euclidean distance between vectors **X** and $\mathbf{X}_i$.

- C_i ($i \in [1,N]$) is the decision of a sub-classifier and is computed thus

$$C_i = \mathbf{sign}(F_i - D(\mathbf{X}, \mathbf{X}_i))$$

where F_i is a positive real number. This produces a decision surface for the sub-classifier that is a

circle, for $Q = 2$
sphere, for $Q = 3$
hypersphere for $Q \geq 4$

- $M = \pm 1$ is the decision of the Compound Classifier and is equal to

+1 if any one of the $C_i = +1$
−1 if all of the $C_i = -1$.

- The $\mathbf{X}_i$ are called *locates*, since they determine the positions of the circles/spheres/hyperspheres.
- F_i is the radius of the *i*th circle/sphere/hypersphere.

To understand the power and flexibility of the CC, we need only consider the two-dimensional case: drop a handful of mixed coins (all circular) onto a table (➲ *Fig. 16.4e*). The shadow they produce is the decision surface of a CC. Notice that the coins may but need not cast one connected shadow.

By adjusting the $\mathbf{X}_i$ and F_i, the position and size of just one circle/sphere/hypersphere sub-classifier can be altered, leaving all others unchanged. Learning rules for the CC have been devised for two quite different conditions:

(a) When two classes A and B (or A and A′) have to be distinguished (*two-class* learning rule, ➲ *Fig. 16.22*)
(b) When the bounds of a single class have to be defined (*1-class* learning rule, learning to detect anomalies, ➲ *Fig. 16.23*)

It is worthwhile recording some additional points about the CC.

(a) So far, no mathematical proof of convergence for the CC learning rules has been found. However, they have been studied extensively by experimentation and have been found to be effective in a wide variety of situations.
(b) Additional rules have been devised for automatically adding/removing subclassifiers, as needed.
(c) A procedure has been devised for finding a good starting state for the CC, so that the learning time is minimised.
(d) Points should be chosen at random from the image(s) used to generate the input to the learning classifier. It is unwise to scan the image in raster fashion, since there may be slow variations in the colour parameters across the image. Failure to comply with this requirement may result in the classifier learning one set of parameter values ($\{\mathbf{X}_i, F_i\}$) near the beginning of the raster scan of the image, only to be forced to revise then later. (This is the same requirement as is applied when computing parameters of a time series iteratively, rather than globally.)
(e) The CC can employ other distance metrics, instead of the Euclidean Distance. So, for example, it can be based on the *Manhattan* (or *City Block*) *Distance*, or *Square Distance*.
(f) The CC has been implemented in fast electronic hardware [6]. It is possible to connect several boards together, to increase the number of subclassifiers almost indefinitely, without increasing the computation time at all.

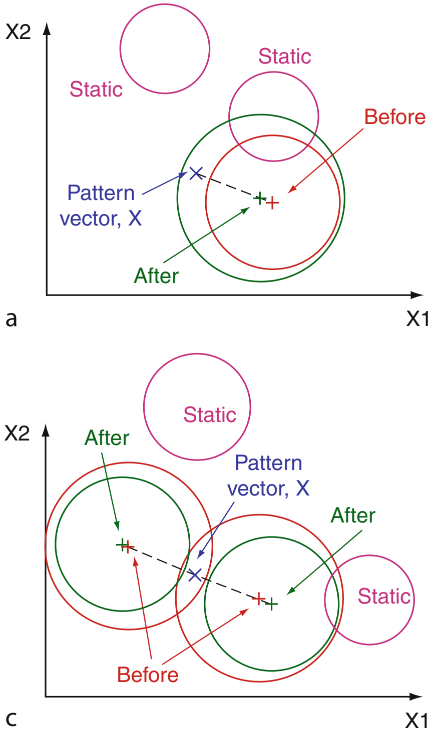

Fig. 16.22

Two-class learning rule for a CC. (a) When M disagrees with T (Teacher decision) and M = −1, the closest circle/sphere/hypersphere is moved towards the vector X and is made larger. Both movement and size changes are very small indeed. (b) When M disagrees with T (M = +1, T = −1) and only one of the subclassifiers produces a decision C_i = +1, that circle/sphere/hypersphere enclosing X is moved away from X and is made smaller. (c) As (b) except that more than one circle/sphere/hypersphere encloses X. In this case, all of them are treated in the same way as described earlier. This process is repeated iteratively, with X vectors selected at random. Additional rules have been devised for adding/removing subclassifiers, as needed [1].

(g) Conceptually, the CC is attractive as it is able to recognise a single compact class among a mass of others. Hence, it is ideally suited to recognising anomalies: a group of hypersphere sub-classifiers encloses the “normal” (i.e., “good”) class. Any deviation outside that region, in whatever direction, is “wrong” and should be signalled as an error.

(h) There is no reason why the inputs to the CC should not be the HSI, YUV or some other colour parameters, instead of the RGB signals that we have proposed. However, little is to be gained by this and it necessarily involves more computation in converting from one set of colour coordinates (RGB) to another. Any two sets that are distinguishable in RGB space are also distinguishable in HSI space, since the transformation between them is reversible. The shape of the surface that separates them will be different. At worst, we will have to use more hypersphere subclassifiers in RGB space but we are saved the effort of converting from HSI to RGB colour coordinates.

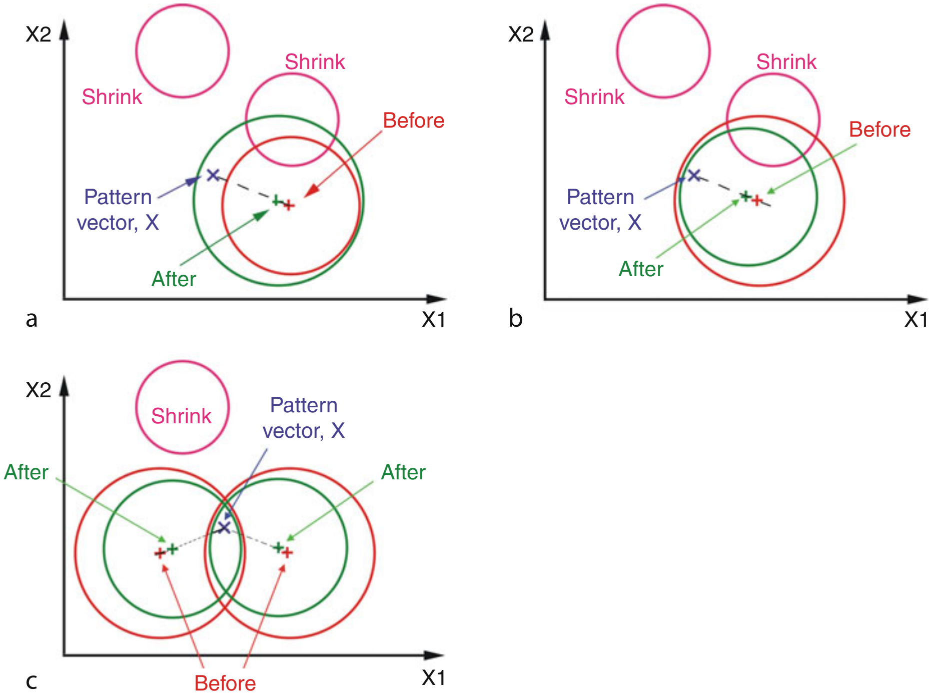

Fig. 16.23

One-class learning rule for a CC. In practice, all changes are much smaller than shown here. (a) When M = −1, the closest circle/sphere/hypersphere is made larger and is moved towards X. All other circles/spheres/hyperspheres are made smaller. (b) When M = +1, and just one circle/sphere/hypersphere encloses X, it is moved towards X and is made smaller. All other circles/spheres/hyperspheres are made smaller. (c) When M = +1 and more than one circle/sphere/hypersphere encloses X, they are all moved towards X and are all made smaller. All other circles/spheres/hyperspheres are also made smaller

16.5.2 Nearest Neighbour Classifier

Mathematically, the NNC is closely related to the Compound Classifier and similar learning rules have been defined. However, the attraction of the NNC is the possibility that exists for an extremely simple design procedure that can make use of very small amounts of data. Like the CC, it has a strong conceptual appeal that owes its origins in the inverse relationship that we instinctively feel should exist between similarity and distance. (This is the *Compactness Hypothesis* and is a central tenet of Pattern Recognition.)

The NNC also stores a set of Q-dimensional vector reference vectors (locates), which we shall again denote by $\mathbf{X}_i$ ($i \in [1,N]$). The Euclidean distance $D(\mathbf{X},\mathbf{X}_i)$ from the input vector $\mathbf{X}$ to each of the $\mathbf{X}_i$ is computed. Each of the $\mathbf{X}_i$ is associated with a particular class label, H_i. (Typically, $H_i \in${“red”,“green”, “yellow”, ...}.) The decision of the NNC is H_j if

$$D\left(\mathbf{X},\mathbf{X}_j\right) < D(\mathbf{X},\mathbf{X}_i), \forall j \neq i$$

(See ➲ *Fig. 16.24*)

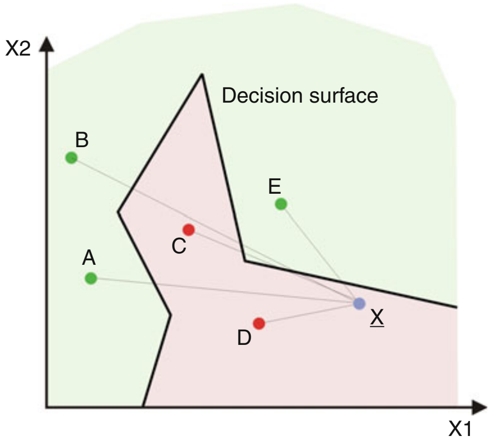

Fig. 16.24
Nearest Neighbour Decision Rule. Locates A, B and E are representatives of class 1; locates C and D are representatives of class 2. X is closer to locate D than it is to any other locate. Hence, it is classified as belonging to class 2, as are all other points in the pink region. The decision surface is piece-wise linear. In 3D space, it consists of planar segments

There are several ways to calculate suitable values for the locates:

(a) For very simple situations where it is clear that there is only one compact cluster for each colour category, the $\mathbf{X}_i$ may be taken to be the means of those classes. This will only be effective if all intra-cluster distances are smaller than every inter-cluster distance. That is, if **X** and **Y** are both associated with class H_i but **Z** is associated with class H_j $(i \neq j)$ then the following condition should be met

$$D(\mathbf{X}, \mathbf{Y}) < D(\mathbf{X}, \mathbf{Z}).$$

(see ➲ *Fig. 16.25*)

(b) In those situations where the colour classes are well separated but do not satisfy the condition just defined, it is possible to employ any one of a variety of cluster analysis techniques. For example, using a procedure called *Maximindist* (described below), it is possible to identify a small set of points that are guaranteed to be representative of each cluster. An elongated cluster is represented by a set of points scattered along its longest axis (➲ *Fig. 16.4e*).

(c) Iterative rules for moving the locates when the decision is wrong have been devised for the NNC. These are very similar to those already detailed for the CC and are summarised in ➲ *Fig. 16.26*. The adjustment made in response to an individual error is very small. Learning is made faster by starting the process with a set of locates found by Maximindist.

A few points should be noted about the NNC:

(i) It is unwise to use any metric other than the Euclidean distance, as the decision surface is unstable under certain conditions.

(ii) The decision surface of the NNC is piece-wise linear.

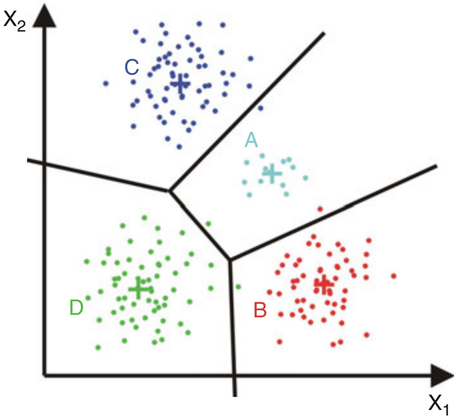

Fig. 16.25

Using class means to define the locates for an NNC is only effective if the colour classes are small, compact and are well separated from one another. In this case, there are some errors, since cluster diameters are not taken into account.

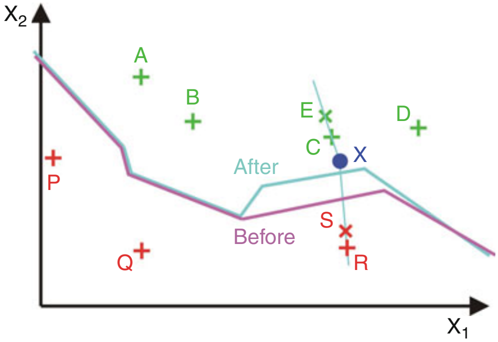

Fig. 16.26

Error correction learning in an NNC. A, B, C, D are locates representing class 1, while P, Q, R represent class 2. The pattern vector X is assumed to have been misclassified as belonging to class 1 instead of class 2. The locate closest to it (C) is moved a short distance away from it (to E), while the closest locate from class 2 (R) is moved a little closer (to S). Although X is not reclassified as a result of this single adjustment of the locate positions, the movement is exaggerated here for clarity. This process is repeated iteratively, with X vectors selected at random

(iii) Any decision surface generated by a multi-layer neural network of Perceptron-like devices can be implemented by an NNC.

(iv) It is possible to implement the NNC using a look-up table (LUT) to perform subtraction and squaring (in a single step) and without taking square roots. This can assist both hardware and software implementations (➜ Chap. 17).

(v) Sometimes, it is possible to identify possible locates by simple visual examination of the three-dimensional scattergram of RGB values.

(vi) The NNC can be applied directly to the RGB signals generated by a colour camera, or to the HSI/YUV parameters. (Some linear rescaling may be necessary to ensure that each input to the NNC has the same range.)

Both the CC and NNC can produce good results in colour discrimination tasks, provided enough care in taken in their design/learning phases.

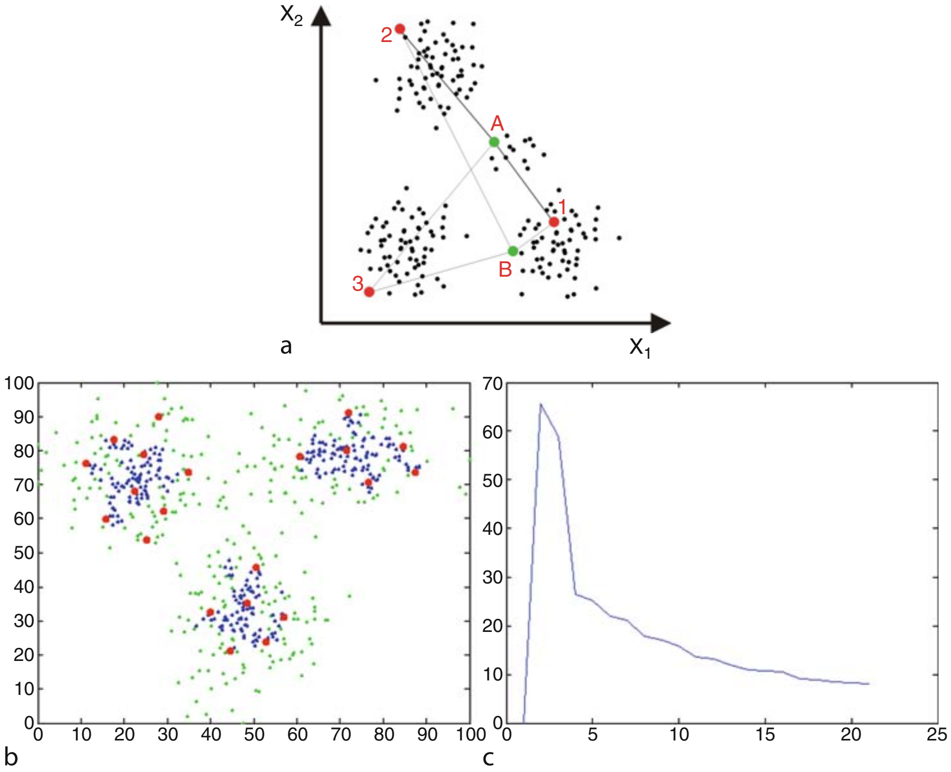

Fig. 16.27

Removing outliers and the Maximindist procedure. (a) Maximindist takes its name from the fact that it relies on finding the maximum value of the minimum distance between a candidate point and those points already stored, in this case {1,2,3}. When trying to find the fourth point, A is preferred to B because it is further away from its closest neighbour (1) than B is from its closest neighbour (also 1). The procedure begins by choosing the first point (1) at random from the given data set. (b) Green: points lying in three clusters, generated using pseudo-random number generators. Blue: points remaining after outliers were removed. (K = 1) Red: 20 points remained after Maximindist was run on the set of blue points. (c) Maximin distance plotted against the number of stored points

16.5.3 Removing Outliers and Maximindist

A point is regarded as an outlier if the distance between it and its nearest neighbour is greater than some pre-defined constant (K) times the average distance between all other points in the data set and their nearest neighbours. Typically, K is about 1 (➲ *Fig. 16.27b*).

It is much easier to appreciate Maximindist from a simple diagram, rather than trying to define it in formal mathematical terms (➲ *Fig. 16.27*).

Abstract: When a vision procedure has been devised, perhaps using an interactive image processing system, it must be engineered before it is ready for use in a factory floor system. A prototype procedure found in this way has probably not been optimised for speed, compatability with other parts of the system, or ease of implementation. It may not even be the most effective procedure of the same general type. For example, it might employ one image filter, such as an edge detector, whereas another would perform just as well and be much easier to implement. This chapter explores a range of grey-scale and binary image processing functions, demonstrating that many algorithms present parallel options. It is well to investigate every stage of an image processing procedure to see if it can be replaced by a more convenient, or more efficient, alternative. Each part of an image processing procedure must be compatible with all of the others. Sometimes, the way an image is represented can make a large difference in the ease of implementation, or speed of execution. On some occasions, a mathematically rigourous procedure (algorithm) can be replaced by a much more convenient "rule of thumb" (heuristic), without serious loss of performance. If used sensibly, heuristics may make a system work in a very much more cost-effective way than would otherwise be the case. Heuristics can sometimes replace algorithms, with little or no loss of performance. In some instances, heuristics can greatly improve the speed compared to an algorithm, so that slightly reduced accuracy is acceptable. It is important to bear in mind what the real objective of a vision system is. Suppose we wish to build a machine to count large numbers of objects like dice. Should we count white rectangles, representing the top surfaces of the dominoes, or black spots and then divide the result by three? On a sufficiently large sample, these two procedures produce similar results. Thinking in terms of statistical performance is an important part of designing an effective vision system. Heuristics can often be made to cope safely with situations that have never been seen before. A "catch all" rule, such as "*If all else fails, switch off the power,*" can guarantee the safe operation of a complex plant, even if it occasionally reduces production efficiency unnecessarily. Emotional objections to procedures that are know to fail occasionally can sometimes be very strong but it is well to consider the frequency of such an event. However costly a mistaken decision is, its overall significance may be small if it occurs very infrequently. Heuristics can often be biased deliberately to improve safety, or to improve productivity. One particularly useful heuristic rule for an automated inspection system is to refer doubtful cases to a human being for examination and/or rework. There is another very useful heuristic that we should always apply: try to improve the quality of the "input" images by adjusting the lighting-viewing conditions!

17.1 Introduction

This chapter is based on three axioms:

1. Machine vision is an engineering discipline, not a mathematical or philosophical exercise.
2. There is no unique way to perform any given image processing function; every algorithm can be implemented in many different ways.
3. A given calculation may be very difficult using one implementation technology but very easy with another.

Given a certain method of implementation, simply reformulating an algorithm can often convert a "difficult" calculation into one that is straightforward, perhaps even trivial. It is important, therefore, that we gain some understanding of the way that algorithms can be reformulated before we consider the choice of implementation technology.

In every engineering design exercise, there are numerous factors specific to the task in hand. These must be carefully considered and properly balanced if we are to achieve a robust and effective system. In the case of machine vision, these include the shape, material and optical properties of the object that is to be examined. Moreover, the modus operandi of the inspection system, its environment within the factory, and the skills and attitudes of the people who will work with it all have a critical role in system design. There are three critically important constraints, which are present in almost every engineering project. These relate to cost, performance and operating speed. Another common constraint is the desire to use technology that is familiar, tried and trusted. Together, these constraints may well preclude the use of certain implementation techniques and hence certain algorithms too. We cannot simply rely on mathematical analysis alone to provide sufficient commendation for using a given algorithm. This point is of fundamental importance for our discussion in this chapter. Our experience has shown that operational, management and performance constraints, such as those just listed, almost invariably impose far tighter control than "academic" discussions about whether we should use, say, one image filter rather than another.

We should never take it for granted that an algorithm must be performed in a given way. In particular, we should not expect that the initial explanation we gave in ➋ Chap. 14 necessarily defines how we are to implement a given algorithm. Indeed, we should always ask ourselves whether the algorithm is expressed in the best way possible and question whether reformulating it would lead to a better implementation. We should also investigate whether a similar algorithm, an approximate method, or an heuristic procedure is good enough for the given application. In the context of designing machine vision systems, *sufficiency*, rather than optimality, is the key concern. We must always be very wary of claims about optimality, because these are almost invariably based on some spurious assumption about what constitutes an "optimal solution." As in any engineering design process, all assumptions must be based on experience, judgement and common sense. We must not rely blindly on mathematical rigour, since mathematics only very rarely provides a true model of the real physical world. An old adage states that "*If you can perform the mathematics, then you don't understand the engineering.*" This is, of course, a gross simplification, but it paraphrases a vitally important truth. The reader should make no mistake about the authors' commitment to using rigourous mathematical analysis, wherever and whenever it is appropriate to do so. The most important point to note, however, is that there is a balance to be obtained: using algorithms, heuristics and approximate methods in a sensible reasoned way can lead to great improvements in the overall efficiency of a machine. The two latter categories of computational procedure may provide the basis for the design of a cost-effective machine vision system that is reliable and robust. On the other hand, mathematical analysis often yields deep insights that are not intuitively obvious. We must not forget, however, that as far as an engineer is concerned, one of the most foolish uses of mathematics is to prove what has been self-evident for years. More irritating still is the abuse of mathematics by using an incorrect or deficient physical model to "prove" that certain things are not true in the real world. To illustrate this point, we need only remind the reader that for many years the known laws of aero-dynamics were not able to "prove" that bumble bees can fly [11]. In other words, formal mathematical analysis based on erroneous/deficient physical or engineering models would lead us to believe that bumble bees cannot fly. The "proof" that this is not so is easily obtained: simply go into a garden on a summer’s day. Sticking doggedly to only those algorithmic techniques with absolutely certain mathematical pedigrees is both limiting and likely to give us a false sense of confidence.

The choice of metric used to quantify algorithm performance almost inevitably involves our making an arbitrary and oversimplified choice. This can seriously affect the conclusions we reach about the performance of a vision system. There is an outstanding example of this in a paper that we encountered recently. An “objective” performance criterion was defined in terms of an *arbitrarily chosen* metric. A number of image filtering methods were then analysed mathematically. As a result, one of them was found to be “superior” to all others. If a slightly different algorithm performance criterion had been selected, then a different filter might have been judged to be “best.” In some situations, the ability to implement an image filter using an electronic circuit module with a power consumption of less than 100 μW might be a more appropriate criterion to apply, rather than some abstract mathematical performance metric. The latter might, for example, be based on the familiar concept of “least squares fit,” but there cannot be any guarantee that this is in any way meaningful in any absolute sense. The reader should understand that we are not arguing that mathematical analysis has no place in the design of machine vision systems. It most certainly has a very important role, but mathematics must take its place alongside many other algorithm selection criteria, in order to obtain a balanced engineering compromise. We are simply arguing that we must not judge the design of a machine vision system using any one-dimensional cost performance criterion. (Even “cost” is a multi-dimensional entity.)

Our objective in this chapter is to explore the possibilities for expressing vision algorithms in a variety of ways. There is also the possibility of using approximate computational methods. Finally, we point out that techniques that are known to “fail” in some situations (i.e., heuristics) can sometimes provide a perfectly acceptable solution to the broader engineering design task.

We will find it convenient to use short mnemonic names to denote what might be quite complex image processing operations. For this reason, frequent use is made of the names of functions implemented in the QT image processing language described in ➲ Chaps. 21 and ➲ 41. The operations of these functions will be described as we encounter them here.

17.1.1 One Algorithm, Many Implementations

We will begin by discussing ordinary arithmetic multiplication. This will allow us to introduce the main points that we wish to emphasise in this chapter. By discussing an apparently straightforward task, that is clearly relevant to many different areas of computation, in addition to machine vision, we hope to explain why we felt it necessary to include this chapter in our book.

Consider the deceivingly simple task of multiplying two numbers together:

$$C = AB \tag{17.1}$$

Multiplication may be performed using a rather complicated digital hardware unit based on an adder, shifter and recirculating data register. In some situations but by no means all, this may be the most convenient implementation technique. Special purpose integrated circuits, based on this idea or arrays of gates, are readily available but in certain applications may not provide the best solution.

Logarithms can, of course, be used to replace the process of multiplication with the simpler operations of table look-up and addition. We can use the well-known relationship:

$$C = \text{antilog}(\log(A) + \log(B)) \qquad (17.2)$$

If the variables A and B are short integers, the log and antilog functions can be performed conveniently using look-up tables, implemented in ROM or RAM (➲ *Fig. 17.1*). The reader will, no doubt, have already anticipated the complications that arise when the variables A and/or B are allowed to assume values close to zero. However, we will not dwell on this topic here.

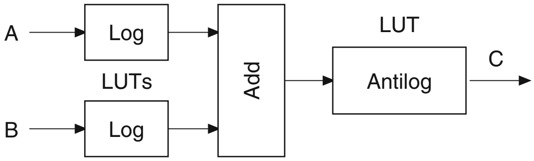
Another possibility is to use the so-called *quarter-squares method*, which makes use of the following identity:

$$A\,B = \left[(A + B)^2 - (A - B)^2\right]/4 \qquad (17.3)$$

Suppose that we are proposing to use an implementation technology which finds it easy to perform addition, subtraction and squaring, perhaps by using a look-up table (➲ *Fig. 17.2*). In this case, the quarter-squares method can be very effective indeed. (Older readers may recall that this method was used in the heyday of analogue computers to perform multiplication.) In certain circumstances, the quarter-squares or logarithm methods, implemented using look-up tables, might be more effective than the direct implementation of➲ Eq. 17.1.

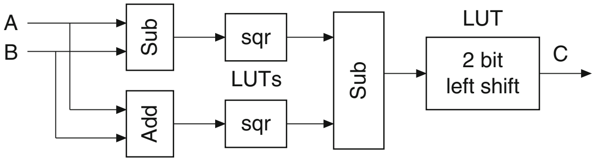
So far, we have tacitly assumed that both A and B are variables. However, if either of them is a constant, the implementation can be simplified quite significantly. If we wish to multiply a given number, represented in digital parallel form, by a constant, the use of a simple look-up table implemented using a Read Only Memory (ROM), is probably the simplest implementation technique (➲ *Fig. 17.3*).

Suppose, however, that the constants are always integer powers of 2. In this case, "multiplication" reduces to a simple bit shift operation, which may be implemented using nothing more complicated than a piece of wire! (➲ *Fig. 17.4*).



■ **Fig. 17.1**

Multiplying two numbers, A and B (typically 8-bit parallel) using logarithms. The *log* and *antilog* functions are implemented using look-up tables, possibly using ROMs



■ **Fig. 17.2**

Multiplying two numbers, A and B (typically 8-bit parallel) using the quarter-squares method. The *sqr* (square) functions are implemented using look-up tables, possibly using ROMs

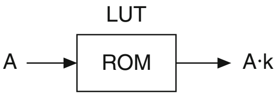


Fig. 17.3
Multiplying a number (typically 8-bit parallel) by a constant

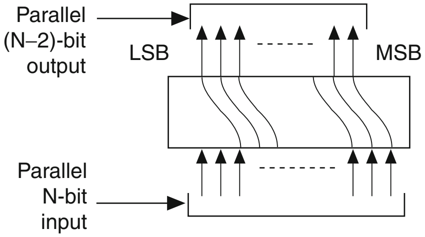

Fig. 17.4
Multiplying a number (typically N-bit parallel) by a constant of the form 2^M, where M is an integer. The figure shows the configuration for M = −2 (i.e., dividing by 4)

The reader might well question whether this discussion has any direct significance for image processing. To see one straightforward example where this relevance can be demonstrated, consider the arithmetic operations needed to implement the linear local operators, viz:

$$E \Leftarrow K_1(W_a A + W_b B + W_c C + W_d D + W_e E + W_f F + W_g G + W_h H + W_i I) + K_0 \quad (17.4)$$

At first sight this seems to indicate that we need to use 10 multiplications and 10 additions. Do we really need to use floating-point, or long-integer, arithmetic? Can we work with, say, an 8-bit representation of intensity (i.e., the variables, A, B, ..., I)? Can we obtain sufficiently accurate results using weights (W_a, W_b, ..., W_i) that are all integer powers of 2? If so, the problem reduces to one where we could use just one multiplication (i.e., K_0 (...)) and nine shift operations. Even if we must use general integer values for the weights, we can probably still manage to use a series of nine look-up tables, implemented using ROM/RAM, to compute the intermediate products $W_a A$, ..., $W_i I$ (➋ *Fig. 17.5*).

17.1.2 Do Not Judge an Algorithm by Its Accuracy Alone

We cannot afford to make a decision about which algorithm to use on the basis of its performance alone. To do so would be nothing short of stupid! There are many different technologies available to us when we come to build a vision system. Indeed, in a single vision system there are inevitably several different image/information processing technologies coexisting and cooperating together. These include optics, opto-electronic signal conversion (camera/scanner), analogue electronics, digital electronics, software. They all have their own peculiar strengths and weaknesses. An image processing algorithm is a mathematical prescription for a computational process which describes the operation of part of the data-processing chain. (When we use the term "image processing algorithm" in connection with a vision

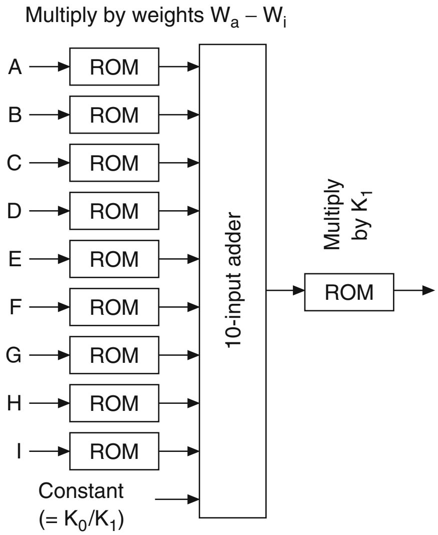

Fig. 17.5
A ROM-based implementation of the 3 × 3 linear local operator (Eq. 17.4) This diagram does not explain how the inputs A, B, ..., I are generated

system, we normally intend it to refer to the later stages in this chain, probably just the digital electronics and the software.)

Clearly, the speed of a machine is of great importance, but even this seemingly simple term has complications, because there are two components:

1. *Throughput rate.* (Number of images processed, or objects inspected, per second.)
2. *Latency.* (Time delay from digitisation of an image to appearance of result.)

An on-line inspection system, working in conjunction with a continuously-moving conveyor, can usually tolerate a high latency, whereas a robot vision system cannot [4]. Hence, the term “real time” needs some qualification, in practice.

A popular way of representing algorithm complexity uses the O(N) notation. Suppose that a certain algorithm requires an execution time of

$$A_0 + A_1N + A_2N^2 + A_3N^3 + \cdots + A_mN^ms,$$

where the A_i ($i=1, ..., m$) are constants and N is the number of data samples. (N is very likely to be related to the number of pixels in the image.) When N is very large, the term A_mN^m dominates all others and hence the algorithm is said to be of complexity $O(N^m)$. We do not always find that a simple polynomial function describes the execution time. For example, certain number-sorting algorithms require an execution time that is proportional to N log(N) (for very large values of N) and hence are said to have complexity O(N log(N)). While some number-sorting algorithms have a higher complexity than this (typically $O(N^2)$), they may actually be easier and faster to implement in digital electronic hardware. For example, a simple *bubble-sort* algorithm (complexity $O(N^2)$) can be implemented in an iterative digital array. *Figure 17.6* shows the organisation of a hardware unit for implementing 3 × 3 *rank filters*

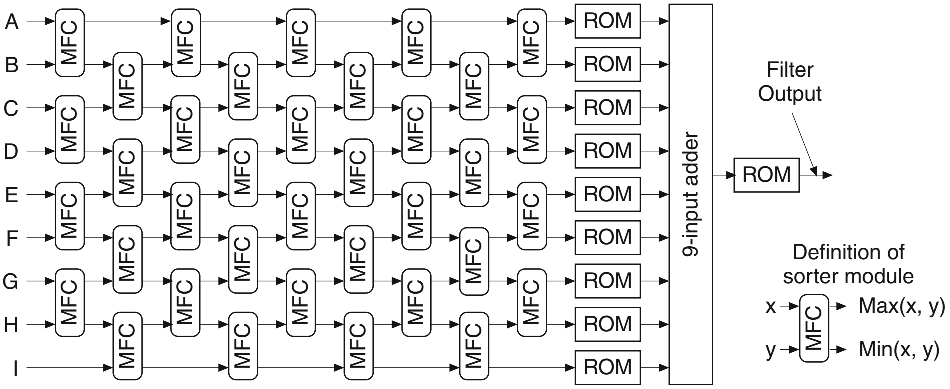

Fig. 17.6
Rank filter implemented using an iterative array performing a 9-element *bubble sort*

(Chap. 14), which require the ranking of a small number of numeric items. This iterative array uses the ideas implicit in the bubble sort. On the other hand, the *merge sort* has complexity O(N · log(N)) and for this reason is often preferred in software implementations. However, this cannot be implemented in digital hardware in such a neat manner. The general point to note is that, although the O(N) notation is very popular with mathematicians, it is not always a useful indicator of speed in a practical system.

17.1.3 Reformulating Algorithms to Make Implementation Easier

We have already made the point that there are many ways to implement a given algorithm and, in the latter parts of this chapter, we will give several examples to illustrate this. There are likely to be many similar image processing algorithms resembling a given procedure. For example, there is a wide range of edge detection operators [e.g., QT operators *sed, red, gra* and *edd*]. The point has been made elsewhere that, if the choice of edge detection operator is critical, then there is a problem somewhere else in the vision system – probably in the lighting! (Appendix C) Bearing this in mind, we may be able to improve the quality of the input image by choosing the best possible lighting, optics, viewing position and camera, and thereby allow ourselves the luxury of using a sub-optimal image filter that is easy to implement.

An experienced vision engineer very often realises that one algorithmic "atom" can be substituted for another in a processing sequence, producing very little effect on the overall system performance. To evaluate possible substitutions of this kind, it is essential to work with a convenient (i.e., *interactive*) image processing "tool kit." An experienced system designer may well be able to anticipate which algorithms can safely be substituted in this way, but "blind" predictions like this are frequently mistaken. To be certain about the wisdom of employing the proposed revised algorithm, it must be assessed in a rigourous experimental manner. Much of the knowledge about what substitutions are sensible might, one day, be incorporated into an expert system but, to date, this has not been done, except at the most trivial level. At the moment, an experienced engineer armed with appropriate tools (such as an interactive image processor like QT or NEATVISION (➲ Chaps. 21 and ➲ 22)) remains the best way to perform the high-level reasoning needed to design/redesign a vision algorithm.

In the previous chapter, we introduced several different types of image representation. As we will soon witness, these are particularly useful because certain algorithms can be reformulated very effectively using one form of image representation (e.g., chain code, run-length code, etc.), rather than the standard array representation. A prime example of this is to be found in the algorithms available for computing the convex hull of a blob-like figure. (Incidentally, this can be implemented even easier using the polar vector representation. See ➲ Chap. 14)

17.1.4 Use Heuristics in Lieu of Algorithms

A heuristic is a "rule of thumb" which is known to achieve a desired result in most cases, without necessarily being able to guarantee that it is always able to do so. On the other hand, an algorithm is always able to achieve the desired result. Why should we be prepared to accept a procedure which is known to fail in some situations? In our normal everyday lives, we use heuristics freely and without any serious misgivings. For example, a person drives to work each morning along a road that experience has shown is able to get him there quickly. However, there are exceptions: one day last week, a car had broken down on the road and the author of this chapter was delayed for several minutes before he could complete his journey. That day, his heuristic for getting to work on time failed but it worked well this morning and it does so on most working days. There simply is no algorithm for getting to work on time. It is clearly impossible, in any practical way, to collect all of the information that would be needed to predict accidents or the breakdown of vehicles on the author's route to work.

17.1.5 Heuristics May Actually Be Algorithmic

Heuristics can be very accurate and may actually be algorithmic without our knowing it. (We may not be clever enough to do the necessary mathematics to prove that a given procedure is algorithmic.) Very general heuristic rules can often cope with unexpected situations more comfortably and often more safely than "algorithms." Once we violate the conditions of use of an algorithm, we cannot guaranteed that it will generate valid results. Mathematical criteria defining conditions of use exist for good reason. If we violate them, we cannot properly anticipate the results. We might, for example, wish to relax the Dirichlet conditions for Fourier series expansion. It is highly unlikely that we could ever know for certain whether the result is mathematically valid, although by experimentation and/or computer simulation, we may be able to satisfy ourselves that it is "good enough." The important points to note are that what we regard as an algorithm may not be so, and that a procedure that is not yet proven to achieve a "valid result" in every situation may in fact do so. The reader will observe a parallel here with Gödel's theorem. There are provable truths (algorithms that are known to be true), unprovable truths (procedures that are not known to be algorithmic but are true), unprovable untruths (e.g., procedures that fail in some as yet undiscovered way), and provable untruths (heuristics that are known to fail occasionally). However, we should not take this analogy with Gödel's theorem too far, since it has no rigourous basis in logic.

17.1.6 Primary and Secondary Goals

Suppose that we are faced with the task of designing a machine that counts coffee beans, given an image such as that shown in *Fig. 17.7a*. Now, we know that we can count blobs in a binary image using the QT operator *cbl*. This, combined with the prior use of a thresholding operator (*thr*), seems highly appropriate, since the latter converts the grey-level input image into a binary image. A simple experiment (*Fig. 17.7b*) soon shows that these two operators [*thr(_), cbl*] are unable to provide the needed precision. So, we soon conclude that we should have used some suitable image filtering (smoothing), to pre-process the images before thresholding. This seems a very reasonable approach and is certainly worth investigating further. However, we must be clear that the real (i.e., primary) objective is counting coffee

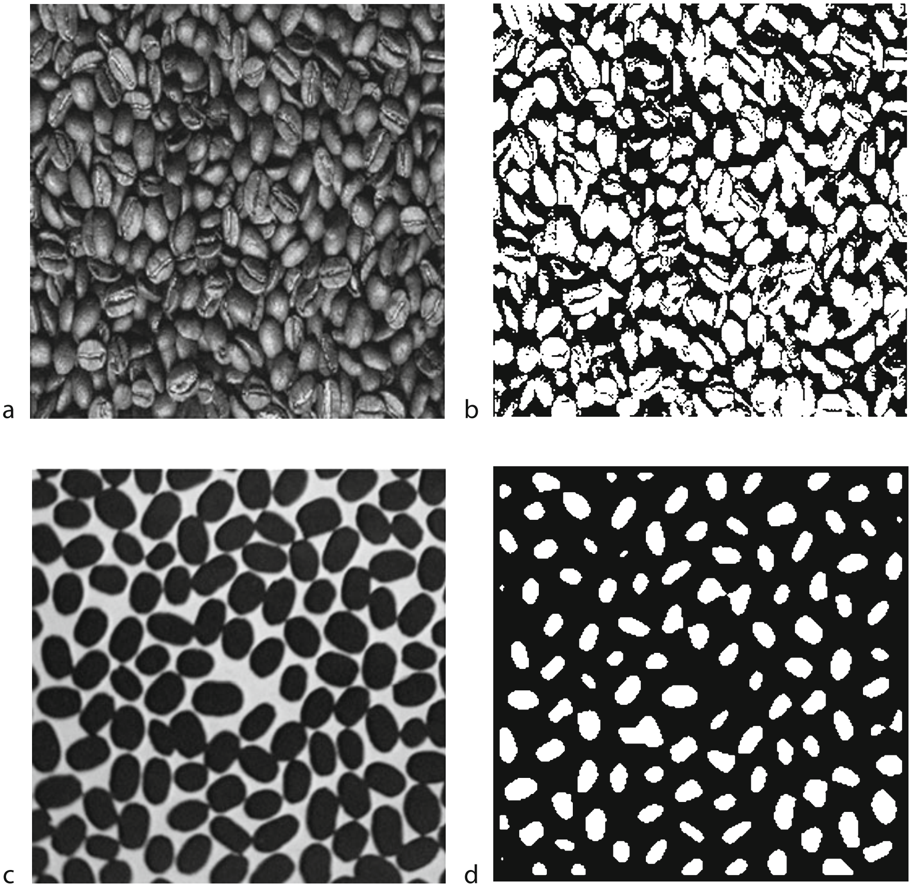

Fig. 17.7

Counting coffee beans. (a) Original image. Front lighting yields an image that is difficult to process. (b) Simple fixed parameter thresholding. Filtering can improve matters but not well enough to give a reliable count. (c) A different original image. Back lighting is superior. (d) Better separation, obtained using *[QT: ecn, thr, neg, gft, enc, raf, thr (100)]*

beans, not blobs in a binary image. In order to make some progress, we were forced to make *some* assumptions but, as we will show, this one is not the best. In this instance, the assumption we have made is that the primary task (counting beans) can be replaced by two or more secondary tasks: filtering, thresholding and blob counting. This is a reasonable working hypothesis but nothing more. After struggling for a long time to find a suitable filter, most people would probably conclude that they cannot generate a suitable binary image for this process to be reliable. (It is impossible, in practice, to obtain a "clean" binary image in which each bean is represented by just one blob.)

Eventually, we reassess our initial assumption and realise that we do not need to produce one blob for every bean. In this type of application, a statistically-valid answer is acceptable. We need to reassess our initial assumption that *cbl* is the way to count blobs. Suppose that a certain filtering and thresholding operation together produces on average 1.53 white blobs per bean, with a small standard deviation. Then, we can count blobs using *cbl*, the Euler number (*eul*), or any of a number of other procedures. In other words, there is nothing special about *cbl*. We might well find that we can substitute other techniques and still obtain a statistically-valid result. (We may find, of course, that the scaling factor relating the "blob count" to the "bean count" has to be revised. Recall that this was 1.53 for the operator *cbl*.) Our initial assumption that *cbl* is "the way" to count blobs and that we could obtain just one blob per bean was inappropriate, even though it seemed so reasonable when we began. Few image processing operations have a better claim to being "algorithmic" than *cbl*, yet we are forced here to concede that this "guarantee of performance" means nothing; we are using an *algorithm* in a process which is being *judged statistically*. By substituting *eul* or another "blob count" procedure for *cbl*, we may be making little or no sacrifice in the overall performance of the bean counting system, or even conceivably improving it. The QT operator *cbl* counts eight-connected blobs, whereas we might have chosen to base the definition on four-neighbours. Whichever we choose, the decision is quite arbitrary. For practical purposes, when counting coffee beans we might well find that *eul* produces results that are just as accurate in estimating the bean count.

In practice, we would probably find it more convenient to alter the method by which beans are presented to the camera. The image processing task is then much simpler and more reliable (➜ *Fig. 17.7c*, *d*).

17.1.7 Emotional Objections to Heuristics

Many people have a serious emotional objection to using heuristics, because they cannot be guaranteed to give the correct result always. Such objections are more likely to arise when there is a known, often deliberately contrived, counter-example which makes a given procedure "fail." People often become confused at such a discovery, however unlikely or unimportant that "pathological" situation may be in practice. Even very intelligent people are often very poor at judging the statistical frequency and/or absolute importance of rare events. One has only to look at everyday life to see how frequently rational judgement is suspended, despite incontrovertible evidence to the contrary. (For example, the popularity of gambling and driving fast, as well as the fear of flying and crime provide four such examples.) If an inspection system is known to ignore or give an inappropriate response, even on very rare or unimportant cosmetic faults, many managers will be unhappy to accept it. This caution will be "justified" on the grounds that senior management will not condone installing a machine with *any* known shortcomings. This thought process is not always rational, since there may be no alternative solution that is able to provide the "correct" results with 100% certainty. The important point to note is that, in reality, there is no sharp dichotomy between algorithms which *always* work and crude, approximate heuristics which do not. The concept of an algorithm-heuristic continuum is a more appropriate model for the situation in the real world. Another point is that the performance of a vision system is often judged *statistically* not "*logically*." This is not a new idea, since we judge people on "statistical" evidence. All that we are asking is that machine vision systems and their component computational processes be judged in the same way.

17.1.8 Heuristics Used to Guide Algorithms

Heuristics can be used to guide algorithms. For example, we may use a heuristic simply to speed up an algorithm. In this case, when the heuristic fails, the algorithm simply slows down but still yields a known result. A prime example of this is to be found in hill-climbing. Heuristics can be very effective at finding local maxima, whereas an exhaustive search algorithm will always find the true maximum. Similarly, a heuristic may be used to speed up the process of finding "good" routes through a maze but an algorithm is able to guarantee that the final result is optimal. Heuristics are useful in those situations where knowledge of one good solution can lead to a rapid means of finding a better solution.

17.1.9 Heuristics May Cope with a Wider Range of Situations

A well-designed set of heuristic rules can often cope with a far wider range of situations than an algorithm is known to cover. This is possible because heuristics are able to encapsulate human experience, using the same language that people use to understand and express them. Such rules of thumb are usually not definable in strict mathematical form and are expressed in terms of a natural language, such as English. Normally such rules are then recoded into a computer language. (Prolog and hence PQT are very appropriate for use in this role. ➋ Chap. 23.) It is entirely inappropriate to try to force mathematics where it does not fit naturally.

Lastly, we simply pose an important question: Is an algorithmic solution really necessary? We often have to overcome ignorance, prejudice and ill-informed opinion in order to overcome the emotional barrier that prevents many people from accepting "solutions that are known to fail." When a non-technical manager is involved in making decisions about the use of heuristics rather than algorithms, there is always the danger that his natural inclination will be to reject heuristics in favour of algorithms, believing that the latter inevitably gives a better result. We hope to show in the pages that follow that this is often not the case.

17.2 Changing Image Representation

In ➋ Sect. 14.1 we discussed a number of ways of representing images in digital form. It will become clear later that some algorithms and heuristics can be expressed more naturally in one form rather than another. For this reason, we will explain first how images can be transformed from one representation to another.

17.2.1 Converting Image Format

The array representation arises naturally from standard array-scan cameras and line-scan cameras which are repeatedly scanned to build up a 2-dimensional image. It is natural to associate each photo-detector site on the camera with one pixel in the digital image. The array representation therefore represents a reasonable starting point for image processing function, and the other coding methods can be derived from it.

17.2.1.1 Array Representation to Run Code Representation

The run code (or run-length code) is a more compact form of representation for binary images than the array code and can be derived from a video signal using fast low-cost electronic hardware (see ➋ *Fig. 17.8*). The operation of this circuit is quite straightforward: Counter 1 indicates how many pixels have been encountered in a raster scan through the image since the last black-white or white-black intensity transition. This value is stored in the RAM. (The box labelled "MUX" selects the input arising from Counter 1.) This counter is reset at the beginning of each new line, and whenever a black-to-white or white-to-black intensity transition occurs. Counter 2 indicates how many items have been stored in the RAM. Notice that a special symbol, called the *inter-line marker*, is stored in the RAM to indicate the end of each row of the image. This symbol is presented to the RAM's *data* input via, the multiplexor (MUX), when the *line sync/new line* signal is high. The format for data stored in the RAM is as follows:

$$\{R_{1,1}, R_{1,2}, \ldots, R_{1,n1}, *, R_{2,1}, R_{2,2}, \ldots, R_{2,n2}, *, R_{m,1}, R_{m,2}, \ldots, R_{m,nm}\}$$

Fig. 17.8

The run code can be generated in simple digital or analogue hardware. A simple low-cost circuit such as this can perform run-length encoding in real time on a video signal. This is important because the run code transforms many "difficult" calculations into trivial ones

where $R_{i,j}$ denotes the ith run in row j and ‘ ∗ ’ denotes the Inter-line marker. Notice that $R_{i,1}+R_{i,2} \cdots + R_{i,ni} \le N$, where N is the number of pixels along each row. The same circuit can be used for both analogue and digital video inputs with very little modification.

17.2.1.2 Array Representation to Chain Code Representation

The chain code can be derived from the array representation of a binary image in at least two ways:

(a) Perform a raster-scan search for an edge. Then, follow that edge until the starting point is revisited. This process is repeated until all edges have been traced (➋ *Fig. 17.9*). In this procedure, each edge point is visited not more than twice. If, as in some applications, we can be sure that there is only one object silhouette (i.e., only one blob) in the binary image, then the algorithm need visit only $(m \cdot n+N_{edge})$ pixels, where the image resolution is $m \cdot n$ pixels and there are N_{edge} edge pixels.

(b) Use pre-processing to label each edge point in the image. The labels (➋ *Fig. 17.10*) indicate the chain code. (Some special symbol is used to indicate non-edge points.) Then, trace the edge to “thread” the chain code elements together into a string [3].

While procedure (b) seems to be more complicated, it is well suited to implementation using dedicated hardware. Either a parallel processor or a pipe-line processor can perform the initial edge labelling at high speed. The latter can, for example, perform the initial edge coding in a single video frame-period. There then remains a serial process in which N_{edge} pixels are visited, as they are “threaded” together.

In algorithm (b), tracing the edges is performed by a serial process, which uses the binary neighbourhood coding scheme explained in ➋ *Fig. 17.10*. The preprocessing engine, whether it be a pipe-line or parallel processor, assigns a number (a pseudo-intensity value) to each pixel to describe its eight-neighbourhood. The serial processor then uses this value as an index to a look-up table, in order to locate the next edge point in the edge to be chain-coded. The same binary neighbourhood coding will be encountered in several places later in this chapter.

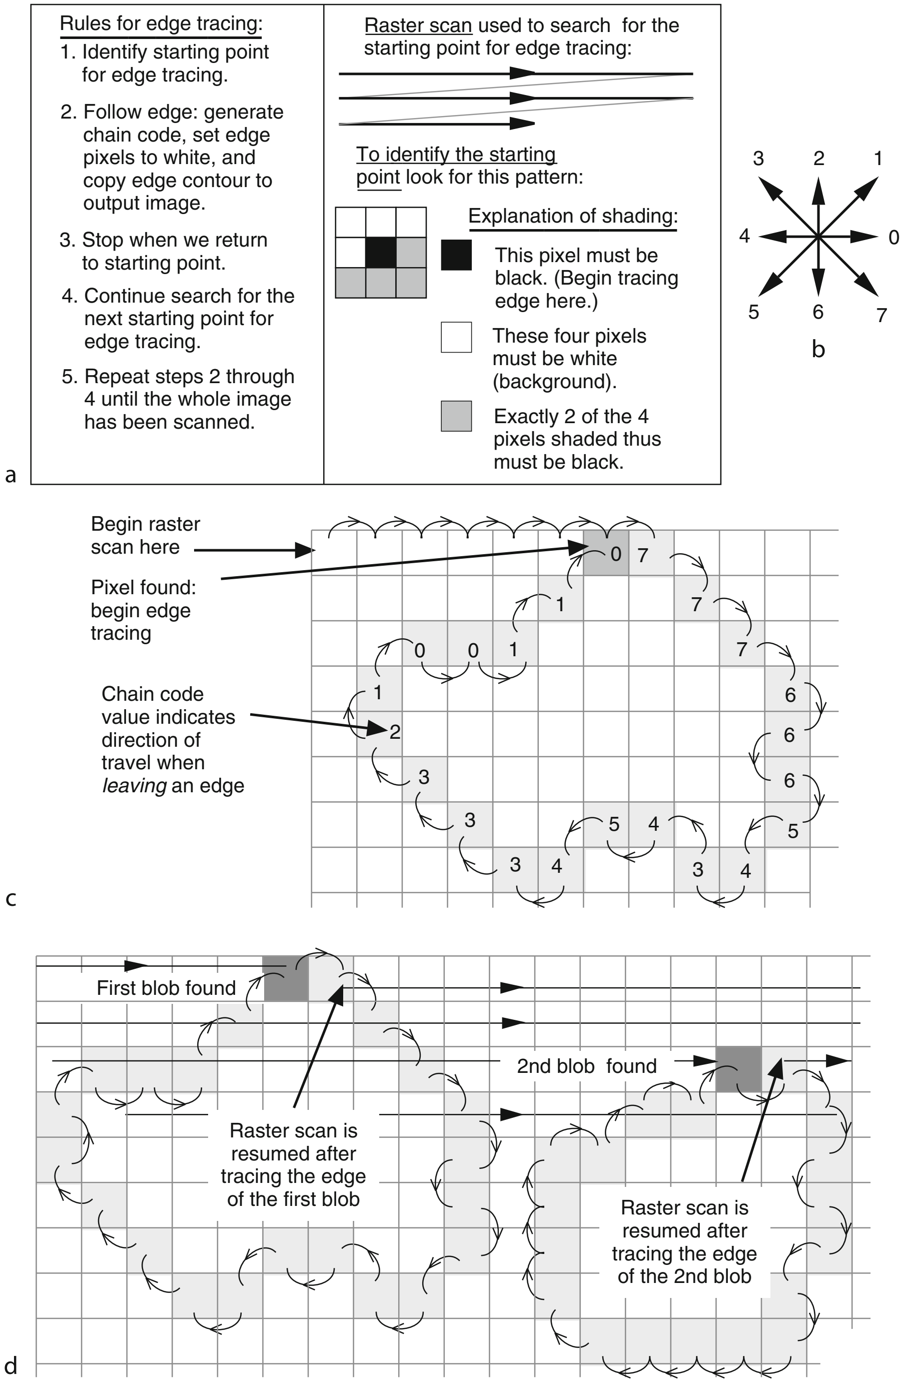
17.2.1.3 Chain Code Representation to Polar Vector Representation

The polar vector representation (PVR) can be derived quite easily from the chain code. To understand how, let us consider a typical chain code sequence:

. . .,2,2,2,3,3,3,3,3,3,4,4,4,4,4,4,4,4,4,4,4,4,4,4,4,4,3,3,3,3,4,4,4,5,5,5,5,5,. . .

Consider ➋ *Fig. 17.11*, from which it can be seen that a chain code value 2 is equivalent to a movement around the edge of one unit of travel at an angle of 90°. In polar vector form, this can be represented as (1, 90°). However, a chain code value 3 is equivalent to a movement around the edge of √2 units of travel at an angle of 135° (√2, 135°). The chain code sequence just listed is therefore equivalent to the following sequence of polar vectors:

. . ., (3, 90°), (6√2, 135°), (16, 180°), (4√2, 135°), (3, 180°), (5√2, 225°),. . .



Rules for edge tracing:
1. Identify starting point for edge tracing.
2. Follow edge: generate chain code, set edge pixels to white, and copy edge contour to output image.
3. Stop when we return to starting point.
4. Continue search for the next starting point for edge tracing.
5. Repeat steps 2 through 4 until the whole image has been scanned.
Raster scan used to search for the starting point for edge tracing:
To identify the starting point look for this pattern:
Explanation of shading:
This pixel must be black. (Begin tracing edge here.)
These four pixels must be white (background).
Exactly 2 of the 4 pixels shaded thus must be black.

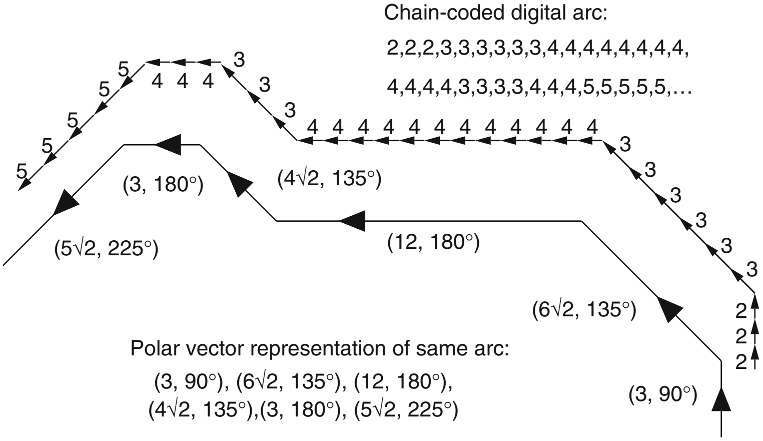

Fig. 17.11

(a) Chain-coded edge (b) Equivalent polar vector representation (PVR)

Thus, we have reduced a chain code sequence containing 37 elements to a polar vector representation continuing just six elements. It may, of course be possible to merge consecutive PVR elements to form longer vectors at angles that are non-integer multiples of 45°. This will make the PVR even more compact. However, this is venturing into edge smoothing, which will be discussed later.

17.2.1.4 Cartesian to Polar Coordinates

Many artifacts that are made in industry are circular, have circular markings, or possess a "wheel spoke" pattern. In order to simplify the processing of such images, it is possible to use a Cartesian-axis to polar-coordinate-axis transformation. If the axis transformation is centred properly, concentric circles are mapped into parallel lines. A series of radial lines is also mapped into a set of parallel lines that is orthogonal to the first set. Performing the axis transformation is not as straightforward as one might, at first, imagine. The reason is that pixels in the two coordinate systems do not have a one-to-one correspondence to one another (➋ *Fig. 17.12*). If we consider the pixels to be points, we can see how we can use interpolation in order to avoid sampling errors. Suppose that a point (i′, j′), defined using in the polar-coordinate axes, maps to the point (i″, j″) located with respect to the Cartesian-coordinate axes. Normally, (i′, j′) does not lie exactly on one of the grid points corresponding to the pixels in the Cartesian-axis image. To estimate the intensity at (i″, j″), we can use simple bilinear interpolation, just as we explained in connection with image rotation (➋ Sect. 2.6).

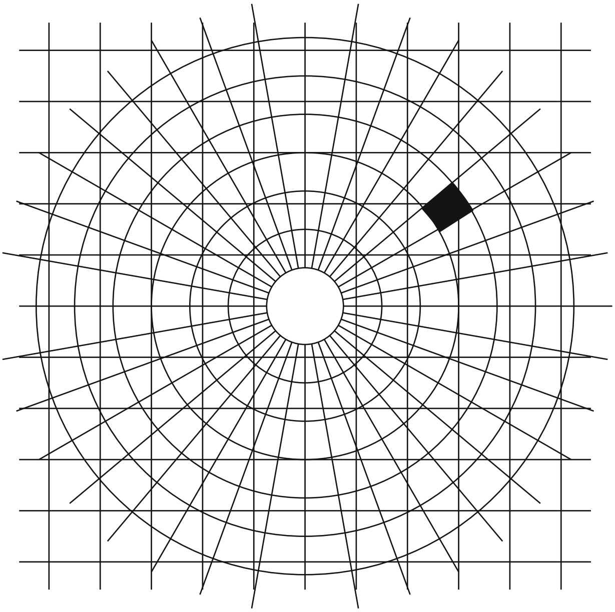

Fig. 17.12

Conversion from Cartesian to polar coordinates. Notice that there is no 1:1 correspondence between pixels in these two image formats

17.2.1.5 Colour Axis Conversion

Most colour cameras used in machine vision generate the RGB colour signals mentioned in ➲ Chap. 10. However, the HSI representation is usually regarded as being more useful for colour recognition. The transformation is defined in terms of the following equations:

$$Hue : H = cos^{-1}\left((2R - G - B)/2\left(((R - G)^2 + (R - B)(G - B)\right)\right)$$
$$Saturation : S = 1 - (3min(R, G, B))/(R + G + B)$$
$$Intensity : I = (R + G + B)/3$$

Given measured values of the signals R, G and B, these equations can be evaluated using software. However, this process must be repeated for every pixel in the input image and hence is likely to be very slow. At first sight it seems unlikely that look-up tables could be used effectively, since there are three variables. However, in most applications, we can safely restrict each of the RGB channels to 6 bits without serious loss of colour information. Even if we have to use 8 bits/channel, the situation is not too severe. The point is that, by using limited-precision colour representation, we make look-up tables quite effective. Since there are three colour channels, each with 6 (or 8) bits/channel, the total number of possible input conditions is 262,144=2^{18} (or 16,777,216=2^{24}). There are three signals (H, S and I) to be computed, each of which requires 6 (or 8 bits). Hence, we require a total of 0.75 MB (or 48 MB) of storage for the colour look-up tables. The cost of ROM/RAM is quite modest, so colour look-up tables provide a convenient option for colour axis conversion. Notice that look-up tables based on RAM/ROM can perform the colour transformation in real time on a digitised standard video signal.

17.2.2 Processing a Binary Image as a Grey-Scale Image

Two separate series of operators appropriate for processing grey and binary images were defined in ➲ Chap. 14. At first sight, it may seem unlikely that grey-scale processing algorithms could be applied to good effect on binary images but, in fact, there is a lot of benefit to be obtained by this simple ploy. For example, we can smooth the edge of a blob in a binary image by applying a low-pass blurring filter, such as the QT operator *lpf*, a few times (M) and then thresholding [QT: *thr*] at the mid-grey level. (We assume that the binary image intensity values are stored as 0 representing black and 255 denoting white.) This process will be represented by [*M•lpf, thr*]. (This notation is not part of QT but is allowed in PQT, its extended version in which QT is integrated with Prolog. ➲ Chap. 23.) It removes thin hair-like protuberances and “cracks” on the edge of a blob. The same grey-scale operator sequence can also eliminate so-called salt-and-pepper noise consisting of small well-scattered black and white spots. The effect achieved is very similar to that of the binary operator sequence [*N•lnb, N•snb, N•snb, N•lnb*], where N is instantiated to some suitable (small) integer value.

The grass-fire transform [QT: *gft*] is one obvious way in which a grey-scale image can be used to good effect to make it easier to analyse a binary image (➲ Fig. 14.10. This operator will be discussed in more detail later in this chapter.) The result of the QT operator *gft* is a grey-scale image in which intensity indicates the distance to the closest edge point. In addition, the operator *cnw* (count white neighbours in each 3 × 3 neighbourhood) generates grey-scale output image from a binary image while still preserving the shapes of blobs. (The binary image can be reconstructed by taking black as 0 and all values in the range 1–255 as white.)

The general linear convolution operator [QT: *glc*] can be used to detect specified patterns in a binary image. For example, the diagonal edge

W	*W*	*W*
W	*X*	*B*
B	*B*	*B*

X = don't care

can be detected by [*glc*(*1,1,1,1,0,−1,−1,−1,−1*), *thr(255)*].

This process can be taken further. The binary neighbourhood coding scheme introduced earlier can be implemented with the general convolution operator using the following weights:

1	2	4
8	0	16
32	64	128

(The QT command is [*glc(1,2,4,8,0,16,32,64,128)*], which generates the value 15 [= 255 × (1+2+4+8)/{1+2+4+8+16+32+64+128}] on the diagonal edge pattern above.)

The QT operator *rin* counts the number of white pixels in each row when it is applied to a binary image, while *rox* may be used to find the "shadow" of a blob.

The QT grey-scale operator *mxi* is very useful for superimposing white lettering (in a binary image) onto a grey-scale picture. On the other hand, a common ploy when processing grey-scale images containing several objects is to process the image first to produce a blob defining the edge of each object. We then select one blob and combine it with the original grey-scale image using the QT operator *mni.*

Several binary operators can be implemented directly using their grey-scale counterparts. Here are some examples:

Binary	**Grey scale**
`exw (expand white regions)`	`lnb`
`skw (shrink white regions)`	`snb`
`ior (OR)`	`mxi`
`xor (exclusive OR)`	`sub, thr(127,127), neg`
`bed (binary edge)`	`sed (approx.)`
`not (inverse)`	`neg`
`cnw (count white 8-neigbours)`	`glc(1,1,1,1,1,1,1,1,1)`
`cln (remove isolated white pixels)`	`glc(−1,−1,−1,−,1,16,−1,−1,−1,−1), thr(128, 254)`

17.2.3 Using Images as Look-Up Tables

Images can be used as look-up tables. For example, a general image warping transformation can be achieved with two images used as look-up tables. In the following equation, {u(i,j)} and {v(i,j)} are two images which, between them, define the warping function

$$c(i,j) = a(u(i,j), v(i,j)), 1 \leq u(i,j) \leq m, n \leq W.$$

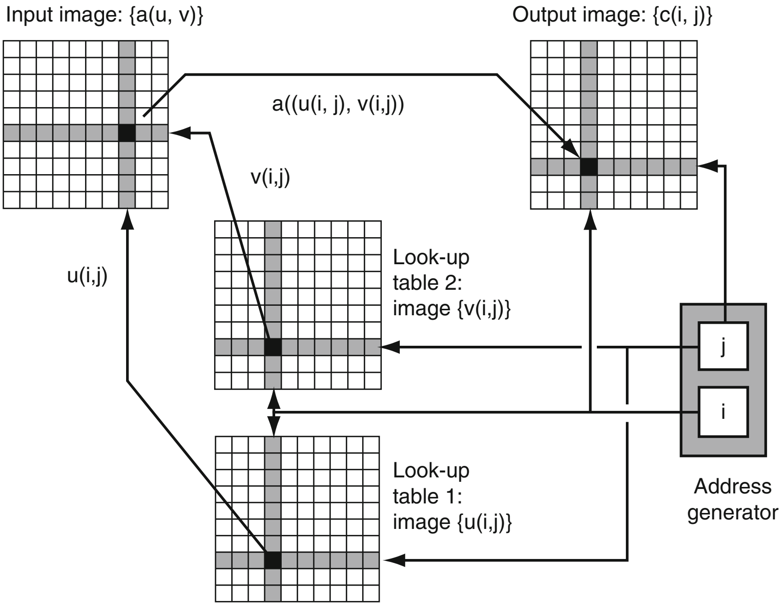

Fig. 17.13
Using images as look-up tables for image warping

The output image is {c(i,j)}; the input image is {a(u,v)}. The intensity of pixel (i,j) in the output image (i.e. c(i,j)) is derived from that pixel in the input image whose x-coordinate is u(i,j) and whose y-coordinate is v(i,j) (*Fig. 17.13*). Notice that the number of grey levels must not be smaller than the number of rows and columns in the images. If there were no warping at all, u(i,j)≡i and v(i,j)≡j. This technique will quite adequately perform geometric transformations where there is a small amount of warping; for example due to slight pin-cushion or barrel distortion, and is suitable for correcting for lens distortion, or the distortion caused by tube-camera scanning errors. It is also suitable for correcting trapezium (trapezoidal) distortion, which occurs when a camera looks obliquely onto a surface. However, it does have problems if the warping is very severe. For example, an approximate Cartesian-to-polar coordinate mapping can be achieved in this way but there are severe difficulties near the centre of the output image. *Figure 17.12* shows why this is so. Since there is no interpolation, each output pixel is derived from just one input pixel. As a result, the mapping is inaccurate close to the centre of the image. However, an annulus whose inner radius is not less than about half of its outer radius can be mapped quite accurately to a rectangle by this method.

17.3 Redefining Algorithms

In this section, we consider how an algorithm may be reformulated while its performance remains unaltered. In later parts of this chapter, we will discuss approximate and heuristic methods.

17.3.1 Convolution Operations

There are two ways to simplify the calculations required by the linear convolution operator [*glc*]:

1. Decomposition into two 1-dimensional operators, acting separately along the vertical and horizontal axes of the image.
2. Iterative application of small-kernel filters, to produce the same effect as a large-kernel filter.

We will now consider these separately in turn and then combine them later.

17.3.1.1 Decomposition

Consider the 7×1 linear convolution operator with the following weight matrix:

1	1	1	1	1	1	1

This filter blurs along the horizontal axis only; vertical intensity gradients are smoothed, while horizontal ones are not. On the other hand, this 1×7 filter

1
1
1
1
1
1
1

blurs horizontal intensity gradients but not vertical ones. Applying them in turn produces exactly the same effect as the following 7×7 filter:

1	1	1	1	1	1	1
1	1	1	1	1	1	1
1	1	1	1	1	1	1
1	1	1	1	1	1	1
1	1	1	1	1	1	1
1	1	1	1	1	1	1
1	1	1	1	1	1	1

Of course, this filter blurs in all directions. If the normalisation constants given in ➔ Sect. 14.2.4 are applied separately for the two 1-dimensional filters, the final result is also normalised correctly. Notice also that the simpler 1-dimensional filters can be applied in either order, without altering the final result.

Let us consider another simple example, where the weights are not all equal to unity and some are negative. Recall that the formula for the Sobel edge detector (➔ Sect. 14.2.5) consists of two parts, each combining blurring in one direction and intensity differencing in the orthogonal direction. Here is the formula for the part which performs horizontal blurring and vertical differencing:

$$E \leftarrow (A + 2\,B + C) - (G + 2\,H + I)$$

This operation can be performed as a horizontal blurring process using the 1 × 3 weight matrix

1	2	1

followed by calculating the vertical difference using this 3 × 1 weight matrix:

1
0
–1

These filters can be applied in either order.

The other component of the Sobel edge detector is $E \leftarrow (A+2D+G)-(C+2F+I)$, which can be computed by applying the 1 × 3 differencing filter with weight matrix

1	0	–1

followed by vertical blurring with this weight matrix:

1
2
1

Again, these operations can be applied in either order. Hence, the Sobel edge detector can be performed using four 1-dimensional filters, which may be easier than implementing it directly with 2-dimensional filters.

Decomposition is important because it replaces a "difficult" 2-dimensional filtering operation by two simpler ones. Filtering along the rows or columns of a raster-scanned image is very straightforward using standard filtering techniques. It is possible to hold the interim results from the first 1-D (row scan) filter in a RAM-based store. This is then rescanned in the orthogonal direction (column scan), thereby generating another digital video signal which can be filtered (➲ *Fig. 17.14*).

It is important to note that not all 2-D local operators can be decomposed into two orthogonal 1-D filters. To see that this is so, we only have to compare the number of degrees of freedom of a 2-D filter (49 for a 7 × 7 filter), with the equivalent figure for the two decomposed filters ($14 = 1 \times 7 + 7 \times 1$). However, most of the more important filters can be decomposed in this way, particularly if they possess both vertical and horizontal symmetry. (The number of degrees of freedom falls to 9 for 7 × 7 bi-symmetrical filters.)

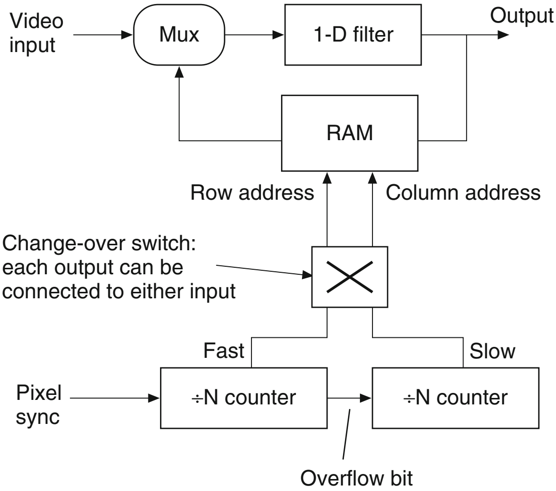

Fig. 17.14
Schematic circuit for implementing decomposable filters. In the first phase, the input image is scanned left-to-right/top-to bottom. (The signal on the line labelled "output" is ignored at this stage.) The image resulting from the row-filtering operation is stored in the RAM, filling it in the same manner. Then, in the second phase, the image is read out of the RAM, scanning the image in the order top-to bottom/left-to-right. The output signal is now taken directly from the line leading out of the 1-D filter

17.3.1.2 Iterated Filters

Consider the following filter

1	1	1
1	1	1
1	1	1

applied repeatedly to a very simple image consisting of zero (black) everywhere, except for a single central white pixel. For simplicity, we will ignore normalisation and assume that the white pixel has an intensity equal to 1. The results of applying the filter once (left) and twice (right) are shown below:

...	...	...	...	...	...	...	...	...	...	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	1	1	1	0	0	0	...
...	0	0	0	1	1	1	0	0	0	...
...	0	0	0	1	1	1	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	...	...	...	...	...	...	...	...	...	...

...	...	...	...	...	...	...	...	...	...	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	1	2	3	2	1	0	0	...
...	0	0	2	4	6	4	2	0	0	...
...	0	0	3	6	9	6	3	0	0	...
...	0	0	2	4	6	4	2	0	0	...
...	0	0	1	2	3	1	1	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	0	0	0	0	0	0	0	0	0	...
...	...	...	...	...	...	...	...	...	...	...

Two more applications yield the following images:

...	...	...	...	...	...	...	...	...	...	...
...	0	0	0	0	0	0	0	0	0	...
...	0	1	3	6	7	6	3	1	0	...
...	0	3	9	18	21	18	9	3	0	...
...	0	6	18	36	42	36	18	6	0	...
...	0	7	21	42	49	42	21	7	0	...
...	0	6	18	36	42	36	18	6	0	...
...	0	3	9	18	21	18	9	3	0	...
...	0	1	3	6	7	6	3	1	0	...
...	0	0	0	0	0	0	0	0	0	...
...	...	...	...	...	...	...	...	...	...	...

...	...	...	...	...	...	...	...	...	...	...
...	1	4	10	16	19	16	10	4	1	...
...	4	16	40	64	76	64	40	16	4	...
...	10	40	100	160	190	160	100	40	10	...
...	16	64	160	256	304	256	160	64	16	...
...	19	76	190	304	361	304	190	76	19	...
...	16	64	160	256	304	256	160	64	16	...
...	10	40	100	160	190	160	100	40	10	...
...	4	16	40	64	76	64	40	16	4	...
...	1	4	10	16	19	16	10	4	1	...
...	...	...	...	...	...	...	...	...	...	...

Inspection of these results shows that we have progressively blurred the spot, which began as a 1-pixel entity and was transformed into an indistinct "fuzz" occupying 9 × 9 pixels. The same result could be obtained applying the following 9 × 9 filter once:

1	4	10	16	19	16	10	4	1
4	16	40	64	76	64	40	16	4
10	40	100	160	190	160	100	40	10
16	64	160	256	304	256	160	64	16
19	76	190	304	361	304	190	76	19
16	64	160	256	304	256	160	64	16
10	40	100	160	190	160	100	40	10
4	16	40	64	76	64	40	16	4
1	4	10	16	19	16	10	4	1

It is, of course, no accident that the weights in this matrix are exactly the same as the values in the fourth image matrix above.

By combining the decomposition and iterated filter techniques, we can simplify this even further. We can obtain the same result as the 9 × 9 filter by applying the 1 × 3 1-D *row* filter with weight matrix [1, 1, 1] four times, and then applying the 3 × 1 *column* filter with weights [1, 1, 1] four times.

17.3.2 More on Decomposition and Iterated Operations

The decomposition technique just described can be applied to a number of other operators. For example, the QT operator *lnb* (largest 8-neighbour intensity value) can also be separated into row and column operations, thus:

$$E \Leftarrow \mathrm{MAX}(D, E, F)$$

followed by

$$E \Leftarrow \mathrm{MAX}(B, E, H).$$

The operator *lnb* computes its output using all of the 8-neighbours. However, if we had defined *lnb* in a different way, using only the 4-neighbours, decomposition in this sense would not be possible.

So far, we have used the results of two filters in series, so that the result of one image processing (row) operator is applied to another (column) operator. However, we could apply two 1-D filters in parallel and then combine the results. Suppose we perform the operations E ⇐ MAX(D, E, F) and E ⇐ MAX(B, E, H) in *parallel* and then combine the results by calculating the point-by-point maximum of intensities in the processed and original images [QT: *mxi*]. The result is exactly the same as the following operator, which combines only the 4-neighbours:

$$\mathrm{E} \Leftarrow \mathrm{MAX}(\mathrm{B}, \mathrm{D}, \mathrm{E}, \mathrm{F}, \mathrm{H})$$

We will refer to this process later, so we will use the mnemonic *lnb4*, to emphasis that it uses only the 4-neighbours. The equivalent decomposition process can be defined for the related operator *snb* (smallest 8-neighbour intensity value).

By repeating the operator *lnb* or *snb*, we can extend the size of the processing window (➲ *Fig. 17.15*). For example, the QT sequence *N•lnb* finds the maximum intensity within each window of size (2 · N+1) pixels. By repeating *lnb4* several times, we find the maximum intensity within a larger diamond-shaped region.

By alternating *lnb* and *lnb4*, we can find the maximum intensity within a regular octagonal region surrounding each pixel. Since this octagon is a better approximation to a circle than either *lnb* or *lb4* alone produces, we may find this combination attractive in certain applications. In the figure, [*5•lnb*] finds the largest intensity within an 11 × 11 window, while [*5•exw*] expands a single white pixel to cover an 11 × 11 square. Alternating *lnb4* and *lnb8* (or *exw4* and *exw8*) generates an octagonal covering. The erosion operators *snb* and *skw* operate similarly on black pixels.

Dilation [QT: *dil*] and *erosion* [QT: *ero*] are two important operators for processing binary images. Since they are so closely related to *lnb* and *snb* respectively, it will hardly come as any surprise that they can be decomposed in a similar way. Indeed all of the remarks made about *lnb* also relate directly to *dil* and those about *snb* to *ero* (binary erosion). This includes the comments made about the 4-neighbour versions.

17.3.3 Separated Kernel Image Processing Using Finite-State Machines

In a series of 23 papers beginning in 1994, Waltz (WAL94a... WAL99b, HUJ95a, HUJ95b, HAC97a, MIL97) described an extremely powerful and radically new paradigm for the implementation of many important neighbourhood image processing operations. These techniques, taken together, have been given the acronym SKIPSM (*Separated Kernel Image Processing using finite-State Machines.* See ➲ Chap. 20). The improvements in performance (speed or neighbourhood size) provided by SKIPSM are so great in some cases as to demand a radical rethinking of what is or is not practical in industrial applications. The SKIPSM approach is mentioned briefly in this section on operator decomposition because it allows the decomposition of a broad range 2-D (and even 3-D or higher) linear and nonlinear operators into a sequence of 1-D operations. This includes many operators which

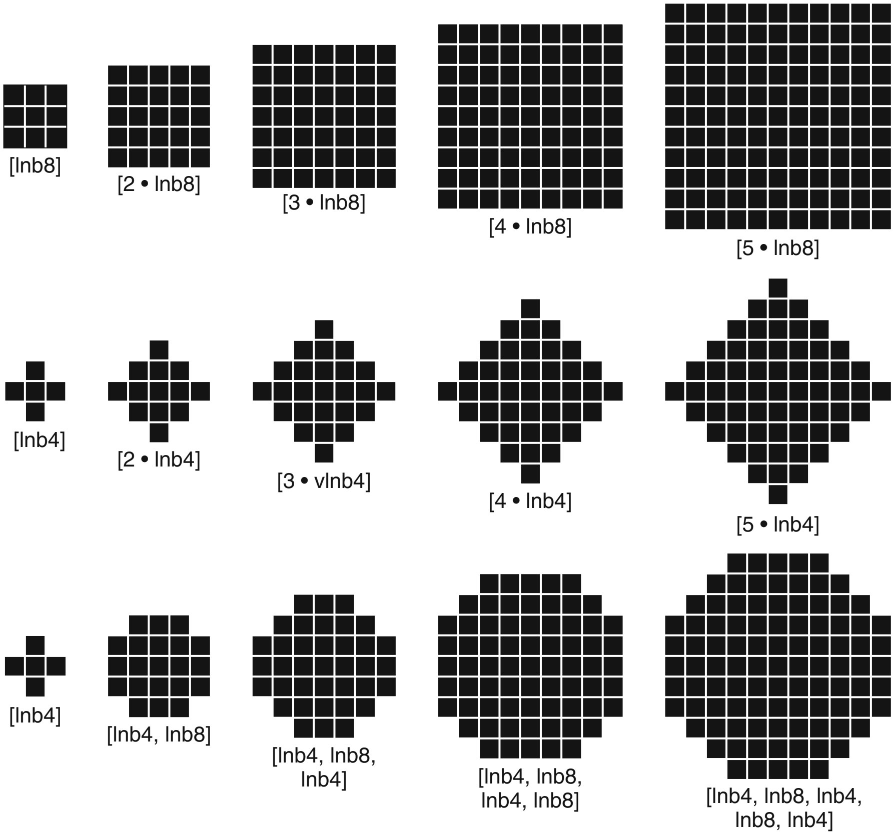

Fig. 17.15
Applying the dilation operators *lnb* and *exw* iteratively (*lnb* operates on grey-scale pictures, while *exw* operates on binary images.)

were previously thought to be non-separable. An example of intermediate difficulty will be presented here.

17.3.3.1 SKIPSM Example

We wish to apply *six* 7 × 9 binary erosion structuring elements (SEs) *on a single raster-scan pass* through the input image. The six SEs are shown in *Fig. 17.16*.

Using the automated SKIPSM code-generation programs, these six operations are individually separated into row operations and column operations. The row operations are combined into a single recursive FSM (finite-state machine), the *row machine*. The six column operations are combined into a second FSM, the *column machine*. These two FSMs are then typically (but not necessarily) implemented as look-up tables (LUTs), as shown in *Fig. 17.17*. Each of the six separate binary outputs is assigned to a single bit plane of the 8-bit output image.

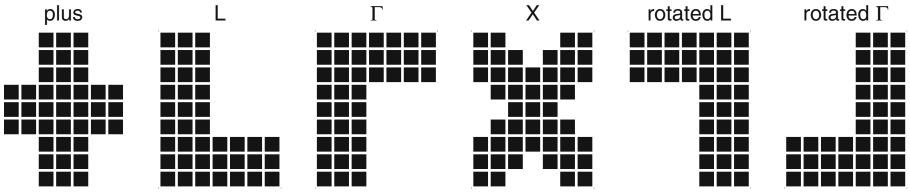

Fig. 17.16
The six 7 × 9 binary erosion structuring elements applied simultaneously in Example 1. Among these, there are only seven distinct row patterns to be encoded by the row machine: 0011100, 1111111, 1110000, 1100011, 1110111, 0111110 and 0000111

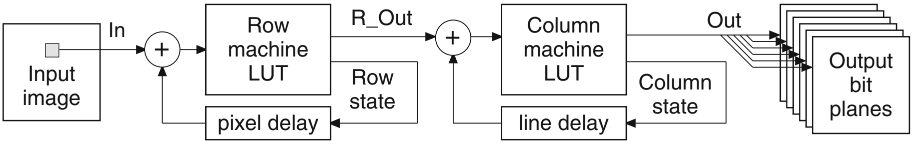

Fig. 17.17
SKIPSM flow chart (applicable to both hardware and software implementations) showing the row and column machines being implemented as look-up tables

The pixel values from the input image are fed to this system in the usual raster-scan order. Each pixel is fetched *once and only once*, because all of the necessary "history" of the image neighbourhood is contained in the *states* of the two FSMs.

The combined row machine has 216 states and, because the input has two levels, its LUT therefore has only 432 addresses. The combined column machine has 1,748 states and 16 input levels. Thus, its lookup table has 10,488 addresses. This is much larger than the row-machine LUT, but is still not excessively large, by today's standards. These LUTs are generated automatically by the SKIPSM software.

Please note a *very* important point here: The execution time for SKIPSM lookup-table-based implementations is *very* fast (requiring only four LUT accesses and two additions or bitwise-ORs), *independent of the size of the neighbourhood and independent of the number of simultaneous operations performed.* Large operations and/or multiple operations require larger LUTs, but execute in the same very fast time as small ones. This fact has been demonstrated repeatedly on actual systems. The SKIPSM approach is described in more detail in ➋ Chap. 20.

17.3.4 Binary Image Coding

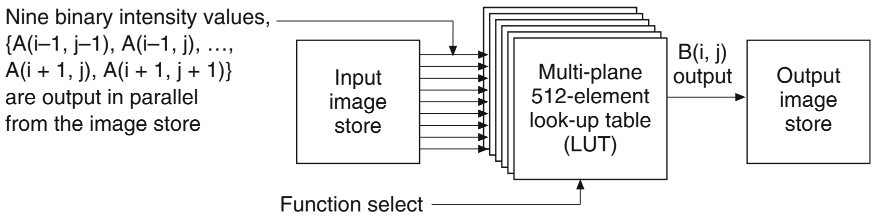
In ➋ Sect. 17.2.1 (➋ *Figs. 17.8–17.10*), we introduced the idea of the binary image coding scheme and in ➋ Sect. 17.2.2 described how the linear convolution operator [*glc*] can be used to generate it. A wide range of binary image processing algorithms can make good use of this coding technique, which is incorporated into the implementation scheme outlined in ➋ *Fig. 17.18*. The important point to note is that any logic function of the nine pixel intensities found within a 3 × 3 window can be "computed" by a look-up table. Here is a list of some of the binary image processing functions which can be implemented in this way.

Operation	QT mnemonic	Comments
Dilate	dil	
Erode	ero	
Binary edge detection	bed	
Remove isolated white points	wpr	
Count white neighbours	cnw	
Critical points for connectivity	cny	
Skeleton joints	jnt	
Skeleton limb ends	lme	
Extend ends of arcs (skeleton limbs)	eel	
Euler number	eul	Extra processing needed
Chain code - preprocessing	fcc	See ❯ Sect. 17.2.2
Grass-fire transform (1 stage)	gft	Included in iterative loop
Skeletonisation	ske	Included in iterative loop

Notice that the binary image coding and the implementation scheme of ❯ *Fig. 17.18* can be used to good effect in the grass-fire transform [QT: *gft*] and the skeletonisation operator [QT: *ske*]. In both cases, a complex logical function is applied within an iterative loop, so high-speed implementation is of increased importance. Implementations using this configuration will be considerably slower than those for the corresponding SKIPSM implementations, as described in ❯ Sect. 17.3.4, but the required look-up tables would be smaller. Therefore, these might be preferred where large look-up tables are not feasible.

17.3.5 Blob Connectivity Analysis

The task to which we will give our attention in this section is that of labelling blobs in a binary image such as shown in ❯ *Fig. 17.19*. All pixels in each 8- or 4-connected blob are assigned an intensity value to indicate the blob identity. Expressed in this way, the requirement seems very straightforward. However, when we consider general shapes about which nothing is known in advance, the real complexity of the algorithm becomes apparent. In particular, intertwined spirals or interleaved comb-like structures make the task far from straightforward.



Nine binary intensity values,
{A(i–1, j–1), A(i–1, j), …,
A(i + 1, j), A(i + 1, j + 1)}
are output in parallel
from the image store
Input image store
Multi-plane 512-element look-up table (LUT)
B(i, j) output
Output image store
Function select

■ **Fig. 17.18**
Using a look-up table to perform a binary image processing operation. The function implemented by this circuit can be altered very quickly by changing the "Function Select" input

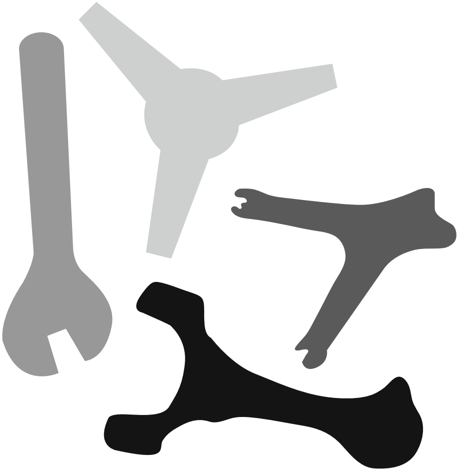


Fig. 17.19
All pixels within a given blob are given the same intensity value. Each blob is assigned a different intensity

Several important image analysis tasks are made possible by blob labelling, including these:

- Identifying the blob with the largest area.
- Eliminating from an image all blobs that are smaller than a predetermined size.
- Associating the holes (or lakes) within a blob with the outer edge of that blob.

17.3.5.1 First Blob-Labelling Scheme

We will describe three quite different algorithms for blob labelling. The first algorithm is explained in *Fig. 17.20* and is based on the array representation of a binary image. This algorithm requires two passes through the image. Thus, each pixel is visited twice. During the first pass, each pixel is assigned a provisional numeric value (label). A blob with a complicated shape may receive two or more different labels. On this first pass, each new "finger" that points upwards is assumed to be a new blob and hence is assigned a new label. During the second pass, these sub-regions are renumbered as required, so that all pixels within a given blob are given the same label.

17.3.5.2 Second Blob-Labelling Scheme

The second blob-labelling scheme represents a fairly minor extension of the algorithm for generating the chain code (Sect. 17.2.1 and *Fig. 17.9a*), and is shown in *Fig. 17.21*. The modified algorithm requires that only the blob edge pixels in the input image be white. All other pixels, including the background and pixels "inside" the blobs, should all be black. This can be achieved by applying a simple "binary edge" processing sequence before the following edge tracing process is started:

1. Set a counter (denoted here as *Counter*) equal to 1.
2. Initialise the output image to black (level 0).
3. Initialise parameters *U* and V to 1.

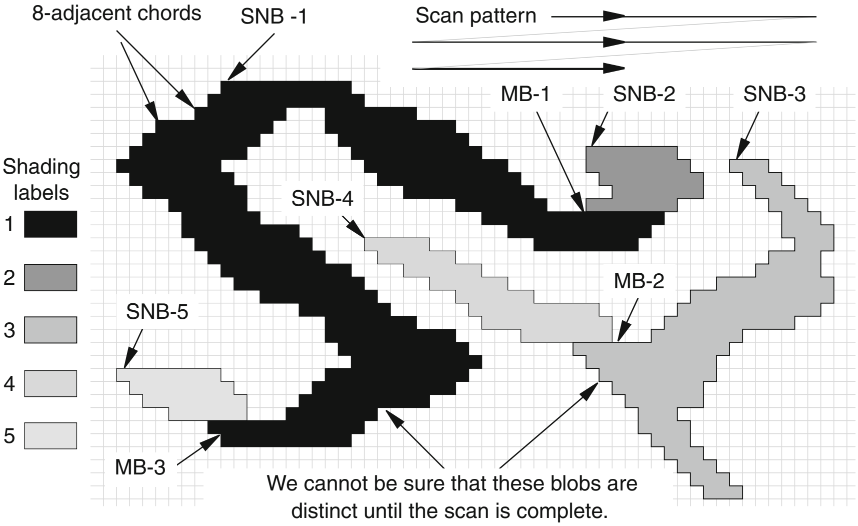

Fig. 17.20
First blob labelling algorithm. This takes place in two stages, each comprising a raster scan of the image. During the first stage, each pixel is assigned an initial label. SNB denotes "starting new blob". MB indicates where parts of blobs are merged. We suspect that a new blob has been found each time we encounter the binary pattern

W	W	W
W	B	X
X	X	X

where W=white (background), B=black (object), and X="Don't care." Each pixel identified thus is given a new initial label. (Pixels SNB-1 to SNB-5) Other white pixels that are discovered to be 8-connected to SNB-i are given the same initial label (i.e., value i). The pixels marked MB-1 to MB-3 indicate where two regions that were originally thought to be separate are discovered to be 8-connected and hence form parts of the same blob. For example, at MB-1, we find that initial labels 1 and 2 represent regions within the same blob and should therefore be merged. Later in the first raster scan, at MB-3, we discover that the same blob also includes region 5. During the second raster-scan, regions 2 and 5 and reassigned with label 1. Of course, regions 4 and 3 are also merged, by mapping all pixels

4. Start a raster scan of the input image at point $[U,V]$. When the first white pixel is encountered, record its position coordinates, $[X_{Counter}, Y_{Counter}]$, then proceed to the next step.
5. Trace the edge contour just found. At each edge pixel $[X_{edge}, Y_{edge}]$ perform the following operations:
   (a) Set pixel $[X_{edge}, Y_{edge}]$ in the input image to level 0 (black).
   (b) Set pixel $[X_{edge}, Y_{edge}]$ in the output image to level *Counter*.
   (c) Stop edge tracing when we revisit pixel $[X_{Counter}, Y_{Counter}]$ in the input image and proceed to the next step.
6. Set $[U,V]=[X_{Counter}, Y_{Counter}]$.

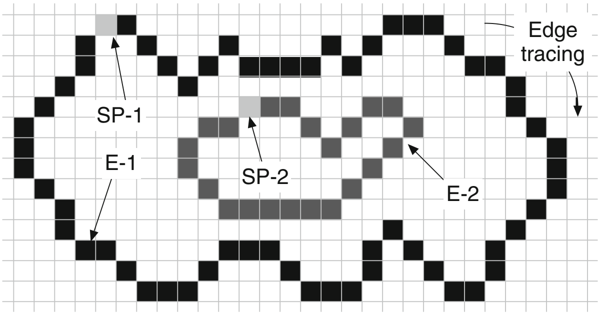

Fig. 17.21
Second blob labelling algorithm. Here there are two blobs, with edges, E-1 and E-2. Following the procedure (step 4), the first starting point (SP-1) is found, and edge E-1 is traced back around to SP-1 (step 5). Then the second starting point (SP-2) is found. And so on

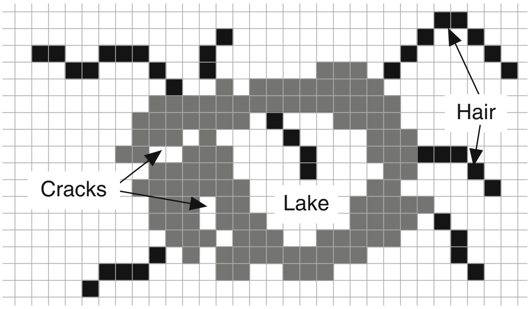

Fig. 17.22
"Hair", "cracks" and a "lake" in a binary object

7. Increment *Counter*.
8. Repeat steps (4) to (7), using the new values for *Counter, U* and *V*.

An important feature of this algorithm is that it cannot tolerate "hairy" edges, since they cause the edge tracer to travel along "blind alleys." ("Hair" is an open-ended digital arc that is only one pixel wide and protrudes outwards from the outer edge contour into the background or inwards from the inner edges of lakes (see Fig. 17.22)). "Hair" can be removed and a closed edge contour created by simple binary image filtering:

skw, exw, exw, xor % Creates an edge just outside object boundary

or

skw, exw, skw, xor % Creates an edge just inside object boundary

One small task remains: differentiating between outer and inner edges. We can use the following masks to identify outer or inner edges (edges surrounding lakes):

Mask for outer edges

B	B	X
B	W	X
X	X	X

Mask for inner edges

W	W	X
W	W	X
X	X	X

(X indicates don't care.) These masks are applied at step 4 to test the pixel located at [$X_{Counter}$, $Y_{Counter}$] in the preprocessed image. The masks are not applied to the edge contour image, just this single point.

17.3.5.3 Third Blob-Labelling Scheme

The third method for blob labelling uses a technique borrowed from computer graphics, where it is used for object filling. We must first define our notation.

1. Let [X_1, Y_1] be a point that is known to lie on the edge of or within the blob that we wish to isolate.
2. Let *L* denote a list of points to be analysed.
3. Let *S* be a list. This will eventually hold the addresses of all pixels that are 8-connected to [X_1, Y_1].
4. Let pixel intensities be represented by 0 (black), 1 (white and not yet analysed), and 2 (white and already analysed).
5. Let N(*X*,*Y*) denote the list of addresses of pixels that are 8-connected to [*X*,*Y*] and have intensity equal to 1. (Pixels of intensity 0 and 2 are ignored when computing N(*X*,*Y*)).

Here is the algorithm, described as a set of simple rules:

1. (a) Initialise *L* to [[X_1, Y_1]].
   (b) Set *S* to [], i.e. the empty list.
   (c) Set pixel [X_1, Y_1] to intensity value 2.
2. (a) If *L* is empty, go to Step 4.
   (b) Otherwise, find the first element of *L* and denote this by [*X*,*Y*].
3. (a) Derive the list N(*X*,*Y*).
   (b) Set the intensity value of pixel [*X*,*Y*] to 2.
   (c) Append N(*X*,*Y*) to *L*.
   (d) Append [*X*,*Y*] to the list *S*.
4. Finish.

The result is a list (*S*) which contains the addresses of all of the pixels that are eight-connected to the starting point [X_1, Y_1]. However, the result (*S*) in a rather inconvenient format, since the image scanning process is performed as we generate N(*X*,*Y*).

In this section, we have seen that three completely different computational techniques can be used to perform blob labelling. We have also seen that sometimes it can be beneficial to store and employ more than one image representation.

17.3.6 Convex Hull

The convex hull of a single connected object (*S*) in a binary image is easily imagined as the region contained within a rubber band stretched around *S*. The convex hull of a set of disconnected objects can also be envisioned in this way. There are several known algorithms for computing the convex hull of a single blob and rather fewer for the more general multiple-blob case. Algorithms for calculating the convex hull of a single blob can be based on the array, run-code, chain-code or polar-vector representations. For the sake of simplicity, we will concentrate in this section on algorithms for computing the convex hull of a single connected blob. This situation is also of greatest interest for industrial applications. However, we must make it clear that, strictly speaking, the convex hull is defined for *any* set of points in a plane, whether or not they are connected to each other.

A very useful point to note is that for any given shape (*S*) there are four very easily identifiable points on its convex hull [WIL89] (see *Fig. 17.23*):

(a) A vertical line through the left-most point of *S*
(b) A vertical line through the right-most point of *S*
(c) A horizontal line through the top point of *S*, and
(d) A horizontal line through the bottom point of *S*

If we were to rotate *S*, we could obtain another four points on its convex hull with equal ease. Of course, to find all of the points on the convex hull requires that we rotate *S* many times and find these four extreme points each time.

This provides the basis for most of the known algorithms for computing the convex hull. Let us now discuss the details of some of these.

17.3.6.1 Array Representation

Consider the set of parallel lines defined by the equation

$$y = x \tan(\theta) + c$$

where c is allowed to vary but θ is a constant. Some of these lines will intersect the given shape *S*, while others will not. The two lines that are tangential to *S* are of particular interest, since they

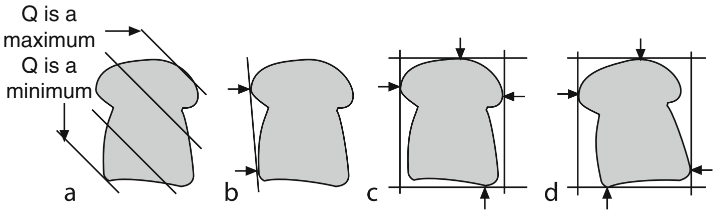

Fig. 17.23

Heuristics for finding a subset of the nodes of the convex hull of a binary object. (a) Finding the values for [*X,Y*] which maximise/minimise Q = (*Y* − mX − c) yields at least two nodes for each pair of values (m, c). (b) This heuristic may find more than two nodes. (c) The top-most, right-most, bottom-most and left-most points of an object indicate (at least) four nodes. (d) Four more nodes can be found by rotating the object and repeating (c)

define (at least) two points on the convex hull of *S* (➲ *Fig. 17.23*). We can find their coordinates in the following way:

1. Evaluate the expression $(Y - X\tan(\theta) - \mathrm{c})$ for all points $[X,Y]$ in the set of points which define *S*. (For convenience, we will also refer to this set as *S*.) Hence, we compute Q, where $\mathrm{Q} = (Y - \mathrm{m}X - \mathrm{c})$, for all $(X,Y) \in \mathrm{S}$.
2. We record those values of (X,Y) which make Q a minimum and a maximum. Let us denote these values by $(X_{min,\theta}, Y_{min,\theta})$ and $(X_{max,\theta}, Y_{max,\theta})$.
3. Then, $(X_{min,\theta}, Y_{min,\theta})$ and $(X_{max,\theta}, Y_{max,\theta})$ are two points on the convex hull of *S*.
4. Additional points on the convex hull of *S* can be found by varying θ and repeating steps 1 through 4.

Notice that for a given value of θ there may be more than one convex hull point on each line (➲ *Fig. 17.23b*). This is a bonus and gives us more convex hull points for less computational effort. However, we cannot be sure that we will obtain more than one point per tangent line.

The above procedure can be used as the basis for a number of algorithms for deriving the convex hull. These will now be described.

17.3.6.2 Scanning the Image Array

The most obvious way to compute the convex hull of a shape *S* is to repeat steps 1 through 4 a large number of times for small increments of θ. Each pair of convex hull points $(X_{min,\theta}, Y_{min,\theta})$ and $(X_{max,\theta}, Y_{max,\theta})$ is computed by scanning the whole image array to find values which are members of *S*.

A second and slightly more efficient algorithm can be obtained by performing the binary edge detector function [QT: *bed*] on the image array before we apply the procedure just described. The savings in computational effort arise because we calculate only the value of Q for edge points – "internal" points are ignored. Notice, however, that each time we add two more convex hull points to the list, each pixel in the *whole image array* must be "visited" once.

17.3.6.3 Chain Code

A third and even more efficient procedure for deriving the convex hull can be based on the chain code and is exactly as defined above, except that we "visit" only the edge pixels. (Background and "internal" points are simply ignored.) This algorithm requires that we compute $(X_{min,\theta}, Y_{min,\theta})$ and $(X_{max,\theta}, Y_{max,\theta})$ from the (X,Y)-coordinates of all of the edge points. This is a trivial calculation based on the following recursive procedure:

$$(X_{i+1}, Y_{i+1}) = ((X_i + H(C_i)), (Y_i + V(C_i)).$$

Here, C_i is the chain code value which corresponds to a movement from the i$^{\mathrm{th}}$ edge pixel (X_i, Y_i) to the adjacent (i+1)$^{\mathrm{st}}$ edge pixel, (X_{i+1}, Y_{i+1}). H(*C*) and V(*C*) are derived from the following table:

C	0	1	2	3	4	5	6	7
H	1	1	0	−1	−1	−1	0	1
V	0	1	1	1	0	−1	−1	−1

Of course, we can modify the chain code generator instead, so that it also records the (X, Y) coordinate values of each of the edge pixels as the chain code is being computed. This will save some further computational effort.

17.3.6.4 Polar Vector Representation (PVR)

A fourth, radically different, algorithm for computing the convex hull can be defined in terms of the polar vector representation (PVR). Another similar procedure based on the chain code also exists but is less efficient [2]. In the following description, we will make use of the fact that the PVR defines a polygonal representation of a shape. We will use N_v to indicate the number of vertices of this polygon, which we will represent by P. The algorithm finds a set of points, which we will call *nodes* and which are the vertices of that polygon which defines the convex hull of P. We will use N_n to indicate the number of nodes. The set of nodes is a subset of the set of vertices. Hence, $N_n \leq N_v$. Also, for many shapes, particularly after edge smoothing has been applied, we find that N_v is *very much less* than the number of edge pixels (N_{edge}).

The first step in the algorithm is to find any one node and a reference axis which passes through it. A simple way to do this is to find the right-most vertex and then draw a vertical line through it (see ➲ *Fig. 17.24a*). Any other line that is tangential to the polygon is acceptable as the initial reference axis. On subsequent steps in the algorithm, the reference axis is redefined by the line joining the two most recently discovered nodes.

Consider ➲ *Fig. 17.24b*, which shows the angle θ formed between the reference axis and the line which joins the most recently found node (labelled ‘2’) to another vertex. The next node to be identified (3) is therefore identified as that vertex where the angle θ is a minimum. To minimise θ, we must analyse at most $(N_v - 2)$ vertices. Vertices labelled ‘1’ and ‘2’ are already known to be nodes of the convex hull and therefore need not be considered again. However, we can improve the algorithm in two ways:

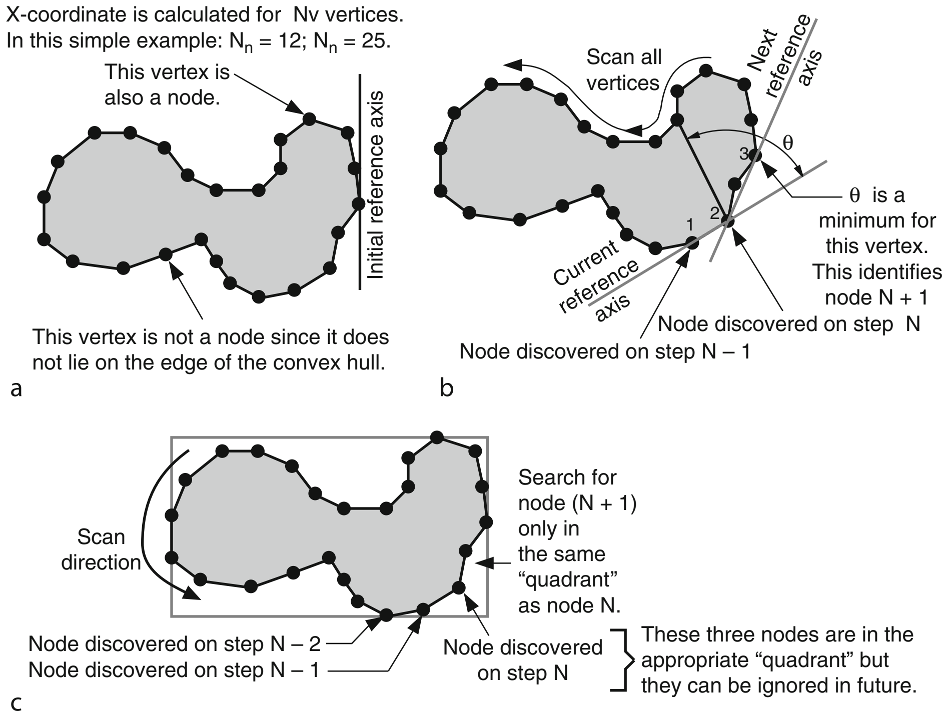
(a) We do not need to calculate the angle θ for those vertices that lie between the node that was identified initially and the one discovered most recently.

(b) We need analyse only vertices which lie in the same “quadrant” of the polygon P. See ➲ *Fig. 17.24c*. The justification for this follows directly from ➲ *Fig. 17.23*.

As a crude approximation, rule (a) halves the amount of computing effort needed, while rule (b) reduces it to 25%. These two savings are cumulative. Hence, the total computational effort in finding all nodes involves roughly $(N_n\ N_v/8)$ angle calculations. An adaptation of this algorithm but based on the chain code has also been devised [7].

17.3.6.5 Parallel Implementation of the PVR/Chain Code Algorithm

It is possible to break the calculation into an arbitrary number of smaller tasks, which can be performed in parallel by a set of processors operating independently of each other. The number of parallel sub-tasks and hence processors is unlimited. The parallel version of the PVR algorithm relies on three phases: finding a sub-set of the nodes of the convex hull; segmenting the edge, and calculating the intermediate nodes for each segment. Here is the algorithm explained in more detail.



X-coordinate is calculated for Nv vertices.
In this simple example: N_n = 12; N_n = 25.
This vertex is also a node.
Initial reference axis
This vertex is not a node since it does not lie on the edge of the convex hull.
a
Scan all vertices
Next reference axis
θ
3
2
1
θ is a minimum for this vertex. This identifies node N + 1
Current reference axis
Node discovered on step N
Node discovered on step N – 1
b
Scan direction
Search for node (N + 1) only in the same "quadrant" as node N.
Node discovered on step N – 2
Node discovered on step N – 1
Node discovered on step N
These three nodes are in the appropriate "quadrant" but they can be ignored in future.
c

Fig. 17.24

Calculating the convex hull from the polar vector representation. (a) Initial reference line is the vertical line through the right-most vertex. (b) The (N+1)st node is derived from the (N – 1)st and Nth nodes. (c) Segmenting the PVR at the top-most, right-most, bottom-most and left-most vertices, creates four sub-tasks which can be performed in parallel

(a) Find a sub-set of nodes of the convex hull. To do this, we calculate the coordinates [X, Y] of each point which maximises the quantity

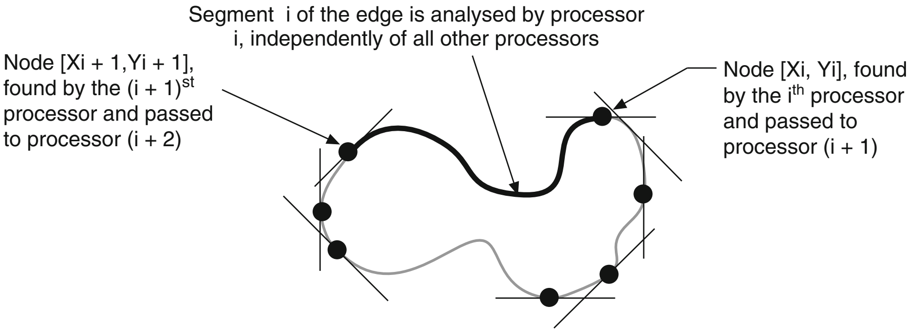
$$Q = (Y - X\tan(\theta) - c) \text{ for } \theta = 0, 360/\mathrm{N}, 720/\mathrm{N}, 1080/\mathrm{N}, \ldots, 360(\mathrm{N}-1)/\mathrm{N},$$

where N is the number of processors used. Of course, all points must lie on the edge of the input shape. This is an N-way parallel process; each process can be performed independently by a (serial) processor.

(b) Each processor passes the coordinates of the nodal point it has just identified to one of its neighbours. We are effectively sub-dividing the edge of the input blob into N segments. In *Figs. 17.23* and *17.24c*, we suggested that we break the edge of the input blob into four sections. This is simply a generalisation of that process. See *Fig. 17.25*.

(c) Find the remaining nodal points, as we did in the fourth PVR method. Each processor has the coordinates of two nodes and therefore finds the other nodes which lie between them.

This algorithm is important because it has deliberately been designed to fit onto an N-way parallel processor. This means, of course, that there is the potential to achieve high operating speed.



Segment i of the edge is analysed by processor i, independently of all other processors
Node [Xi + 1,Yi + 1], found by the (i + 1)st processor and passed to processor (i + 2)
Node [Xi, Yi], found by the ith processor and passed to processor (i + 1)

Fig. 17.25
The convex hull calculation lends itself to implementation in parallel processors

17.3.6.6 Run Code

Another ingenious algorithm for finding the convex hull uses the run code [10]. However, this will not be explained in detail here, since it is not possible to do so quickly and easily. This algorithm is suitable only for a serial processor and hence is most appropriate for implementation in software.

17.3.7 Edge Smoothing

As an abstract concept, edge smoothing needs very little explanation, even to the reader with little prior experience of machine vision. The algorithmic procedures which nominally perform edge smoothing are highly varied and are based on several different image representations. There are subtle differences among these competing techniques, which may be important in some applications but for most are insignificant. A procedure which embodies edge smoothing and relies upon these minor differences is likely to be over-sensitive for most industrial applications. In such situations, the system design engineer is more likely to find other more profitable ways of improving the machine. Adjusting the lighting/viewing subsystem is often far better!

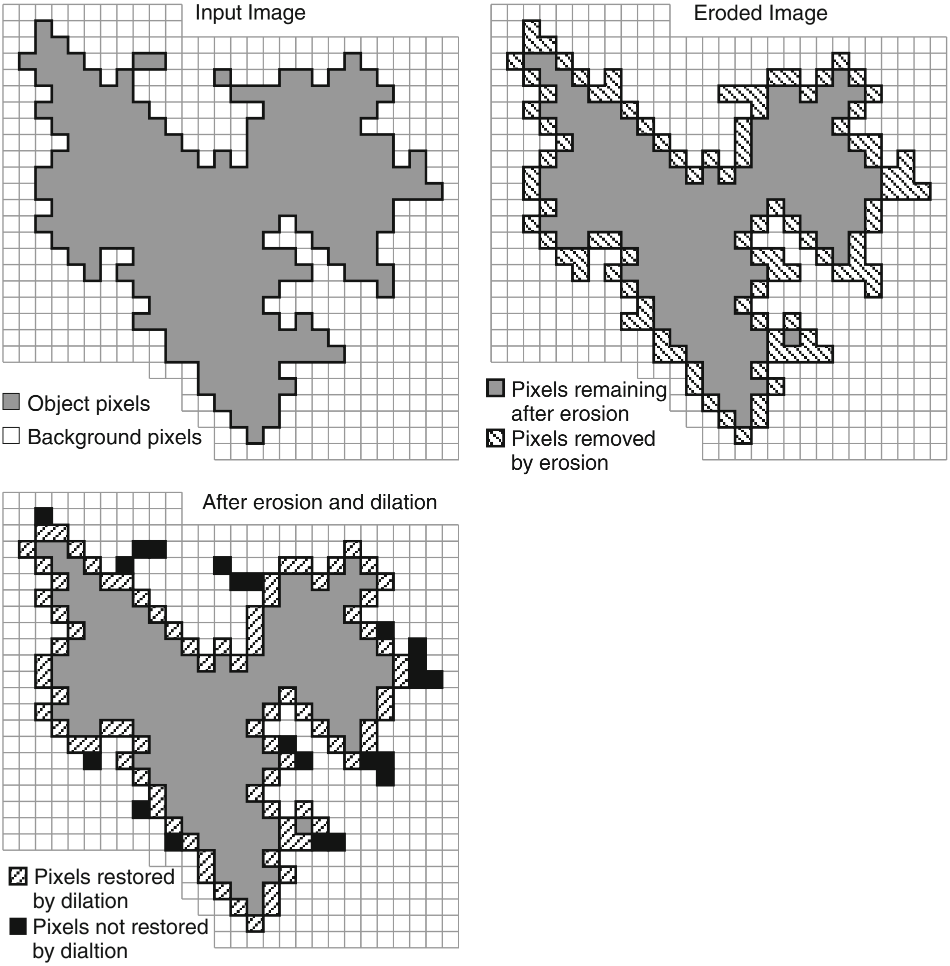
It should be understood that the objective for edge smoothing is not specified in absolute terms. Hence, we take it that we may make a free choice of whichever edge smoothing technique happens to fit in best with our broad objectives. We might, for example, find that for a particular system the chain code provides a suitable data structure for implementing a multi-step algorithm. In this event, we would naturally use one of the edge smoothing operators that is based on the chain code. In certain other situations, however, the hardware might employ a different image representation. In this case, we find ourselves using an edge-smoothing procedure which behaves in a slightly different way. The point is that we simply should not put ourselves in a position where it matters that we select one edge smoothing algorithm rather than another. This is yet another illustration of a very important general principle: *Ease of implementation is as important as performance.*

17.3.7.1 Edge Smoothing in QT

The morphological operator *closing* performs one type of edge smoothing, in which thin "cracks" are eliminated (see *Fig. 17.26*). Let closing(N) be defined as N • exw, N • skw.

Remember that *exw* denotes expand white regions and *skw* signifies shrink white regions. Similarly, closing which is defined as follows N • skw, N • exw eliminates "hair" (*Fig. 17.22*). Both "hair" and "cracks" can be eliminated by concatenating these two operators as follows:

$$\text{closing}(N),\ \text{opening}(N).$$



Input Image
Object pixels
Background pixels
Eroded Image
Pixels remaining after erosion
Pixels removed by erosion
After erosion and dilation
Pixels restored by dilation
Pixels not restored by dialtion

Fig. 17.26
Edge smoothing by erosion and dilation (*upper left*). Input image (*upper right*). After erosion [*skw*] (*lower left*). After erosion and dilation [*skw, exw*]

In some circumstances, it may be advantageous to reverse the order of execution:

$$\text{opening}(N), \ \text{closing}(N).$$

17.3.7.2 Smoothing the Chain Code

Consider the chain code sequence "..., 0, 0, 0, 1, 7, 0, 0, 0,...." It is immediately obvious that the sub-sequence "1,7" is a small glitch. This might arise from camera noise and digitisation effects, and should be replaced by "0, 0". This makes the edge represented by the sequence (...0, 0 0, 0, 0, 0, 0, 0,....) smoother (*Fig. 17.27a*). In a similar way, the sharp corner represented by the chain code sequence "..., 0, 0, 2, 2, ..." could be replaced by the smoother curve represented by "..., 0, 1, 2, ..." (*Fig. 17.27b*). We can, of course, take this further and look for more complex sub-sequences which represent sharp corners and glitches. For example, the chain code sequence "..., 0, 0, 0, 0, 2, 2, 2, 2, ..." might be replaced by "..., 0, 1, 1, 1, 2, ..." (*Fig. 17.27c*).

A fast low-cost edge-smoothing device based upon the chain code can be built using a shift register and look-up table (*Fig. 17.28*). The same general principle could be used to good effect in software.

17.3.7.3 Smoothing the Polar Vector Representation

In one of the simplest edge-smoothing schemes based on the PVR, two adjacent elements are merged if they are nearly aligned. Thus, two consecutive PVR elements, $[r_1, \theta_1]$, $[r_2, \theta_2]$ are replaced by a single vector $[r_{1,2}, \theta_{1,2}]$ if θ_1 and θ_2 are nearly equal (see *Fig. 17.29*). The resultant vector is obtained using the standard vector addition formulae:

$$r_{1,2} = \text{sqrt}\left\{[r_1 \ \cos(\theta_1) + r_2 \ \cos(\theta_2)]^2 + [r_1 \ \sin(\theta_1) + r_2 \ \sin(\theta_2)]^2\right\}$$
$$\theta_{1,2} = \tan^{-1}([r_1 \ \sin(\theta_1) + r_2 \ \sin(\theta_2)]/r_1 \ \cos(\theta_1) + r_2 \ \cos(\theta_2)])$$

The rule for deciding whether or not to merge two PVR elements may be expressed in a number of ways:

1. Merge all pairs of adjacent elements $[r_i, \theta_i]$ and $[r_{i+1}, \theta_{i+1}]$, if $|\theta_i - \theta_{i+1}| \leq d_1$, where d_1 is some parameter we choose to suit the application requirements.
2. Merge all pairs of adjacent elements $[r_i,\theta_i]$ and $[r_{i+1},\theta_{i+1}]$, if $|r_{ij} - r_i - r_{i+1}| \leq d_2$, where d_2 is some parameter we choose to suit the application requirements.

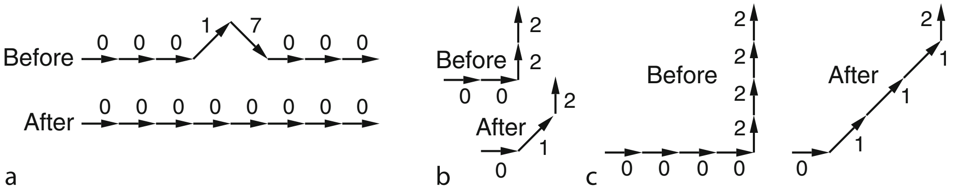


Fig. 17.27
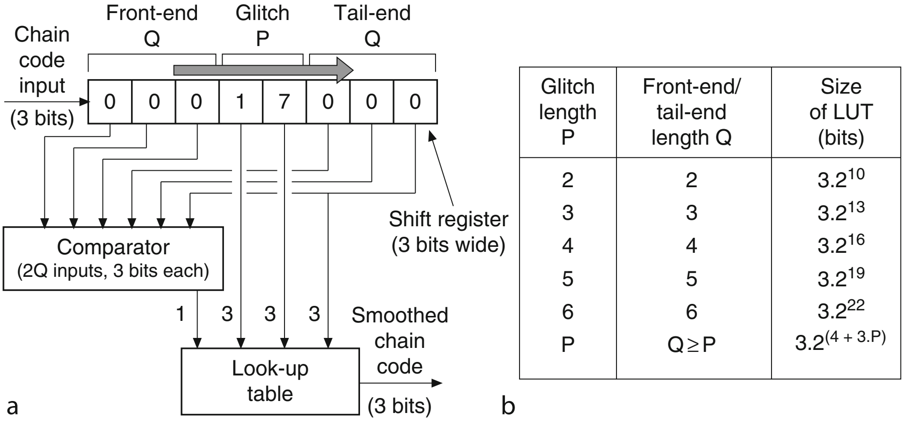
Edge smoothing: filtering the chain code. (a) Replacing glitches (b) Smoothing corners (mild) (c) Smoothing corners (more pronounced)



Glitch length P	Front-end/ tail-end length Q	Size of LUT (bits)
2	2	3.2^{10}
3	3	3.2^{13}
4	4	3.2^{16}
5	5	3.2^{19}
6	6	3.2^{22}
P	Q≥P	$3.2^{(4 + 3.P)}$

Fig. 17.28

Filtering the chain code. (a) This circuit can detect and remove glitches of the form A^Q,S(P),A^Q, where P and Q are integers and S(P) is a chain-code sequence of length P. The front-end and tail-end sub-sequences are both of length Q. (b) Size of the look-up table as a function of glitch length (P) and front-/tail-end length (Q)

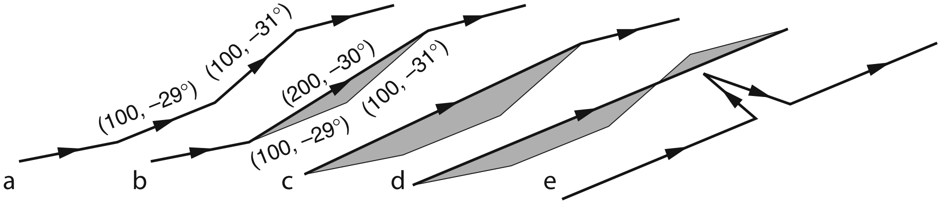


Fig. 17.29

Edge smoothing: processing the PVR. (a) Original edge, consisting of 4 PVR elements. (b) Replacing two nearly collinear vectors by vector addition. (c) Replacing three vectors. Notice that the error, measured by the shaded area is small, whereas the length of the resultant vector is quite long. (d) Replacing four vectors. Notice that there are both small positive and small negative areas (i.e., shaded areas above and below the resultant vector), which tend to "cancel" one another. (e) Glitch can be detected quite easily since there are two long vectors that are nearly in line and two short ones between them

3. Merge all pairs of adjacent elements [r_i,θ_i] and [r_{i+1},θ_{i+1}], if the triangle enclosed by the three vectors [r_1,θ_1], [r_2,θ_2] and [$r_{1,2}$,$\theta_{1,2}$] has an area that is less than d_3, where d_3 is some parameter we choose to suit the application requirements.
4. Investigate all pairs of elements in the PVR coding of an edge but merge only one pair at a time. Obviously we could choose to merge a pair of PVR vectors if they minimise any of the criteria used in 1–3.

Defining suitable rules for detecting and removing glitches, such as

$$\ldots, [100,\ 37^\circ],\ [1,\ 127^\circ],\ [1, -52^\circ],\ [100,\ 37^\circ], \ldots$$

will be left as an exercise for the reader. (The rules become fairly obvious if we represent the PVR graphically.) Notice that a glitch can always be identified from the PVR as being either "hair" or "crack" (➋ *Fig. 17.22*), since the inside of the blob is always on the left (or right) of the vectors.

➋ *Figure 17.30* shows the effects of applying PVR edge smoothing to the outline of a model car. By applying the smoothing operator iteratively, long PVR elements are created, which in this case can be identified easily with the roof, windscreen and hatchback of the vehicle. The edge smoothing process is, in effect, performing a feature-identification operation. This very useful side effect is not shared by any other edge-smoothing procedure. This illustrates an important general principle: We must always be alert to such "side effects", since they can significantly alter our judgement of a procedure.

17.3.7.4 Dog-on-a-Leash Algorithm

Another edge smoothing operator can be defined in terms of the chain code, using a model based upon the idea of a person taking a lazy dog for a walk (see ➋ *Fig. 17.31*). The point C represents the person and A the dog, which is always a given distance behind. On this occasion, distance is measured in terms of the number of chain code steps between dog and the person. The dog is on a leash whose centre point is D. (The model is somewhat unrealistic because the length of the lead varies, while the dog is a set number (N) of paces behind the man.) The locus of D as the person and dog traverse the edge of the blob forms the desired smoothed edge.

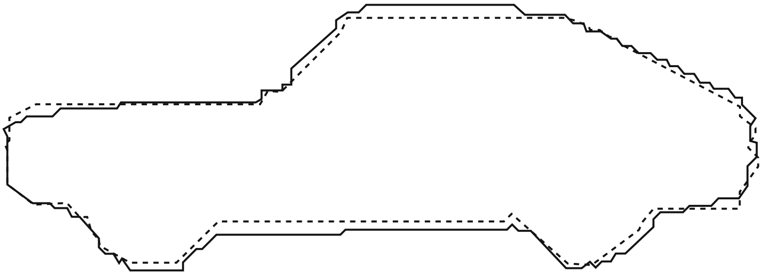

Fig. 17.30
PVR edge smoothing example

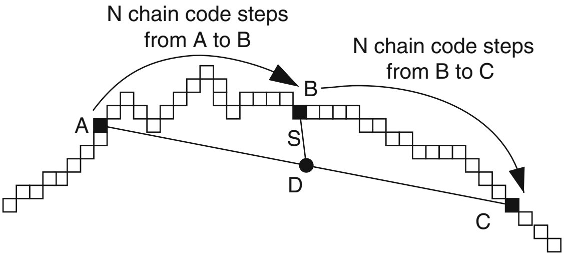

Fig. 17.31
Dog-on-a-leash algorithm for edge smoothing. The locus of D forms the smoothed edge. The distance S is a measure of the local curvature and provides a useful method for detecting corners

This operation can be expressed conveniently in terms of the chain code and polar vector representations.

An added benefit of this edge-smoothing algorithm is that it is very closely related to another which highlights corners and therefore acts as feature detector. Consider ➋ *Fig. 17.31* again. The point B is mid-way between A and C, again measured in terms of the number of chain-code steps. The Euclidean distance between B and D is measured for each edge point. (B is assigned an intensity value proportional to S.) The larger S is, for a given arc length N, the smaller the radius is of that circle that intersects points A, B and C. Hence, bright points indicate corners (i.e., points of high curvature). Clearly, it is possible to combine both edge smoothing and corner detection into a single routine. As before, this "free benefit" can make one technique preferable over another.

17.3.7.5 Processing the Binary Image as a Grey-Scale Array

Consider the following QT command sequence applied to a binary image (➋ *Fig. 17.32*) smooth_edge(N) defined as N•lpf, thr, for some suitable value of N. (Typically, $1 \leq N \leq 10$.) Using the blurring operator (i.e. low-pass filter) *lpf* on binary images is perfectly acceptable, since they are simply special cases of grey-scale images. (We use the convention that white is represented by level 255 and black by zero.) By applying *N•lpf* to a binary image, we generate a multi-level ("grey scale") image in which the intensity at any given point indicates how many white pixels lie nearby. If we then threshold the resulting image, we create a new binary image. The overall effect is to smooth edges in a way that is at least intuitively acceptable. The parameter N can, of course, be adjusted to taste: larger values of N produce a greater degree of smoothing.

There is an additional point to be made here. We may wish to smooth only convex corners and not concave ones, or vice versa. This can be achieved by smoothing edges as above and then combining the processed image with the original (binary) image. The QT sequence

smooth_convex_corners(N) defined as wri, smooth_edge(N), rei, mxi

(achieves this Note, *wri* saves an image on disc and *rei* reads an image from disc.)

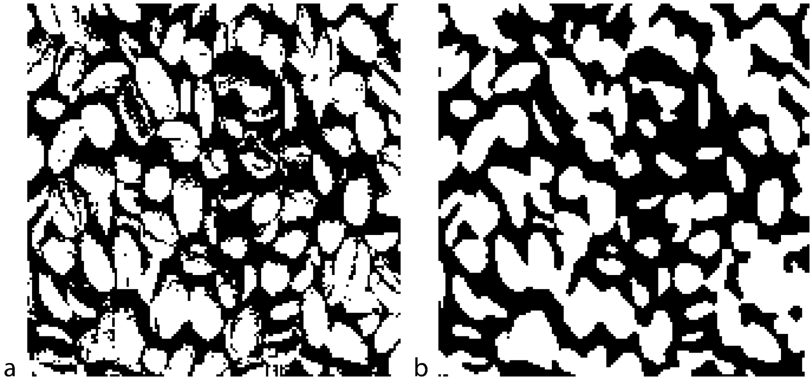

Fig. 17.32
(a) Original (binary) image, derived from ➋ *Fig. 17.7* by applying [*heq, thr(100)*] (b) Result of applying [*raf, thr*] to (a)

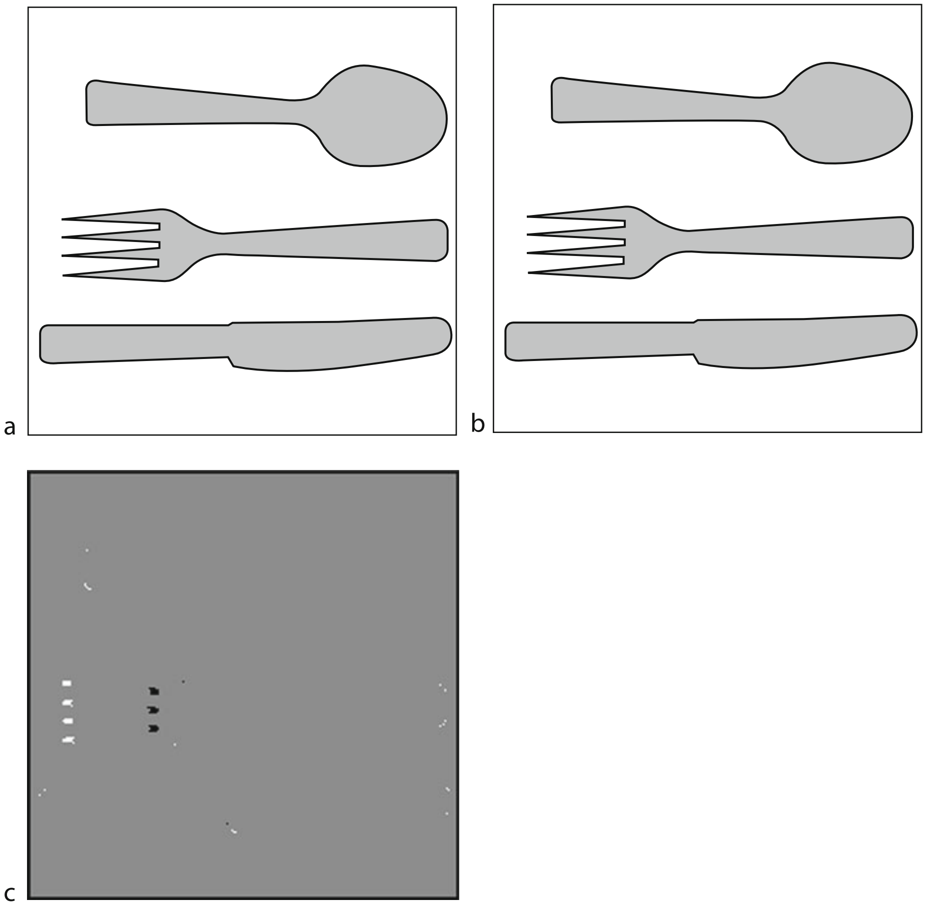

Fig. 17.33
(a) Original (binary) image (b) After applying [*3 • (raf, thr)*]. The tips of the tines and the bottoms of the spaces between the tines have been smoothed most effectively. (c) Result of subtracting (b) from (a)

A typical result obtained by applying *smooth_convex_corners (3)* to a binary image is shown in *Fig. 17.33*. Notice that the tips of the tines and the bottoms of the spaces between the tines can be detected and hence smoothed separately.

17.3.7.6 Edge Coding

Several more algorithms for edge smoothing can be derived from a type of edge-tracing algorithm which has not been mentioned previously. This starts at some convenient edge point P which might, for example, be the right-most point lying along the horizontal line passing through the centroid (CG in *Fig. 17.34*). Let D_i denote the distance around the edge from P to a given edge point Q_i. Furthermore, let R_i be the distance from the centroid of the blob to Q_i. Notice that D_i may be estimated from the chain code simply by counting

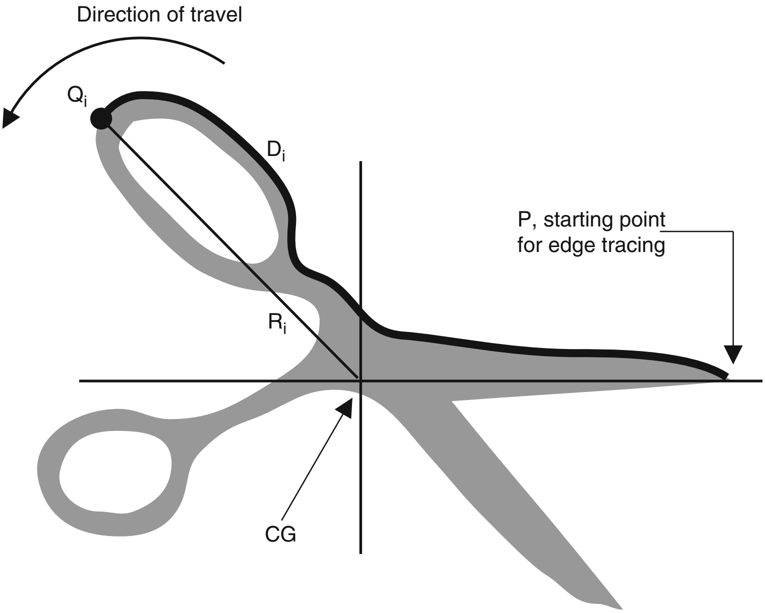

Fig. 17.34
Coding the edge of a blob by expressing the radius R_i (measured from the centroid CG) as a function of the distance D_i around the edge. D_i is measured by ($\surd 2 \bullet N_o + N_e$)

odd-numbered values, each of which contributes an increment of √2, and even numbered values, which contribute an amount 1.0. Clearly, R_i is a single-valued periodic function of D_i. The period is equal to the crude perimeter estimate

$$\sqrt{}2N_o + N_e$$

where N_o is the number of odd-numbered chain-code elements and N_e is the number of even-numbered elements.

There are several ways to devise an edge-coding scheme based on this coding technique. All of the following suggestions are based on conventional low-pass filtering methods typically used by electronics engineers to attenuate the high-frequency components in a time series:

- Simple N-element averaging (typically N=3, 5, 7, ...).
- Weighted-value smoothing, an extension of the previous idea which reduces the effects of distant events on the output signal.
- Fourier transform. This uses the fact that R_i is a periodic function of D_i.
- Walsh/Haar transform. Again, this makes use of the periodicity of R_i.

17.3.8 Techniques Based on Histograms

The importance of the histogram for machine vision can hardly be overstated, since parameters for many useful functions can be derived from it. Hence, the ability to find novel ways to compute the histogram opens up new opportunities for improving processing speed. Sometimes, as we will see, it is not necessary to calculate the complete histogram, since only one or two numeric values derived from it may be important for a specific application. We will touch on this point several times subsequently in this section.

The direct implementation of the histogram is straightforward. We scan the whole image and, at each pixel visited (i,j), we find the intensity A(i,j) and then increment the A(i,j)-th element in a (1+W)-element vector. (The minimum intensity in the image is zero, and W denotes the maximum intensity.) Initially, every element in this vector is set to zero. The U$^{\text{th}}$ element in the histogram indicates how many times the intensity value U occurs in the image.

Several approximate methods for computing the intensity histogram are known. First, we may sample the image to obtain an approximation to the histogram that is less accurate but can be calculated more quickly. The simplest way is to sub-sample the columns and/or rows and then calculate the intensity histogram on the lower resolution image. It is often found that reducing the spatial resolution of an image makes little difference to the result, since calculating the histogram is an integrative process. Of course, pictures which contain a few large nearly-homogenous regions produce the most stable histograms when calculated in this way. The effects of changing the resolution can be investigated experimentally by running the following QT program with different values of N:

```
N•psq,      % Halve spatial resolution when we increment N by 1
N•pex,      % Return image to the original size
hpi.        % Calculate the histogram
```

Another reduced-precision method relies on the use of a Hilbert-curve sampling pattern (➔ *Fig. 17.35*). Notice that the Hilbert curve meanders through the image, providing a uniform sampling density everywhere. The sampling density can be controlled by a single parameter.

An option that we may use very effectively in some situations derives the histogram in the normal way but only on some important sub-region of the image (known as a *region of interest*,

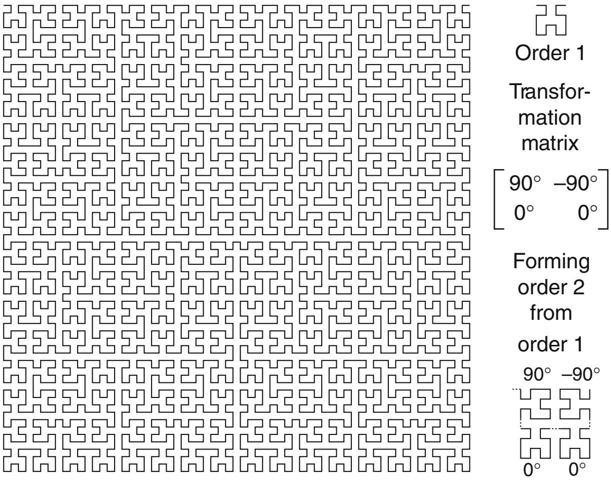

Fig. 17.35

Hilbert curve of order 5. Notice that the sampling density is uniform and can be varied at will by using Hilbert curves of different orders to sample the image. Higher-order Hilbert curves are derived by applying the transformation matrix shown above recursively

or *ROI*), ignoring other irrelevant parts. (This may achieve more useful results than the direct method, since non-relevant parts of the picture are ignored.)

It is possible to invent lots of other sampling schemes, which are combinations of or derivations of these basic ideas. One such hybrid scheme uses a low-precision scan (e.g., Hilbert-curve or raster) to locate a region of special interest and then employs higher-resolution sampling (perhaps of a different kind) to derive a high-precision histogram for a small part of the image.

17.3.8.1 Cumulative Histogram

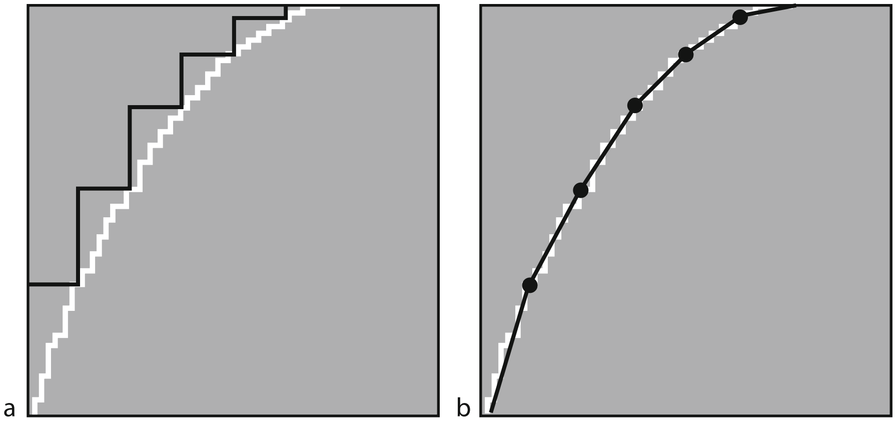
If the histogram is defined as the elements of the vector {H(i), i = 0,1,2, ..., W}, then the cumulative histogram is given by the recursive relationship

$$C(i) = C(i-1) + H(i), \text{with } C(0) = 0.$$

Clearly, the cumulative histogram can be derived simply, by integrating the intensity histogram. However, there is another possibility which might, in some situations, be superior. Assume that we possess some very fast (hardware) device for performing thresholding and pixel counting. (A very simple trigger circuit and pixel counter will derive one new element for the cumulative histogram every frame period.) We can easily compute the cumulative histogram by progressively adjusting the threshold parameter. This technique lends itself very well to sampling the cumulative histogram. As before, we can exchange processing speed for precision. We have to realise that the cumulative histogram finds its main application in deriving the look-up table used for histogram equalisation [*heq*] and that the cumulative histogram is monotonically increasing. With this in mind, we can see the advantage of sampling the cumulative histogram; we can use simple (e.g., linear) interpolation and just a few sample points on the cumulative histogram to obtain an approximation to the exact histogram-equalisation intensity-mapping function (➲ *Fig. 17.36*).

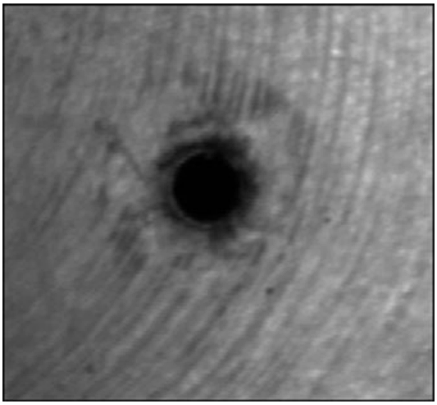
A completely different approach to approximating histogram equalisation relies on the fact that, in many applications, the images obtained at nearby moments in time are statistically very similar. In this situation, successive frames in the signal obtained from a video camera will generate similar histograms. A small object moving in front of a featureless background will generate an almost identical histogram in successive video frames (➲ *Fig. 17.37*). A web-like product will similarly generate very similar histograms from images derived from areas that are close together. (Many changes in the web are due to slowly changing factors, such as roller wear, coating material viscosity, etc. Of course, defects in the web may cause significant and very sudden changes in the histogram.) When the histogram is changing slowly, the histogram equalisation mapping function derived on one image can be applied to another image, digitised soon afterwards. This provides the basis for an approximate method of performing histogram equalisation in real time (i.e., full video frame rate) but with a 2-frame delay [8].

1. Frame 1: Calculate the intensity histogram of image 1.
2. Frame 2:
   (a) Derive the cumulative histogram. (Integrate the histogram.)
   (b) Rescale the cumulative histogram to form the mapping function.
   (c) Load this function into the look-up table.
3. Frame 3: Apply the mapping function to video frame 3.



■ **Fig. 17.36**

(a) Approximating the cumulative histogram. *White*: cumulative histogram of the beans image (See ➔ Table G.4). *Black*: cumulative histogram generated by applying *sca(3)* to the beans image. Notice that the staircase touches the true cumulative histogram exactly at seven places.
(b) Applying linear interpolation between these points produces a close fit to the true cumulative histogram



■ **Fig. 17.37**

The intensity histogram is very nearly constant, even if the major feature of the image wanders over a large area. Since the histogram of the machined background is nearly constant everywhere, it does not matter exactly where the camera is located in relation to the hole

17.3.8.2 Local-Area Contrast Enhancement

This is a non-linear filtering technique that is particularly useful for processing images derived from textured surfaces [5]. Histogram equalisation is performed on a relatively small region of the input image (e.g., 25 × 25 pixels) but only one pixel value is retained from this calculation. The processing window is scanned across the picture in a raster-like manner. At each step, the histogram-equalisation process is performed. Let us assume that the image contains N^2 pixels and that the processing window contains P^2 pixels. Then, the direct implementation requires that we performing N^2 histogram equalisation operations on P^2 pixels, keeping only N^2 pixels. We can do better than this! Let us consider what histogram equalisation actually means. Suppose that after histogram equalisation has been performed within a certain processing window $V_{i,j}$, we find that the new intensity value of a certain pixel (i,j) is $Q_{i,j}$. (As usual, the maximum value is W and the initial value of pixel [i,j] is $A_{i,j}$.) Then, a proportion $Q_{i,j}/W$ of the pixels in the window $V_{i,j}$ were darker than $A_{i,j}$. This is useful because it allows us to perform histogram equalisation for a single point, simply by counting how many pixels in the window $V_{i,j}$ are darker than $A_{i,j}$. This little trick has no real value for (full image) histogram equalisation but it can be useful for local-area histogram-equalisation, where we have to perform the same operation many times. The revised algorithm for local area contrast enhancement is therefore as follows. (The processing window $V_{i,j}$ is centred on the point [i,j]. To ensure that $Q_{i,j}$ is a true count of the number of pixels in $V_{i,j}$ that are brighter than $A_{i,j}$, we assume that $V_{i,j}$ contains $P^2 \leq W$ pixels.)

1. Set the raster-scan counters [i,j] to their initial values.
2. Count how many pixels in $V_{i,j}$ are darker than $A_{i,j}$. Denote this value by $Q_{i,j}$. (Notice that $0 \leq Q_{i,j} \leq P^2 \leq W$.) Set the intensity at point [i,j] in the output image to $Q_{i,j}$.
3. Increment the raster-scan counters and repeat step 2 for all pixels in the input image.

Notice that we have managed to reduce the calculation to one in which we merely perform $(P^2 - 1)$ comparisons for each pixel. We have eliminated the need to calculate the histogram directly.

17.3.8.3 Percentage Threshold

Let us turn our attention now to another histogram-based function, that of finding a threshold parameter which will divide the image in a given ratio. That is, given a parameter R (where $0 \leq R \leq 100$), what threshold parameter will segment the image so that R% of the pixels becomes black and $(100 - R)$% white? The cumulative histogram allows this parameter to be calculated directly. A particularly useful trick when using PQT is to perform histogram equalisation followed by fixed-value thresholding. For example, [*heq, thr*] segments the image so that 50% of the image is black, while [*heq, thr(200)*] makes 78% black [= (200/255) × 100%]. In more general terms, the following program makes R% of the thresholded image black.

```
heq,                 % Histogram equalisation
T = 255 ∗ R/100,     % Rescale percentage R to intensity scale, [0, W]
thr(T).              % Threshold so that R% is black and (100−R)% is white
```

(This is a possible way to implement the QT operator *pth.*) If we compute the intensity histogram first, we can terminate the integration process early, when R% of the total number of pixels in the image has been taken into account.

17.3.8.4 Contrast Enhancement

The PQT operator *enc* calculates the minimum and maximum intensities in an image and then rescales all of the intensity values, so that the darkest pixel becomes black and the brightest becomes white. This simple procedure is very effective in many applications but it is sensitive to noise. A more robust scheme for contrast enhancement is as follows: Let T(R) be that threshold parameter which ensures that R% of the threshold image is black. Let R_1 and R_2 be two parameters defined by the programmer. (Typically $R_1 = 5\%$ and $R_1 = 95\%$.) Then, we modify all of the intensities in the image, so that pixels of intensity less than or equal to $T(R_1)$ become black, pixels of intensity greater than or equal to $T(R_2)$ become white, and those in the intermediate range $[T(R_1), T(R_2)]$ are rescaled in a linear manner. This calculation is easily achieved using the cumulative histogram. However, note that we do not need all of the information in either the histogram or the cumulative histogram. We need only two values: R_1 and R_2. When using certain types of hardware (for example, the fast threshold and pixel-counting device mentioned above), we may not need to compute the histogram at all. Another point: once the values of R_1 and R_2 have been found, we can use a look-up table, rather than an arithmetic unit, to perform the intensity-scale mapping.

17.4 Approximate and Heuristic Methods

So far in this chapter, we have concentrated almost exclusively on algorithmic methods. Now, we turn our attention to approximate and heuristic techniques. There are several ways in which heuristics can be used in Machine Vision:

- To replace an algorithm
- To extend the range of application of an algorithm
- To make an algorithm run faster
- To do something useful when there is no known algorithm
- To do something useful when using an algorithm would be impractical

Machine Vision is a pragmatic subject. If we were to insist on using only algorithmic methods, our scope for building machines that are useful in practice would be severely curtailed. In this section, this point will be illustrated many times over.

17.4.1 Measuring Distance

Distance is an important parameter that is required in a very wide range of inspection applications. If we are asked to monitor the size distribution of granular material, we do not require a precise measurement of each particle. We often need to know the general trend, so that we can determine whether the particles are getting bigger or smaller. When grading carrots, parsnips, etc., we do not need to know the length precisely, since the concept of length is itself ill-defined for such an object. Similarly, when measuring the eccentricity in the placement of a piece of cherry on top of a cake, we do not need to know the result precisely. Again, there are fundamental limits, since the position of an object of indeterminate shape such as a piece of cherry cannot be defined precisely. (The centroid is often used to define position but there is nothing absolute about this.)

As we will see in this section, there are many ways to measure distance and hence linear dimensions. These alternative measurements do not always coincide exactly with what we normally call "distance", which we can measure using a tape-measure, micrometer or caliper gauge. However, they are often easier to calculate and will suffice for many applications. We use the term *Euclidean distance* to refer to the measurement that these instruments yield. In everyday life, we often use the phrase *as the crow flies* to emphasis that we are using the Euclidean distance. Astronomers and radar systems engineers relate distance to the time it takes for light or radio waves to travel between two points. These are simply ways of measuring Euclidean distance. However, vehicle drivers are well aware that a meaningful concept of "distance" must be related to the available roads. In this situation, the Euclidean distance metric is not the most meaningful.

The grass-fire transform was defined in ➋ Sect. 17.3 in terms of the Euclidean distance. As we will see later, it is often implemented using iterative techniques, which do not measure distance explicitly. Certain binary morphological operators can be regarded as performing a similar function to a *go/no-go* gauge and hence are size-sensitive. We will also describe a grey-scale morphological operator that implements the grass-fire transform and hence implicitly measures distances.

Let us now define the concept of Euclidean distance in formal terms. We will do so for a 2-dimensional space since we are interested in pictures. However, we should point out that the concepts we are about to discuss can be extended easily to 3- and higher dimensional spaces. Let $[X_1, Y_1]$ and $[X_2, Y_2]$ be two points within an image. Then, the Euclidean distance between them is

$$D_e([X_1, Y_1], [X_2, Y_2]) = \surd\{(X_2 - X_1)^2 + (Y_2 - Y_1)^2\}$$

As we hinted earlier, there are numerous alternatives to the Euclidean distance, which may be rather easier/faster to calculate in practice and which are intellectually just as valid. Here are the definitions of just two of them:

$$\text{Manhattan (city block) distance :} \quad D_m([X_1, Y_1], [X_2, Y_2]) = |X_2 - X_1| + |Y_2 - Y_1|$$
$$\text{Square distance :} \quad D_s([X_1, Y_1], [X_2, Y_2]) = \text{MAX}(|X_2 - X_1|, |Y_2 - Y_1|)$$

The Manhattan distance indicates how far a person would walk or drive in some North American cities, where the roads form a neat orthogonal grid. When travelling in such a city, it is perfectly natural to relate journey times to the Manhattan distance (i.e., number of city blocks to be traversed), rather than the Euclidean distance. The Square Distance is also more natural in some circumstances. For example, a *bang-bang* servomechanism operating a multi-axis robot will respond in a time that is proportional to the *Square Distance* to be travelled.

All three of these metrics have their uses for machine vision. In some situations, we may be able to use the squared Euclidean distance, D_{e2}, ($= D_e^2$) and thereby avoid the square-root operation.

$$D_{e2}([X_1, Y_1], [X_2, Y_2]) = (X_2 - X_1)^2 + (Y_2 - Y_1)^2$$

In mathematical terms, D_{e2} is not, strictly speaking, a distance metric, since it violates one of the essential conditions, namely that

$$D(A, C) \leq D(A, C) + D(B, C).$$

In mathematics, two other conditions are imposed on a distance metric:

$$D(A, A) = 0$$

and

$$D(A,B) = D(B,A)$$

Note that D_e, D_m and D_s are all particular cases of the *Minkowski r-distance*, which is defined thus:

$$L_r([X_1,\ Y_1],\ [X_2,\ Y_2]) = \sqrt[r]{(X_2 - Y_1)^r + (Y_2 - Y_1)^r}$$

In the limit as r tends to infinity, L_r approaches the Square distance. Hence, we refer to D_s as the L_∞ metric. Clearly, L_1 is the Manhattan distance and L_2 is the Euclidean distance. The equation

$$L_r([X_1,\ Y_1],\ [X_2,\ Y_2]) = K,$$

where K and r are constants, defines a symmetrical closed figure. Just as a circle is defined by the Euclidean distance, D_m produces a diamond-shaped figure, while D_s generates a square. The linear weighted sum ($D_m + \surd 2\ D_s$) generates an octagon, which is a more accurate approximation to a circle than either D_m or D_s alone.

The relevance of this discussion becomes clearer when we consider the effects of various operations in digital images. We have already seen in ➋ *Fig. 17.15* that applying the QT operator *exw* (expand white regions) more than once generates a 3 × 3 square from a single isolated white pixel. In other words, *exw* effectively draws contours of constant Square distance. On the other hand, *exw4*, the 4-neighbour version of *exw*, generates a diamond and hence is linked to the Manhattan distance.

Note that *exw4* may be implemented using the QT sequence

$$\mathrm{glc}(0,1,0,1,1,1,0,1,0),\ \mathrm{thr}(1).$$

The sequence

$$N \bullet (\mathrm{glc}(0,1,0,1,1,1,1,0,1,0),\ \mathrm{thr}(1),\ \mathrm{glc}(1,1,1,1,1,1,1,1,1),\ \mathrm{thr}(1))$$

generates an octagon.

Suppose now that we wish to find the farthest point in a blob, measured from some convenient reference point, such as its centroid. (This forms a useful basis for measuring object orientation.) An obvious way to do this is to scan the image computing D_e, D_m or D_s, as appropriate, for each pixel. However, this is wasteful of computing effort, if we need to do this calculation often. We can, for example, employ the QT operator *hic* to generate a reference image, which we then store for future use. *hic* generates an image in which the intensity at each point (i,j) is proportional to the Euclidean distance between (i,j) and the centre of the image. The image to be analysed is then shifted so that the reference point is coincident with the centre of the stored image (i.e., the brightest point in the output of *hic*), and these two images are combined, using *mni* (point-by-point minimum of intensities). The pixel in the resulting image at which the intensity is a maximum indicates the pixel within the blob that is farthest from the reference point.

The grass-fire transform is based on the concept of distance from the nearest edge pixel (➋ *Fig. 17.38*). While we describe the grass-fire transform informally using the concept of (Euclidean) distance, a practical implementation is most unlikely to calculate this or any of the aforementioned distance metrics directly. One possible implementation of the grass-fire transform employs a 3 × 3 local operator, applied recursively until the image does not change.

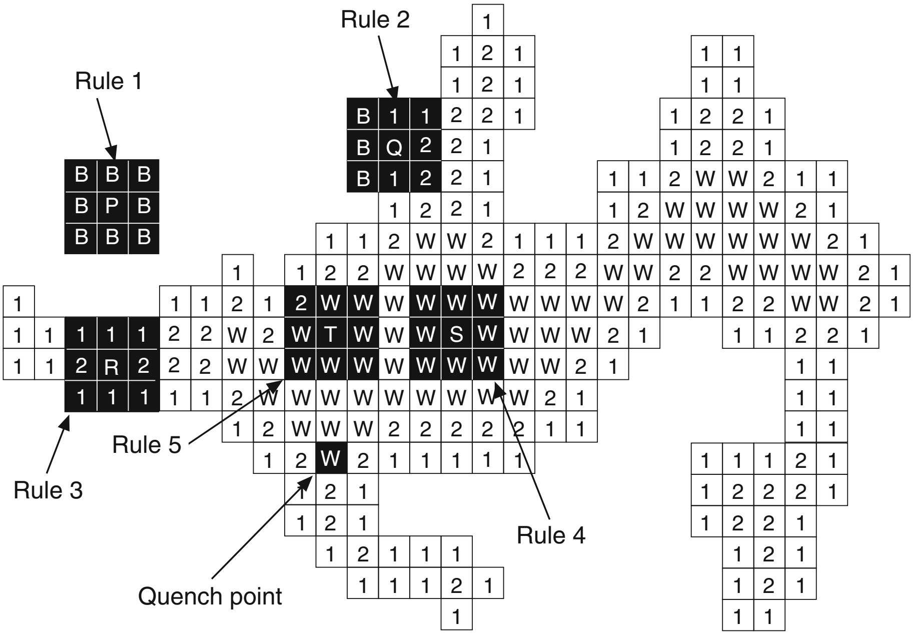


Fig. 17.38

Algorithm for the grass-fire transform. The black 3 × 3-pixel windows relate to cycle 1 (Rules 1 and 2), cycle 2 (Rule 3) and cycle 3 (Rules 4 and 5)

First, we have to decide whether to base the calculation on the 4- or 8-neighbours. (The latter effectively measures the Square distance to the nearest edge pixel. The former measures the Manhattan distance.) One possible implementation of the grass-fire transform is defined below. Initially, all pixels within an image are either white (level 255, inside a blob-like figure), or black (background). Consider pixel [i,j], whose intensity will be denoted by I(i,j). Those pixels in its (4- or 8-) neighbourhood will be denoted by N(i,j).

1. If I(i,j) = 0, [i,j] is a background pixel, in which case, we do not alter it. (Point P in *Fig. 17.38*)
2. If I(i,j) = 255 and at least one pixel in N(i,j) is black (level 0), we set I(i,j) to 1. These are the pixels just inside the edge of the blob (Point Q in *Fig. 17.38*).
3. If a pixel [i,j] already has a value other than black (0) or white (255), we do not alter it (Point R in *Fig. 17.38*).
4. If a pixel is white and all points in N(i,j) are white, the fire has not reached point [i,j] yet and we do not alter I(i,j) (Point S in *Fig. 17.38*).
5. If at least one of the points in N(i,j) has a value other than 0 or 255, we set I(i,j) to (Z+1), where Z is the minimum value for pixels in N(i,j). We ignore level 0, i.e., black, when computing I(i,j) (Point T in *Fig. 17.38*).

Rules 1–5 are applied to all pixels in the image. The whole process is then repeated recursively, until no pixels are altered (i.e., rule 5 is not invoked during a complete cycle through the image). Notice that we have not specified the order in which the pixels are processed, which gives us the chance to employ either a raster scan or an "onion peeling" scan. (The latter is faster and is discussed in the following section.)

If N(i,j) contains only the 4-neighbours of [i,j], the grass-fire transform generates a shading which records the Manhattan distance to the nearest edge point. On the other hand, if N(i,j) defines the 8-neighbourhood, the procedure records the Square distance. By alternating the procedure using 4- and 8-neighbours, we effectively combine the Manhattan and Square distances, so that the grass-fire transform records the octagon distance mentioned above (➲ *Fig. 17.15*).

While other procedures for implementing the grass-fire transform exist, we will not describe them here, other than to say that the SKIPSM approach (➲ Sect. 17.3.3 and ➲ Chap. 20) allows other distance measures to be defined by making use of arbitrarily-shaped structuring elements. The point to note is that there is no single "right way" to perform this calculation. We are used to measuring the shortest route between two points in terms of the Euclidean distance between them. However, we cannot say that the Euclidean distance is "right" and all other distance measures are "wrong." The implication for the grass-fire transform is that there is not just one procedure. Indeed, there are many and we must choose the one we want to use after considering its performance and its implementation.

Another point worth mentioning here is that the grass-fire transform can be regarded as providing a convenient alternative to an important subset of the binary morphological operators. The latter can be used to detect features that are within prescribed size limits (effectively measuring distance again). Notice, however, that the binary morphological operators do not measure distance or size explicitly; they are more akin to a *go/no-go* gauge, since they determine where an object that is the same size and shape as the structuring element will fit. The shape of the structuring element can, of course, be selected at will to be a circle, square, diamond or octagon, or any other figure of our choosing. Grey-scale morphological operators can be used to measure distance directly, using any distance metric. ➲ *Figure 17.39* explains

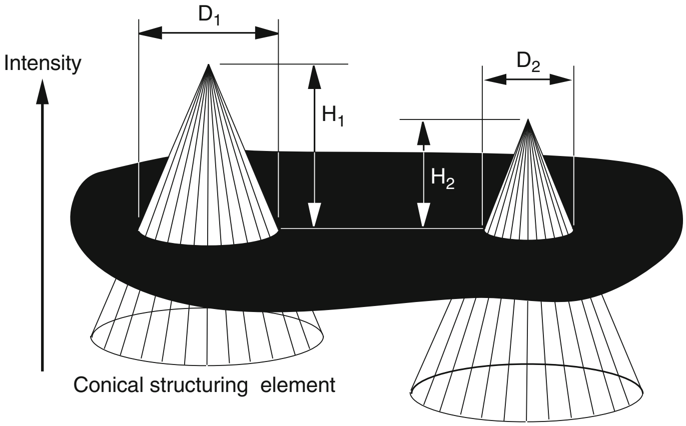

Fig. 17.39

Using grey-scale morphology to measure Euclidean distance. The structuring element is a right circular cone. The intensity surface (black region) contains two holes. The height of the tip of the cone (H_1, H_2) is directly proportional to the hole diameter (D_1, D_2)

how a grey-scale morphological operator can be used to implement the grass-fire transform based on the Euclidean distance.

17.4.1.1 Similarity and Distance

Suppose that we have derived an ordered set (vector) of numeric measurements from an image. These measurements might, for example, define the components of the colour vector at a given point, in which case, they would simply be the RGB (or HSI) signals, derived by a video camera. Another possibility is that these measurements summarise the overall texture within an image. Alternatively, the measurement vector might describe some feature such as a spot-like defect on a web. (Our inspection task then would be to identify the type of defect.) Whatever it represents, let us denote this set of measurements by $X = (X_1, X_2, ..., X_q)$, where q is a positive integer, typically in the range 2–20. In order use X to identify a given image feature it would be reasonable to compare it with a number of stored reference vectors, which we will represent by $Y_i = (Y_{i,1}, Y_{i,2}, ..., Y_{i,q})$, where i is a positive integer in the range [1,N]. A possible measure of *dissimilarity* between the features described by X and Y_i is given by the Euclidean distance:

$$D(X, Y_i) = \sqrt{\left(\left(X_1 - Y_{i,1}\right)^2 + \left(X_2 - Y_{i,2}\right)^2 + \left(X_3 - Y_{i,3}\right)^2 + \cdots + \left(X_q - Y_{i,q}\right)^2\right)}$$

There are many other ways to perform classification using the concept of distance as a measure of dissimilarity [1]. It is not our intention to review all of these in detail here. Instead, we will merely mention one important technique, nearest neighbour classification. (See ❯ Chaps. 16 and ❯ 24). In this scheme, we find the Y_i which minimises $D(X, Y_i)$ in order to recognise the feature or pattern associated with the vector X. Each of the Y_i is carefully chosen to represent or typify some cluster or group within the data set and is therefore called an *exemplar.* Y_i is associated with an appropriate label, C_i, which indicates the type of pattern, feature or event which gave rise to it. More than one Y_i may be given the same label, indicating that they correspond to the same pattern class. Several learning rules are known for designing the nearest neighbour classifier, some of which are liable to store a large number of exemplars. This can cause a problem not only for storage but also for the speed of computation. It is possible to improve the speed of the nearest neighbour calculation by subdividing the Y_i into groups, each of which is assigned a *super_exemplar.* The set of super-exemplars will be represented by $\{Z_j\}$. Notice that $\{Z_j\}$ is a proper sub-set of $\{Y_i\}$. (i.e., $\{Z_j\} \subset \{Y_i\}$) During a pre-processing phase, each of the super-exemplars, Z_j, is linked to another sub-set of the exemplars (Q_j), which are all known to be close to Z_j. (Again, $Q_j \subset \{Y_i\}$) Then, classification of X proceeds as follows:

1. Find a near neighbour to X among the set $\{Z_j\}$. This will be denoted by Z_j.
2. Find the nearest neighbour to X among the set Q_j. Denote this by W_k. (Assuming that the preprocessing phase has been properly designed, step 2 always finds the *nearest* neighbour to X among the set $\{Y_i\}$ and the number of computational steps is very much reduced. The details are tedious to explain and would distract us from our main theme.)
3. Associate the pattern which gave rise to the measurement vector X with class C_k. (Recall that W_k is the nearest neighbour to X among the set $\{Y_i\}$.)

This is an example of an heuristic being used to improve processing speed. The procedure is not algorithmic because we cannot guarantee that it will achieve a speed increase, although we can be certain that it will always find the nearest neighbour. The improvement in processing speed is achieved at a certain cost, by increasing the computational load in the pre-processing phase. This is akin to using an optimising compiler to reduce the computational effort needed at run-time.

17.4.1.2 Skeleton and the Medial Axis Transform

The skeleton of a blob-like object can be defined in terms of the grass-fire transform as the set of *quench points*. A quench point is one where two or more advancing fire lines converge at the same time and derives its name from the fact that there is no more combustible material there left to burn (➲ *Fig. 17.38*). Another definition of the skeleton relies on the fact that every point on it lies equidistant between two or more edge points. Neither of these definitions is very convenient as the basis for use in a practical application where high speed is needed. A more pragmatic approach is represented by the so-called *onion-peeling* procedure. For the sake of simplicity, in the following explanation, we ignore the possibility of there being lakes present, since they cause complications and obscure our understanding of the heuristic. The basic onion-peeling procedure may be described as follows (➲ *Fig. 17.40*): We trace the edge of the blob, as if we were chain coding it. As we do so, we delete (set to black) each pixel visited *unless it meets any one of these three conditions*:

1. It has only one white neighbour. Such a point is part of the skeleton and is therefore retained.
2. If it is critical for the connectivity among its remaining 8-neighbours. (c.f. the QT operator *cny*, (➲ Chaps. 19 and ➲ 41)) Again, such a point is part of the skeleton and is retained.
3. It is a skeleton point. (No skeleton point is ever erased.)

We repeat the process until there are no more changes possible. The resulting figure is the skeleton. However, the match-stick figure generated thus is not quite the same as that formed by the quench points generated by the grass-fire transform. (The latter is called the *medial axis transform*.) The onion peeling procedure has been found to be perfectly acceptable in all practical applications that the author has studied. Moreover, it somewhat faster and generates a "clean" skeleton, with very fewer short side branches than the quench-point method.

The onion-peeling procedure could be modified to generate the grass-fire transform, also. How this could be achieved is fairly obvious from ➲ *Fig. 17.40*.

The problem mentioned earlier relating to lakes is illustrated in ➲ *Fig. 17.41*. Notice how the skeleton is "tightened like a noose" around the lakes. To avoid this, we have to modify the procedure just described, so that we alternately trace once around each outer edge, then once around each inner edge. This involves additional rules, which inevitably slow down the procedure. For many purposes, however, the simpler heuristic will suffice, despite its known limitations on objects containing lakes.

17.4.1.3 Remarks

In this section, we have discussed several varied procedures, all of which are based on the concept of distance. First, we showed that it is possible, in many situations, to avoid the rather complicated calculation needed for the Euclidean distance. This can be achieved by using the

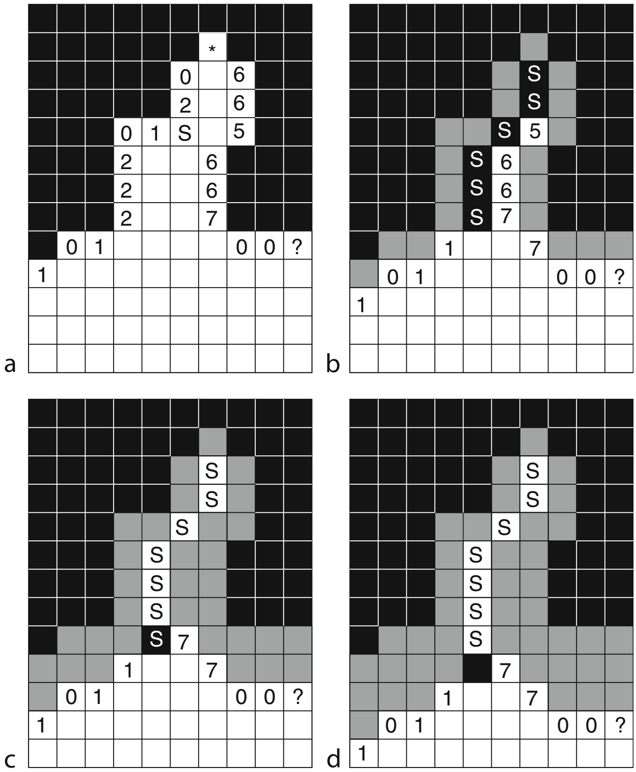

Fig. 17.40

Generating the skeleton of a blob by the onion peeling procedure. For clarity, only part of the blob is shown. When the edge follower reaches the right-hand-side of the sub-image shown here, it continues tracing the outer edge of the blob in a counter-clockwise direction until it eventually reaches the left-hand side again. Numerals 0–7 indicate the direction of travel of the edge follower. (same as chain code) 'S' is a skeleton point. (a) First cycle: '*' indicates the starting point. When the edge follower reaches the top-most '0', it tries to revisit the starting point. This signals the beginning of the second cycle. (b) The second cycle consists of these moves: S, S,5,6,6,7,7,0,0,...,1,0,1,1,S,S,S,S. (c) The third cycle consists of these moves: 7,7,0,0,...,1,0,1,1,S. (d) The fourth cycle consists of these moves: 7,7,0,0,...,1,0,1,1,S

Square or Manhattan distance measures instead. These can often be substituted directly for the Euclidean distance. We have shown that it is often possible to avoid the distance calculation altogether, by using iterative filtering techniques. We can also use iterative processing to implement the grass-fire transform, while the skeleton can be derived by a process that is effectively a modified form of edge tracing. Morphological operators can measure object size in a binary image without the use of distance measurement and, as we have seen in Sect. 17.3.3, we can implement these using look-up-tables. Although the nearest neighbour classifier is implicitly based on the concept of distance, the use of *near* neighbours allows us to improve the processing speed, by the simple expedient of eliminating calculations that are obviously unnecessary.

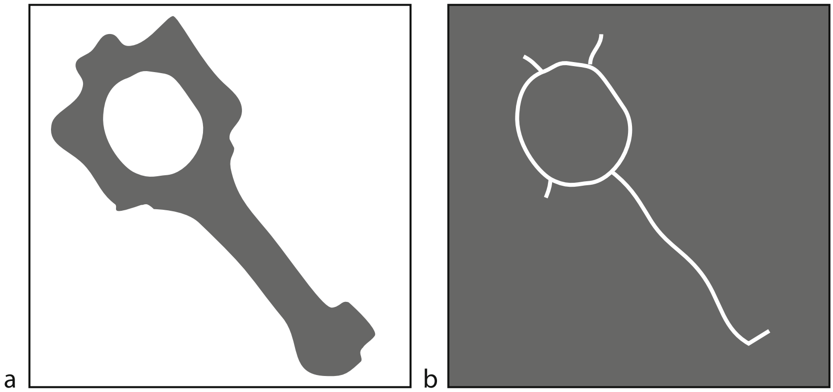

Fig. 17.41
An undesirable feature of the simple onion-peeling procedure. The skeleton is "tightened like a noose" around the lakes

17.4.2 Fitting Circles and Polygons to a Binary Object

In this section, we will consider various ways of representing a blob-like object with another figure (i.e., a circle or polygon). We have already considered this topic in some detail in Sect. 17.3.6, where we discussed the derivation of the convex hull. Intuitively, we may feel that this figure has a unique relationship to the shape that it represents, since it satisfies these three criteria:

(a) It is convex.
(b) It totally encloses the given shape.
(c) It is of minimal area.

While the figures about to be discussed do not possess all of these properties, they do, nevertheless, provide the basis for a range of useful analytical tools and in some circumstances can be used in lieu of the convex hull. Of course, there is no unique circle or polygon, including the convex hull, that properly represents *all* important features of a given blob. For this reason, we have to be careful to use the most appropriate one for a given application. In the following discussion, we will relax conditions (b) and/or (c), and impose other, equally valid criteria. Some of the figures that result are larger than the convex hull, while others do not contain all of the pixels within the given shape. We must not presuppose, however, that this invalidates them or makes them any less useful. Indeed, most of these alternative procedures are easier/cheaper to compute than the convex hull and, in many cases, possess features that are just as useful in practice. Since there is no "optimal" way of representing a blob by a circle or a polygon, the choice of which one to use in a given application depends upon its specific requirements.

17.4.2.1 Coin-in-a-Slot Procedures

Consider the task of inserting a coin into a slot-machine. We will generalise this to consider shapes other than circles being pushed through a slot. The size of the slot is, of course, deliberately chosen to match that of the object to be passed through it. An important parameter of a shape is the size of the smallest slot that it can pass through. However, this statement does not specify the problem fully In effect, there are several possible solutions, depending on the answers to the following questions:

(a) Are we allowed to manoeuver the shape as it goes through the slot, or must it pass "straight through"?
(b) Are we allowed to reorient the shape before we pass it "straight through" the slot?

A complex iterative procedure is required to draw the minimum-size circle that encloses a given blob, touching it at three points (➜ *Fig. 17.42*). One important circle that can be drawn rather more easily around a given blob is the one that intersects the two edge points that are farthest apart. This can be obtained by the edge-following process, and generates the bounding circle of minimum area.

Now, suppose that we are allowed to rotate the shape before passing it through the smallest possible slot. In this case, to find the minimum size of the slot we can use another edge-tracing procedure. Let E be the set of edge points, which contains N_E pixels. The Euclidean distance between two edge points A and B will be denoted by D(A,B), $A \in E$, $B \in E$. Given an edge point P, we simply find another edge point Q that maximises D(P,Q). Let us denote this value by D_P. We repeat this process for all edge points ($P \in E$), and then calculate the minimum value of D_P. A simple procedure of this kind requires $O({N_E}^2)$ time. A modest reduction in computational effort (about 50%) can be achieved by tracing only those edge pixels that have not already been considered. (Recall that D(A,B) = D(B,A). See ➜ *Fig. 17.43*.)

We will now describe a faster but approximate procedure for estimating the same parameter (➜ *Fig. 17.44*). Let us take two edge points A and B that are spaced $\lceil N_E/2 \rceil$ chain-code steps apart. (We are forced to round ($N_E/2$) up or down quite arbitrarily, since we do not know whether N_E is odd or even. The chain code must be regarded as forming a circular list structure, since the starting point is quite arbitrary and must be treated in the same way as all other

Scanning the edge using two points (A,B) which are separated by ⌈$N_E/2$⌉ chain-code steps

points.) We then calculate the Euclidean distance between them, D(A,B). We then move A and B simultaneously around the edge of the blob, and find the position which maximises the value of D(A,B). At this position, we find the mid-point of the line AB, which is then taken to be the centre of the circle to be fitted to the given blob. This simple procedure does not always find the same circle as the previous method but it is likely to be much faster, since the computation time rises as $O(N_E)$.

17.4.2.2 Circumcircle Based on the Centroid

Another circle whose parameters are easy to compute is concentric with the centroid of the blob and has a radius equal to the distance from the centroid to the furthest edge point (➋ *Fig. 17.45*). This circle is usually larger than that produced by the three previous methods but is usually faster in software. Estimating the centroid requires $O(N^2)$ time, where N defines the image resolution, and locating the most distant edge point from the centroid takes $O(N_E)$ time. The following PQT command sequence also draws this circle:

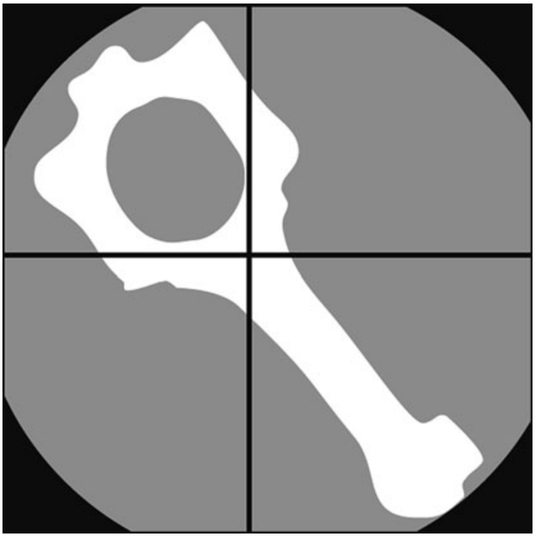
```
cbl(1),        % Check that there is only one blob
[X,Y] = cgr    % Centroid is at [X,Y]
```

```
hic(X,Y),       % Draw intensity cone
mni,            % Mask cone by the input blob
Z = gli         % Find intensity at the furthest point from centroid
swi,            % Switch current and alternate images
thr(Z),         % Threshold the cone – produces a solid white disc
```

17.4.2.3 Circle of Equivalent Area

Our next method for fitting a circle is to find the area (A) of the given blob. Then, take the radius to be √(A/π). Again, the centre of the circle is set to coincide with the centroid of the blob. Of course, this circle does not contain all of the points within the blob unless it happens to be a circle. This procedure is particularly useful for display for a human operator, since both size (area) and position are preserved (➔ *Fig. 17.46*). Here is the QT program for generating this circle.

```
[X,Y] = cgr,            % Centroid is at [X,Y]
A = cwp,                % Count white points
B = int(sqrt(A/pi)), X1 = X-B, Y1 = Y-B, X2 = X+B, Y2 = Y+B,
zer,                    % Black image
cir(X1,Y1,X2,           % Draw disc – specify corners of enclosing rectangle
Y2,255),
```



■ **Fig. 17.45**

The cross-lines indicate the centroid and the circle is tangential to the edge at its farthest point from the centroid

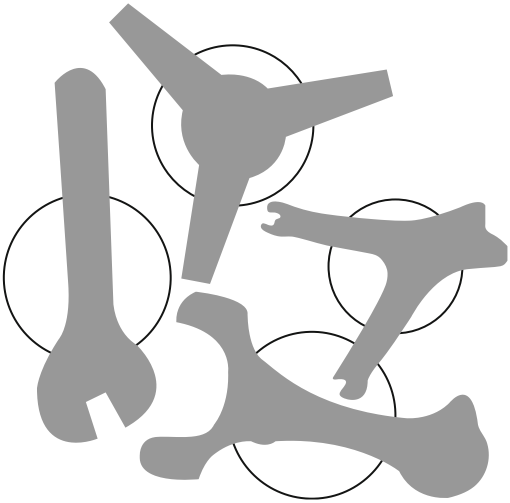


Fig. 17.46

Circles drawn by the QT command *dab*('*dec*'). Each circle has the same area as the shape it represents

17.4.2.4 Fitting a Circle to a Nearly Circular Object

The next method for generating a circle to represent a given blob is most appropriately used when that blob is itself nearly circular, or it contains a well-defined region where the edge is a circular arc. It is particularly useful for estimating the radius and centre of curvature and is used, for example in Chap. 31 to compute the radius of curvature of the shoulder of a glass vial. Given three edge points, $[A_x,A_y]$, $[B_x,B_y]$ and $[C_x,C_y]$, we can use the following formulae to estimate the position of the centre $[P_x,P_y]$ and radius, R, of that circle which intersects all three points:

$$\begin{aligned}
D &= 2\left(A_yC_x + B_yA_x - B_yC_x - A_yB_x - C_yA_x + C_yB_x\right)\\
P_x &= \left(B_yA_x{}^2 - C_yA_x{}^2 - A_yB_y{}^2 + A_yC_y{}^2 + C_y{*}B_x{}^2 + B_yA_y{}^2 + A_yC_x{}^2\right.\\
&\quad \left. - B_yC_y{}^2 - B_yC_x{}^2 - A_yB_x{}^2 + C_yB_y{}^2 - C_yA_y{}^2\right)/D\\
P_y &= \left(C_xA_x{}^2 + C_xA_y{}^2 + A_xB_x{}^2 - C_xB_x{}^2 + A_xB_y{}^2 - C_xB_y{}^2 - B_xA_x{}^2\right.\\
&\quad \left. - BxA_y{}^2 - A_xC_x{}^2 + B_xC_x{}^2 - A_xC_y{}^2 + B_xC_y{}^2\right)/D\\
R &= \sqrt{\left(\left(A_x - P_x\right)^2 + \left(A_y - P_y\right)^2\right)}.
\end{aligned}$$

(This is the basis of the QT command *fcd.*) To estimate the radius of curvature of a supposedly circular arc, three well-spaced edge points are chosen. The position coordinates (Px, Py) and radius (R) are then calculated. Notice that, if $[A_x,A_y]$, $[B_x,B_y]$ and $[C_x,C_y]$ lie too close together, wild fluctuations in the estimated values for Px, Py and R can occur in response to quantisation effects and camera noise. In order to obtain an accurate fit, we can perform this process repeatedly, as $[A_x,A_y]$, $[B_x,B_y]$ and $[C_x,C_y]$ are moved progressively around the arc. At each position, we place a spot at the centre of the estimated circle. Gradually, as more and more edge points are analysed, a pattern emerges, often in the form of several bright fuzzy spots, each one indicating the centre of curvature of a separate circular arc (➔ *Fig. 17.47*). This provides a useful method for detecting circular arcs arising from partially occluded circular discs. The other methods described here are unable to perform this function. If the arc being analysed is a nearly circular ellipse, or in the shape of an egg or rugby-ball, the set of points plotted in this way may trace a curve, rather than form a compact cluster (➔ *Fig. 17.48*).

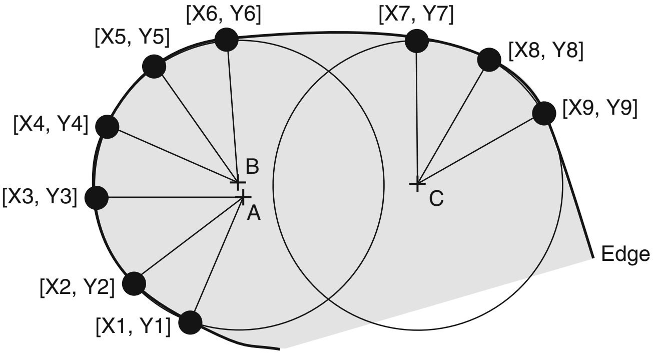

Fig. 17.47
Three edge points, such as [X1,Y1], [X2,Y2], [X3,Y3], can be used to fit a circle (centre A) to a small portion of the edge. This process can be repeated many times to yield a succession of circles (centres B and C). Notice the tendency of the centres of these circles to cluster together (points A and B), if the edge contains a long circular arc. This clustering is evident in ➔ *Fig. 17.48*

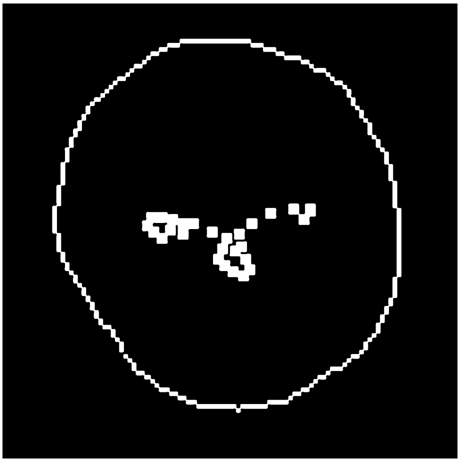

Fig. 17.48
The centres of the circles fitted to the edge of a satsuma (a member of the citrus family of fruit) form a diffuse cluster, since the edge is not a perfect circle

17.4.2.5 Polygonal Representations of a Blob

Several algorithms for calculating the convex hull of a blob-like figure have already been described in ➲ Sect. 17.3.6. In contrast to this, our objective here is to demonstrate that, for many purposes, there exist perfectly acceptable alternatives (heuristics) that are likely to be easier to calculate but which generate approximations to the convex hull. It is possible, for example, to define a tree-like structure (akin to a concavity tree) to represent a shape in terms of its minimum bounding circle [*mbc*] rather than its convex hull. Sometimes the approximation to the convex hull can be quite crude. Apart from rectangles, we might choose to use triangles, pentagons, hexagons, octagons, hexadecagons or one of the circles defined earlier in this section. In many application, these are all valid approximations. We need to adopt a pragmatic attitude, so that any technique that produces acceptable results at a tolerable computational cost can be used. Whether or not a given approximation will suffice depends, of course, on the application.

17.4.2.6 Minimum-Area Rectangle

One of the simplest of these approximate methods uses the minimum-area rectangle (QT operator *mar*, ➲ *Fig. 17.49*). Notice that the sides of this rectangle are parallel with those of the image. The minimum and maximum X- and Y-limits of a blob can be found very easily, whether we base our calculations on an array, the run-code, chain code or the polar vector representation. The procedure for finding the maximum/minimum of a sequence of numbers is straightforward, and we will not dwell further on this point.

17.4.2.7 Minimum-Area Octagon and Higher-Order Polygons

A minimum-area octagon whose sides are all inclined at an integer multiple of 45° relative to the sides of the image can also be generated easily. One way to derive this figure is explained in ➲ *Fig. 17.50* and relies on the use of various intensity wedges. (These have intensity contours (isophotes) inclined at different angles.) The wedge images can be stored, rather than recomputed for each new image that is to be processed. This ploy saves computation time

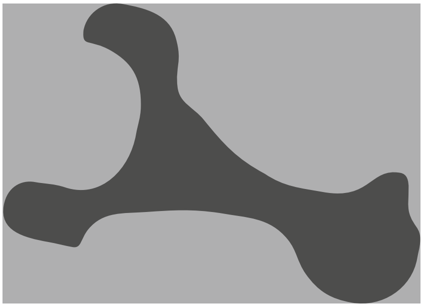

Fig. 17.49
The minimum-area rectangle whose sides are parallel to the image border

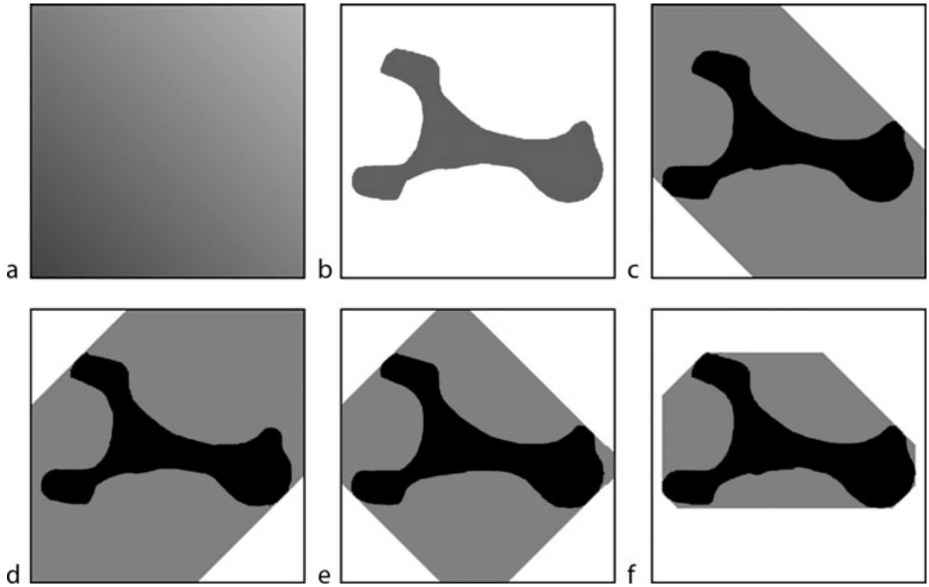

Fig. 17.50

Generating a minimal octagon to fit a given blob (i.e., automobile connecting rod). (a) Intensity "wedge." (b) Input shape applied as a mask to intensity wedge. (Grey-scale range expanded for clarity.) (c) Maximum and minimum intensities found in (b) are used as parameters for thresholding (a). (d) As in (c) but using a different wedge. (e) The stripes in (c) and (d) are combined [QT: *mni*]. (f) The octagon was generated in the same way as (e) but *four* stripe images were combined

but may require a little more hardware, i.e., extra memory. (Digital storage is so inexpensive nowadays that this is a small price to pay for increasing the processing speed.)

The minimum-area octagon is a closer approximation to the convex hull than is the minimum-area rectangle, simply because the former has twice as many sides. A multi-sided polygon can make the approximation even more accurate and can be generated by a simple extension of the same procedure. For example, we might choose to approximate the convex hull by a hexadecagon (16 sides), in which case, we generate and store eight wedge images (➲ *Fig. 17.51a*). However, there is no reason why we should restrict ourselves to generating a *regular* polygon. Using a simple QT program, we can generate a polygon with as many sides, inclined at any angles, as we wish. The program details need not concern us here.

17.4.2.8 Minimum-Area Rectangle

It is quite easy to construct a minimum-area rectangle whose sides are inclined at some arbitrary angle to the image axes. This can be achieved simply by rotating the input blob, then constructing the minimum-area rectangle as before, and finally reversing the rotation. As an illustration of this, the following QT program derives the smallest rectangle whose sides are parallel/normal to the principal axis derived from the original image (➲ *Fig. 17.51b*).

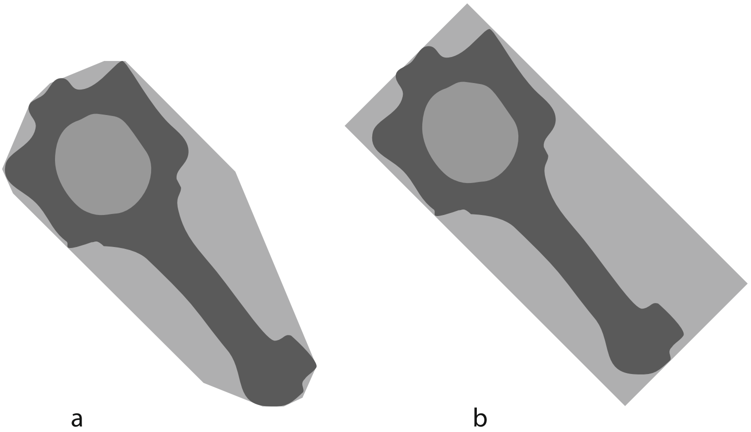

Fig. 17.51
(a) Minimal area hexadecagon whose sides are oriented at angles of 0°, 22.5°, 45°, . . ., 337.5°.
(b) The minimum area rectangle whose orientation is determined by the principal axis

```
[X,Y,A] = lmi               % Centroid (X,Y) & orientation of principal axis
[Xw1,Yw1,Xw2,Yw2] = dgw,    % Image size
Xw = (Xw2−Xw1)//2,          % Width of the image
Yw = (Yw2−Yw1)//2,          % Height of the image
X1 = Xw−X,                  % How much to shift image in X direction
Y1 = Yw−Y,                  % How much to shift image in Y direction
X2 = −X1,                   % How much to perform reverse shift (X direction)
Y2 = −Y1,                   % How much to perform reverse shift (Y direction)
psh(X1,Y1),                 % Shift so blob is at centre of the image
B = −A,                     % Negative of angle of orientation
tur(A),                     % Normalise orientation
mar,                        % Minimum area rectangle (hollow)
blb,                        % Fill the minimum area rectangle
tur(B),                     % Reverse rotation
psh(X2,Y2),                 % Reverse shift
```

Image rotation is not normally regarded as being very satisfactory because it frequently creates ragged edges. Notice, however, that the program above always rotates a rectangle, which makes the effect less pronounced than it would be if we rotated the input blob a second time. The second image rotation can be avoided altogether, since we need only compute the coordinates of the *corners* of the rectangle generated by *mar*. We then calculate their new positions after rotation and construct a (hollow) rectangle, simply by drawing its sides as four digital straight lines.

The astute reader will have noticed by now that we do not need to rotate the input image either, since we could derive the orientation of the axis of minimum second moment (using *lmi*), then trace the blob edge to find the extreme points along that axis and normal to it. There are many ways to implement nearly every algorithm!

17.4.2.9 Remarks

In this section, we have discussed a variety of techniques for generating figures such as rectangles, polygons and circles to represent a given shape. By the word "represent" we mean that we replace the given shape by another which in some way simplifies the subsequent calculation or display of the image. By choosing the most appropriate data-extraction procedure, we can remove unwanted information while retaining other data that is able to summarise some significant property of the given shape. We may wish to preserve position and orientation, but ignore the complexity of a meandering edge contour. On the other hand, we may wish to compute the "density" of a shape by comparing its area to that of its convex hull, or the minimum bounding circle. There are numerous options; the biggest mistake of all is to believe that just one of them (e.g., the convex hull) is inherently "better" than all of the others.

17.4.3 Determining Object/Feature Orientation

Perusal of the Computer Vision literature quickly reveals that the Hough transform is a very popular method for fitting a straight line to a set of disconnected colinear spots in a digital image. On the other hand, it has not gained anything like the same level of support with Machine Vision system designers. In this section, we will discuss why this has happened and we will look at alternatives to the Hough transform (➋ Chap. 18) that can perform a similar function.

First, let us explain what the Hough transform (HT) does. Given a digital image containing a set of disconnected spots, the HT can detect a subset of those spots that lie along a straight line (➋ *Fig. 17.52*). That line can be at any orientation and be in any position. The HT can also be used to join together fragments of a "broken" straight line that might arise, for example, from applying an edge detector (e.g., *sed*) and thresholding to a low-contrast image. The fact that the HT can detect sets of collinear spots aligned at any orientation is both its strength and its weakness. Obviously, it is necessary sometimes to work with images whose structure is completely unpredictable. This is the domain of Computer Vision research. On the other hand, Machine Vision system designers nearly always know, in general terms, what format the images will have. This knowledge means that very general procedures such as the HT are often not needed, since less expensive techniques will suffice and may give better results, since they are more specific.

Consider the task of determining the orientation of an object such as a machine component. In many cases, we can use the outer edge to determine the object orientation. We might instead use holes, 3-D shape or vividly coloured regions, etc., to perform the same function. We might sometimes be forced to use "internal" edges but we can, in some instances, make them more pronounced by using specialised lighting techniques. We must always be careful to distinguish between the primary task (i.e. finding the orientation of the object) and the secondary task (e.g., finding the orientation of a given edge in an image). Consider the image shown in ➋ *Fig. 17.53*. This has several "strong" features, which create a high local contrast (e.g., holes, outer edge) and "weaker" ones, principally the "internal" edges. In order to determine the orientation and position of this particular object prior to directing a robot to pick it up, we would be foolish to rely on the weak features, whose structure is, in any case, complicated compared to that of some of the stronger ones. As a general principle we should,

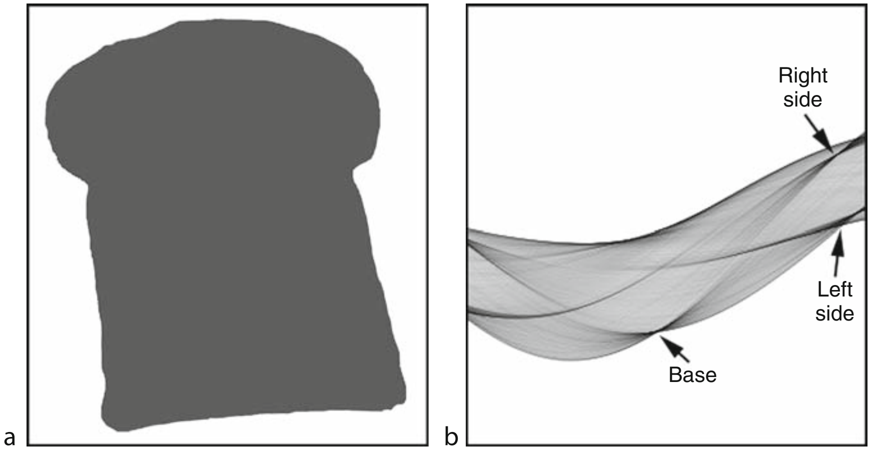

Fig. 17.52
Hough transform applied to the silhouette of a slice of bread. (a) Original image. (b) [*QT: bed, huf, neg, 2•sqr*] applied to (a). (The sub-sequence [*neg, 2•sqr*] simply improves the contrast for human viewing.) Notice the three dark points, which indicate the base and sides of the loaf, and that the sides are nearly parallel (i.e., nearly same position along the horizontal axis)

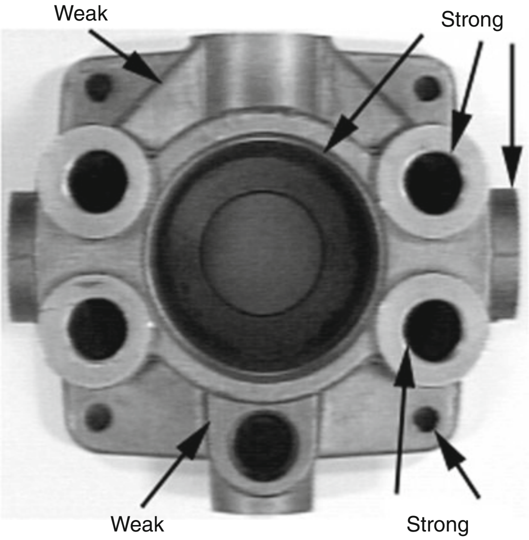

Fig. 17.53
The Hough transform could, in theory, be used to determine the orientation of this object (an hydraulics manifold) by using it to detect one of the four linear features, two of which are labelled ''weak.'' However, this would not provide as reliable a result as a technique based on higher contrast features, such as the holes and the outer edge contour (labelled ''strong'')

wherever possible, extract and measure features that are both robust and easy to analyse. In most case, internal edges are often not so satisfactory in one or both of these respects.

Among the alternative procedures for determining object orientation that are open to us are these:

- Principal axis (axis of minimum second moment) (PQT command *lmi*).
- The line joining the centroid to the edge point that is farthest from the centroid.
- The line joining the centroid of the object silhouette to that of the largest bay.
- The line joining the centroid of the object silhouette to that of the largest lake.
- The line joining the centroid of the largest bay to that of the second largest bay.
- The line joining the centroid of the largest lake to that of the second largest lake.
- The line joining the centroid of the largest bay to the centroid of the largest lake.

Clearly, there are many other options (Appendix F). To be accepted for use in a vision system, the designer must believe that the HT is demonstrably better than all of these competitors. Moreover, to avoid using a computationally expensive technique such as the HT, the designer has many optical tricks at his disposal to make the task simpler for the image processor.

Now, let us consider analysing sheet material made in the form of a web that is formed, treated, coated and printed using rollers. All predictable features, such as printed patterns, are precisely aligned to the edge of the web, assuming that it is well made. Faults on the web are, by definition, not predictable and could, in theory, occur in any orientation. However, there are two points to note:

1. We do not normally need to know the orientation of a single blob-like fault, such as a spot caused by localised chemical contamination, material fault, coating blemish or a squashed insect.
2. Certain faults which are caused by the manufacturing process are always aligned along the up-down axis of the web. For example, a very common type of fault is caused by a piece of material being dragged along the surface of the web, leading to a scratch in the direction of the web motion. Another commonly occurring fault is manifest as a point-like fault repeated periodically. It is not difficult to see that this is caused by a foreign body adhering to one of the rollers used to manufacture the web.

In neither case do we need to measure the orientation of anything on the web, except perhaps along accurately defined axes. We will return to this later, since it enables far less computational work to be used. It is a common requirement for web products to have well defined surface-texture properties but, once again, these can almost always be related to the web axes.

These arguments suggest that the HT is not very useful for machine vision, where verification rather than recognition is required. There are, of course, many other application tasks, such as robotic trimming of vegetables, decorating cakes, guiding a sewing machine, etc., that we should consider to make our argument comprehensive in its scope. However, despite their many years of experience in this field, the author has never felt the temptation to resort to using the Hough transform, because other techniques have proved equally or more effective and certainly more attractive in terms of the computational effort they require. To be fair in this discussion, we should point out that certain authors do use the HT extensively and have demonstrated good results (see ➲ Chap. 18) [6]. While not criticising our colleague, we simply point out that there are many instances where other techniques can achieve the same primary purpose as the HT without incurring its high computational cost. For this reason, we will discuss other procedures below:

1. Radon transform
2. “Island hopping”
3. Polar-to-Cartesian coordinate-axis transformation

17.4.3.1 Radon Transform

The Radon transform (RT) is effectively a reformulation of the HT but does lend itself to greater versatility, as we will see later. To compute the Radon transform of a given binary image, we consider a thin strip inclined at an angle ϕ to the coordinate axes and located at a distance d from the centre of the image (➋ *Fig. 17.54*). This strip will be denoted by S(ϕ,d). Its precise width need not concern us for the moment. Let us count the number of white pixels in S(ϕ,d) and denote this number by μ(ϕ,d). Then, we compute μ(ϕ,d) for all possible values of ϕ and d. As we do so, we construct an image whose coordinate axes are ϕ and d, and whose intensity is given by μ(ϕ,d). This is the Radon transform of the input image. The Radon transform should, of course, be defined in formal mathematical terms as an integral involving two continuous variables, ϕ and d. In fact, the discrete nature of a digital image means that we can compute only an approximation to the Radon transform.

One of the most obvious ways to implement the Radon transform is to rotate the image by an amount ϕ and then integrate the intensities along the picture rows. (The QT sequence [*tur(A), rin*] expresses the rotation-integration operation succinctly.) The right-most column of the resulting image will exhibit a strong peak, if we happen to have rotated the input image so that a set of collinear points is aligned horizontally (see ➋ *Fig. 17.55*). We do not of course,

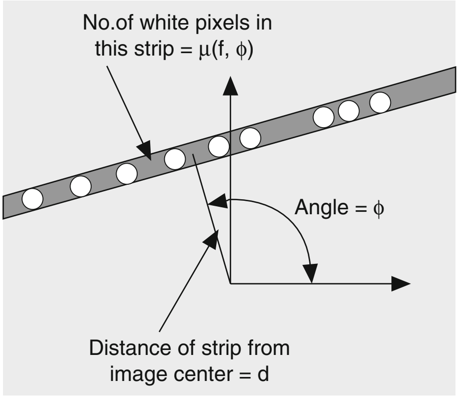

Fig. 17.54
The intensity is integrated along the dark grey strip S(ϕ,d). (In a binary image, we simply count white pixels within S(ϕ,d).) This yields the value μ(ϕ,d)

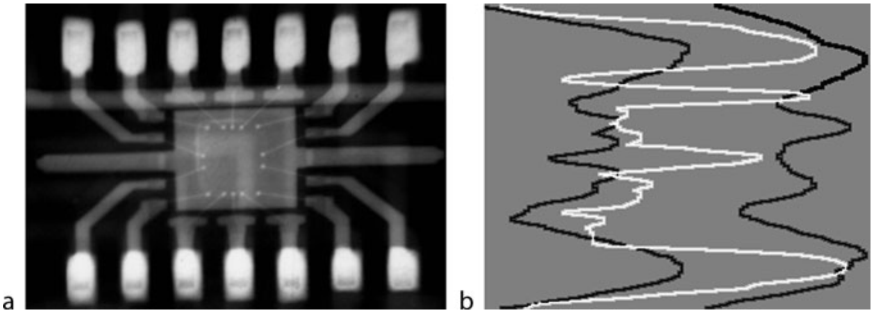

Fig. 17.55
The Radon transform detects linear features in grey-scale images. (a) Original image: microfocal x-ray of a small integrated circuit. (b) Three intensity profiles, obtained after applying [*tur(Angle), rin*]. (White curve, Angle = 0°. Black curves, Angle = ±10°.) Notice the strong narrow peaks that are visible only in the white curve. These identify the linear features just below the upper-most row of pads (i.e., very bright rectangles) and across the centre of the image

always need to construct the whole RT image. For example, we may know that the spots are likely to lie along a line whose orientation is within tightly defined limits. There are several special cases which make this ploy effective:

1. The horizontal and/or vertical axes of the input image may have some special significance in physical space. For example, the horizontal axis of the image may represent the vertical (Z) axis in [X,Y,Z] space, or the vertical axis of the image may correspond to the direction of travel of a moving web or conveyor belt. In the latter case, the photo-detector array on a line-scan sensor would correspond to the horizontal axis of the image.
2. We can obtain a crude measure of orientation quickly and easily from some other features before applying a more refined procedure based on the RT.
3. We know beforehand what angles are critical. (For example, we may have learned that diagonal streaks are indicators of some undesirable "fault" condition, whereas, horizontal ones are benign.)

The point to note is that in many instances we do not have to compute and analyse the full Radon Transform image.

The QT operator sequence [*tur(A), rin*] may be used as the basis for simply detecting the presence of a collection of "colinear" spots, without actually constructing the Radon transform image. This leads us to a simplified version of the Radon transform which is perfectly adequate for many purposes. Of course, we need to repeat the procedure many times in order to detect a set of spots, that can be aligned at any angle.

In some cases, we might usefully split the analysis in two stages: a low-resolution initial RT scan, leading to and a second, more refined process based on the first. This can be expressed in QT, but again the program cannot be included here because we have not yet described all of QT's relevant features in sufficient detail.

17.4.3.2 "Island Hopping"

In order to appreciate how straight lines can be reconstructed from a set of disconnected spots by the so-called "Island Hopping" procedure, we need to describe another idea first. We will therefore describe the *fan* operator. Consider two points [X1, Y1] and [X2, Y2]. The *fan* operator searches a wedge or fan-shaped region of the image for a white pixel (see *Fig. 17.56*). The search begins at the point [X2, Y2] and is concentrated within a circular segment of angular width defined by the parameter A. The fan-shaped search area is centred on the line defined by [X1, Y1] and [X2, Y2]. The address of the first white pixel found defines two variables X and Y. It is easiest to think of the fan program being applied to an image consisting of single isolated white pixels. Then, given two starting points, a third point that is approximately aligned with them is found. A fourth point can be found by applying the fan operator recursively. The mental picture that inspired this procedure, which the author called "island hopping" was that of a frog jumping from one lily pad to another. The frog has a limited range for each jump and has a narrow field of view.

Figure 17.57 shows the result of applying *island hopping* to a picture containing isolated white pixels, some of which are aligned approximately. In this example, the angular width of the fan-shaped scan area is quite large.

17.4.3.3 General Remarks

The Radon transform can be used to detect thin streaks and aligned spots in a grey-scale image, whereas the Hough transform, as it was defined in Chap. 14, cannot. Thus, the Radon transform provides not just a convenient alternative to the Hough transform but also offers interesting possibilities for analysing grey-scale images, which the HT cannot match.

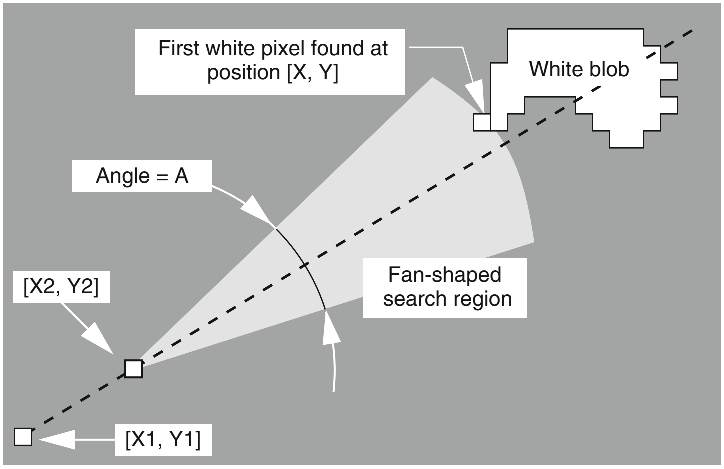

Fig. 17.56
The fan predicate used as the basis for "island hopping." The points [X1,Y1], [X2,Y2] and the angle A are specified when fan is called. The point [X,Y] and its distance from [X2,Y2] are then computed

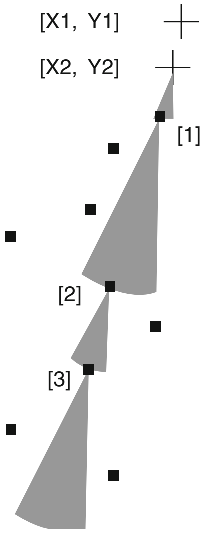

Fig. 17.57
Applying *island_hopping* to a simple test image. [X1,Y1], [X2,Y2] are the starting points. Numerals in brackets indicate the order in which the other points lying along the same line are detected

On the other hand, the Hough transform can be modified to detect other curves of known form. For example, it can be used to detect circles, even when they are overlapping. The generalised Hough transform [6] can even detect partially occluded shapes, such as touching/overlapping automobile connecting rods. While the Hough transform is able to accommodate broken contours, this property is shared with the Radon transform too. Although this chapter is not concerned with implementation hardware, it is interesting to note that a cylindrical lens and a line-scan camera provide a very convenient means of performing the calculations necessary to implement the RT.

17.5 Additional Remarks

We are near the end of this chapter, which has touched on a wide variety of algorithms and heuristics. It is appropriate therefore to review the lessons learned. The discussion above does not constitute a comprehensive review of these computational techniques; it is merely a discourse on the folly of taking too a narrow view of which algorithm to use. In the following chapters, we should bear in mind that virtually no algorithm is so important as to be regarded as “essential.” Of course, it would be difficult to manage without using operators such as *threshold* [*thr*] and *negate* [*neg*] but bear in mind that even these can be implemented in several different ways.

17.5.1 Solving the Right Problem

Although much of this book concentrates on algorithmic/heuristic techniques suitable for use in machine vision systems, we have repeatedly emphasised that they must operate in harmony with the other parts of the system. Indeed, they should be designed/selected specifically with this in mind. Thus, we should not quibble about whether, for example, the Sobel edge detector is theoretically "better" than the Roberts operator, since they are similar in their performance. If it matters which one we use, then something else is wrong, probably the lighting-viewing sub-system (Appendix C). There are numerous other examples of this general principle. We have at our disposal many different computational tools and often have several options for each algorithmic step in a processing sequence. We must be careful, therefore, that we address the most important questions. Very often, we find that whether we choose algorithm A or B is nearly irrelevant in terms of the results we finally achieve, compared to the far great differences that exist in the speed and cost of implementing them. We have constantly asserted that Machine Vision is a specialised area within Systems Engineering and, as a result, we must optimise all parts of a system separately and ensure that they will work together harmoniously. The real challenge is to ensure good system integration, since without this no system will ever be truly successful.

We must be clear about our primary purpose in building a vision system. It is not to prove how clever we are by using sophisticated techniques. Nor is it to analyse images in a preconceived way; we must be flexible in our thinking. Consider, for example, the task of finding the orientation of a machine component. We might be tempted to employ the Hough or Radon transforms, since they are so general. When demonstrating our academic prowess becomes a factor in our thinking, the design will inevitably be a poor one. We have at our disposal many different techniques for determining object orientation and these can be based on a variety of features, such as corners, bays, holes, coloured regions (e.g., flashes, logos, etc.) We must bear in mind that our primary objective is to determine the orientation of an object, not find the orientation of a straight line in an image. We might decide that the latter forms a useful secondary goal. However, we might find instead that, by altering the image acquisition sub-system a little, we can achieve our primary goal very much more cheaply, and more reliably.

17.5.2 Democracy: No Small Subset of Operators Dominates

One thing has emerged clearly but has, so far, not been stated yet with sufficient force, namely that image processing procedures for machine vision are highly varied. A machine vision system can and, at the moment, almost certainly should be designed for a specific task. Another important lesson is that the image processing procedure needed for a real-world Machine Vision application is complex. In QT terminology, it is not a single operator. Instead, it requires a large set of operators, controlled in a sophisticated way. We cannot therefore pick on any one step and say that implementing this is crucial to solving the problem. Thus, we must never concentrate on implementing only one operator, since they are all vitally important. Hence, we must not allow ourselves to be persuaded to use a particular implementation technology simply because one of the elements in a processing sequence could make good use of it. A little while ago we mentioned the fact that the Radon transform can be implemented using a cylindrical lens and a line-scan camera. This combination is of no use whatsoever for such tasks as implementing the convex hull or Sobel edge detector, thresholding an image, or computing its histogram, etc. In the same way, a parallel processor that is appropriate for implementing a convolution operator is virtually useless for processing the chain code. A symbolic processor (e.g., Prolog) that can make inferences about canary yellow being "similar" to sulphur yellow is similarly limited when we need to perform histogram equalisation. Thus, we must be prepared for the inevitable fact that we will have to use an implementation technology that is nearly optimal on part of the algorithmic sequence and less efficient on others. This is why we felt it desirable to include in this book a chapter where we highlight the potential for reformulating the algorithms. In this way, we can circumvent at least some of the difficulties that would ensue when we fix the implementation technology.

Let us end this section with a question for the reader to ponder. Suppose that we had an implementation technology that was nearly ideal for all component parts of an algorithm except for one important element, such as measuring blobs. Our hypothetical machine might be able to perform all of the "difficult" calculations, such as convex hull, blob shading, Hough transform, "island hopping," colour recognition, etc. Would not such a machine be virtually useless in practice? We must consider the implementation of the algorithm in its entirety?

17.5.3 Lessons of This Chapter

- Every algorithm can be implemented in many different ways. (➲ Sects. 17.1.1, ➲ 17.3.5–17.3.7) Even standard arithmetic operations, such as multiplication, can be implemented in more than one way.
- We should not judge an algorithm by its accuracy alone (➲ Sect. 17.1.2) Many other factors are at least as important. These include speed, cost of implementation, compatibility with existing equipment, interfacing to people and machines, conforming with company policy, etc.
- Reformulating an algorithm may make its implementation very much easier.
- We must be careful to address the important primary questions and must not fall into the trap of believing that secondary issues are all-important (➲ Sect. 17.5.1).
- No single algorithmic/heuristic procedure should be allowed to dominate our design, since all elements within an algorithmic sequence are of equal importance (➲ Sect. 17.5.2).
- We can often use heuristics in lieu of algorithms to good effect (➲ Sect. 17.1.4).
- Changing the image representation can make certain algorithms/heuristics very much easier to implement.
- We can sometimes employ grey-scale operators on binary images to good effect (➲ Sect. 17.2.2).
- We can use images as look-up tables for operations such as image warping (➲ Sect. 17.2.3).
- We can represent many of the more useful convolution operators as separate row and column operations (➲ Sect. 17.3.1).
- We can approximate many of the more useful large-window convolution operators by iteratively applying a sequence of small-window operators (➲ Sect. 17.3.1).
- Several non-linear neighbourhood operators (both binary and grey-scale) can be implemented by separating row and column operations.
- Separated-Kernel Image Processing using finite State Machines (SKIPSM, ➲ Sect. 17.3.3 and ➲ Chap. 20) allows a wide variety of morphological and other binary and grey-scale image processing operators to be implemented (exactly) at high speed in both software and hardware.
- There is no unique algorithmic definition for certain operations that are specified in natural language (e.g., edge smoothing). Hence many operators exist.

- Histograms calculated on one image can be used as the basis for processing another image, if the images are derived in quick succession from a slowly changing scene.
- Image statistics derived using a low-resolution sampling of an image may be accurate enough for certain purposes.
- We can save a lot of processing effort by concentrating on those regions of a picture where the processing is relevant to achieving the desired result. These are called *Regions of Interest.*
- Heuristics may be faster than algorithmic methods.
- Algorithms do not produce a reliable result if we violate their conditions of use.
- A given algorithm may be theoretically attractive but it may not solve our primary application task. The latter is not image processing *per se* but making decisions about real objects in the physical world.
- Heuristics can fail but this may be insignificant in practice, if they are designed and tested properly.
- Since heuristics are rules of thumb, we can add broad general rules which are safe, even if they are not always efficient.
- A heuristic may, in fact, be algorithmic, even though we do not know it to be so, because we have not been able to derive the necessary mathematical proof.
- Heuristics may be used to replace an algorithm, or to augment it.
- Heuristics may be used to make an algorithm run faster, without necessarily making its performance any less satisfactory.
- Heuristics may be used to extend the range of application of an algorithm.
- Heuristics can often "save the day" when there is no known algorithmic alternative.
- Heuristics can often achieve useful results when the use of an algorithm is impractical.
- We can often make heuristics as accurate as we wish, simply by doing more computational work.
- Elements in a processing sequence can often be combined to produce a simpler, more direct result. For example, the QT sequence [*neg, thr(100,123)*] could be implemented in one new single-pass operator.
- Look-up tables are very effective for implementing a wide range of image processing operators and are potentially very fast, when implemented in both software and hardware.
- Techniques that are attractive for Computer Vision and other (i.e., non-industrial) application areas for Machine Vision are not necessarily of much use in our subject area. (For example, they may be too general, and therefore unable to exploit application constraints.)
- Heuristics may be very different in concept from the algorithms they displace.
- We must judge heuristics objectively in the light of statistically rigourous testing.

18 Object Location Using the HOUGH Transform

E. Roy Davies

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_18,

Abstract: This chapter considers how best to locate 2D object shapes in digital images. Simple paradigms such as boundary tracking followed by analysis of centroidal shape profiles lack robustness and are incapable of coping with occlusion, breakage or gross shape distortions, whereas the Hough transform readily overcomes these problems as an integral property of its voting schema. This is an important advantage, especially in practical situations such as those where lighting is non-ideal. In addition, the Hough transform is excellent at locating straight lines, circles, ellipses and other well defined shapes: it can even locate arbitrary shapes that are defined by so-called *R*-tables. The method also has the advantage of being able to make sense of patterns of point features, and is far less computation intensive than the maximal clique graph matching method often used for this purpose. Being a form of spatial matched filter, the Hough transform has high signal-to-noise sensitivity, and for simple shapes is highly efficient, but when applied to arbitrary shapes of variable orientation, size and individual variability, measures have to be taken to limit its computation. Overall, the Hough transform provides a very useful, robust search technique for locating known types of object in digital images.

18.1 Introduction

This handbook has already examined basic methods of image processing and has shown how objects can be located in 2D images using techniques such as thresholding and morphology. Another elementary procedure is boundary tracking: this normally leads to shape analysis via 1D representations such as the well-known centroidal profile, which is a polar (r, θ) plot of the object boundary [1]. Unfortunately, this approach is limited when the shape is at all complex because then multiple values of r occur for one or more ranges of values of θ. While this problem can be overcome – for example, by taking the maximum value of r for any θ – the method has very poor robustness. Thus serious problems arise if the boundary is broken, if part of the boundary is occluded, or even if two objects are merely touching. This demonstrates that more advanced methods are needed for recognising objects in practical situations when the images are non-ideal or when "nasty realities" occur. Bearing in mind that robust solutions are mandatory in factory environments, that lighting can never be perfect, and that we have to deal with real objects which may have subtle shapes and profiles, there is a definite need for more sophisticated methods. At the same time, rapid search through large images is often required, since factory applications have to work in real time – a very demanding scenario. Thus any method that is to be adopted has to fulfil a number of important conditions.

In this chapter we shall find that inference methods provide a way forward, and that the Hough transform is perhaps the most important example of such methods. Towards the end of the chapter we shall describe other approaches such as graph matching, and demonstrate certain equivalences to the Hough transform technique. However, to start the discussion, we shall return to fundamentals and explore the intrinsic value of template matching, which is probably the most obvious solution to the matching problem but yet is subject to horrendous computational difficulties that have to be solved in one way or another.

18.2 Template Matching: The Need for Inference

Template matching is probably the most obvious method that can be used for object recognition. It involves systematically moving a template of the object to be recognised over the image – typically in a raster scan – and recording the positions of any matches. In this way it is intended that all objects of the selected type be both recognised and accurately located. The first problem that arises with this method is its unreliability. Because of the variability of both the original objects and their images, exact matches cannot be expected, so some relaxation of the recognition conditions is vital. Variability takes a great many forms:

1. The objects may have slightly different sizes and shapes, and in general 3D sizes and shapes will have to be considered.
2. They may have surfaces that have varying roughness, brightness and colour.
3. They may have gross defects in size, shape, roughness, brightness and colour.
4. They may appear at different distances and orientations in both 2D and 3D.
5. They may be viewed in different lighting conditions, and the lighting conditions may vary.
6. There will be digital quantisation effects, due to the particular spatial, grey-scale or colour resolution that is used.
7. There may be added digital noise.
8. There will in general be lens distortion, though this may largely be corrected.
9. There will be camera calibration problems, though these may be solved with fair accuracy.

Overall, various degrees of normalisation against camera and viewpoint variation can be applied, and with care the remaining errors will be small. Resolution can be made adequate and digital noise can be suppressed. Thus, in general, imaging problems can largely be overcome. However, the intrinsic variability of objects is a problem. Varying surface roughness – or texture, as it appears in the images – has to be tackled statistically rather than logically, since it contains a large random component. This leaves the large variations in shape of many items such as cereal grains and vegetables, not to mention articulated objects including items as different as insects and pliers. It is also the case that many small objects cannot be lit uniformly, and therefore acquire shadows, while their images often have a degree of fuzziness, which amounts to a perception of additional variability or ambiguity in shape. In general, real or perceived variability is a major problem, and much of it is due ultimately to the quality and maintainability of the illumination field.

It is useful to consider these variations as degrees of freedom of the images that are obtained from the camera. In any 2D image we have two degrees of freedom for position: this means that for a 256 × 256 pixel image and a 32 × 32 pixel object, some 32 million operations are required to search the entire image. However, the 2D orientation of any object will normally be unknown, and this extra degree of freedom will boost the number of operations to over 10,000 million. Variable size adds another degree of freedom, so the number of operations may well exceed 10^{12}. However, this is far from the end of the story, since variable shape adds many additional variables, as does variable surface texture, variable intensity and variable colour. While each of these additional variables may have only restricted range, their number (as in the case of shape) is enormous. This leads to so many potential operations for any rigorous template matching operation that a complete rethink of the position is called for. Essentially, the problem is that the whole template matching approach is one of *deductive* recognition, and this embodies a serious flaw. The solution is to *infer* rather than to deduce the presence of objects.

The crucial step to achieving this is to note that very small objects or features have very few degrees of freedom, so the computational penalty for locating them is tolerable. For example, finding edge points in a 256 × 256 pixel image can involve as few as 1 million operations, if say a Sobel operator is used: such operations need only take a few milliseconds on a PC and would not require the use of any special hardware accelerator chips. The problem is that once all the edge points in an image have been found, integration of the knowledge is non-trivial, and could itself require considerable computation. It should now be noted that such knowledge is incomplete, so it is no longer deducible, with certainty, what objects may appear in any image: deduction thus has to give way to inference; i.e. we have to infer the presence of the objects from their features.

Inference requires special techniques, and it ought to be said that these techniques are not as infallible as deduction: they can go wrong and can lead to erroneous hypotheses. Thus, in principle, the hypotheses need to be checked before they can be used in real applications. We say "in principle" because there are situations where checking may be superfluous. For example, on a widget line we only expect widgets, and on a biscuit line we only expect biscuits: we don't need to check or even test for biscuits on a widget line. In general, there may indeed be an overwhelming probability that any hypothesis that is made will actually be correct – in which case additional tests will not be called for. On the other hand, while chocolate biscuits may be the only objects on a chocolate biscuit line, biscuits that touch during the chocolate coating process are liable to end up stuck together. This, then, is a condition that does need to be checked for. Overall, it is the balance of probabilities that has to be borne in mind when considering any checks that have to be made. Note that, in general, objects will be checked and inspected immediately after detection, so false alarms are not overly harmful except to the extent that processing speed may be suboptimal. In what follows, we shall refer to the hypothesis checking process from time to time, as relevant in particular cases.

Finally, another important factor is that inference is not simply defective in its need for post-checking: relinquishing pure deduction actually leads to cognitive advantages in that the presence of partially occluded or defective objects is automatically allowed for. What has to be resolved at the checking stage is not only whether the object is in the hypothesised class but also whether it is a perfect example of that class or otherwise what deficiencies it may have.

Before proceeding further on the methodology of inference, we consider the types of feature that can profitably be used to trigger object detection.

18.3 Relevant Features

As pointed out above, the reason for finding objects from their features ultimately devolves into the much smaller size of the latter. In fact, one of the effects of small size is a limit on the variability and indeed on the number of types of feature it is possible or desirable to use. Perhaps the most obvious types of feature are edge points, which can be detected using Prewitt or Sobel edge detection masks of size 3 × 3 pixels [1]. Nevertheless there are three other types of feature that can be recognised using masks of this size: line segments, small holes and corners. Typical masks for the four respective features are:

$$\begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} -1 & 2 & -1 \\ -1 & 2 & -1 \\ -1 & 2 & -1 \end{bmatrix} \begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix} \begin{bmatrix} -4 & -4 & -4 \\ -4 & 5 & 5 \\ -4 & 5 & 5 \end{bmatrix}$$

However, it turns out that in different practical applications, somewhat larger masks may be preferable. For example, for line segment detection it may be necessary to match wider line segments, so 5 × 5 or 7 × 7 masks may be needed. A similar situation may arise if larger holes have to be located. Finally, rounded corners may necessitate use of larger masks. It will also be necessary to use a number of masks of different orientations, and the number of masks will tend to increase with size. Subtleties of shape, as with sharpness of the corners, may also be more important with larger mask sizes. Here we shall not be prescriptive, but merely note that the numbers, sizes and coefficients of the masks will need to be adapted to the particular cases and applications. Our specific concern in this chapter is how to collate the information emerging from the feature detectors.

One final point is that edge and line segment detectors will be intrinsically capable of providing estimates of direction as well as information on feature location. This additional information can be of very great value for improving not only the accuracy of whole-object location but also the efficiency and speed with which it can be achieved. This point will be emphasised a number of times below. Suffice it to say here that once the *x*- and *y*-components (g_x, g_y) of intensity gradient have been ascertained, the intensity gradient vector $\mathbf{g} = ge^{i\theta}$ may be determined from the vector-based equations:

$$g = \left(g_x{}^2 + g_y{}^2\right)^{1/2} \tag{18.1}$$

$$\theta = \arctan\left(g_y/g_x\right) \tag{18.2}$$

Similar formulae have been shown to apply for suitably designed line segment masks [1].

18.4 The Hough Transform Approach

As indicated above, the Hough transform [2] provides a suitable strategy for inference. It relies on the representation of objects of a given type by a set of *p* parameters: thus, any particular object of this type which appears at a particular position with a particular orientation is allocated a certain location in a *p*-dimensional parameter space spanned by the *p* parameters. It is not necessary for the *p* parameters to be the *x* and *y* coordinates of the centre of mass of the object or its orientation *θ* relative to a known axis in it, though that is possible. However, there must be a one-to-one relation (In fact, we shall see below that it need not be as restricted as one-to-one, though this is the simplest scenario to envisage at this stage.) between the position and orientation parameters and the parameter space coordinates. The crucial point is that we must be able to transfer feature points from image space to the parameter space, to form the Hough transform, and transfer data back from the parameter space to image space, to show where particular objects have been found in the image.

The other important aspect of the Hough transform is that the feature points vote in the parameter space for successful parameter space combinations, so that by the time all the feature points have been considered, the points in parameter space which have the most votes can be taken to represent the most likely sets of parameters for objects appearing in the original image: at that stage the objects have essentially been located – though as indicated earlier, their existence is in the nature of a hypothesis until further verified by direct matching in the image.

The importance of all these details will become clearer in the following sections, where we will show how the Hough transform can be applied to recognise and locate straight lines, circles, ellipses and more general shapes.

18.5 Line Detection

In this section we show how the Hough transform may be used to locate straight lines in digital images. Following the statements made in the previous section, it is first necessary to decide upon a parametrisation for the straight line. The most obvious one corresponds to the equation

$$y = mx + c \tag{18.3}$$

The two relevant parameters, which have particular values for a particular line, being m and c. Accordingly we construct a parameter space with coordinates (m, c). Once an edge point (x, y) is found in an image, all possible values of m and c that lie on the dual line:

$$c = y - xm \tag{18.4}$$

are taken and accumulated as votes in the parameter space. In this case the set of votes will itself form a line in the parameter space. Any other edge point in the original image will give rise to another line in the parameter space. Clearly, after many edge points have been dealt with, many lines of votes will be found to cross at a particular point in parameter space, and this point is essentially a dual of the original line in image space. Hence the parameter space crossing point – which is the highest peak of votes in that space – can be projected back to identify the relevant line in the original image.

While the procedure outlined above is adequate in principle, it is actually clumsy and computation intensive in practice. First, it cannot cope well when the line is nearly parallel to the y-axis, as then the gradient m will be very large or even infinite. This means that this particular parametrisation is inconvenient: it is usually replaced by the normal co-ordinate (ρ, θ) parametrisation of the line (➲ *Fig. 18.1*). The normal co-ordinates can be calculated by replacing m and c by the following expressions. (The significance of ➲ Eq. 18.5 is that the gradient of the line is perpendicular to the edge normal.)

$$m = -\cot\theta \tag{18.5}$$

$$c = \rho \operatorname{cosec}\theta \tag{18.6}$$

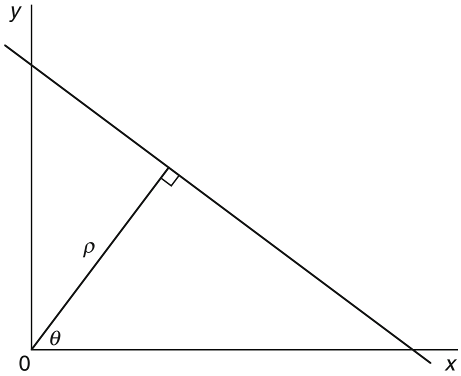

Fig. 18.1
Normal parametrisation of a straight line

Hence, we deduce:

$$y = \rho \operatorname{cosec} \theta - x \cot \theta \tag{18.7}$$

$$\rho = x \cos\, \theta + y \sin\, \theta \tag{18.8}$$

Once the parametrisation is fully defined, the computation of the Hough transform and the projection of the result back to image space can proceed as before (Note that under the normal parametrisation, the line of votes in the (m, c) parametrisation becomes a sine wave of votes, which amounts to a change of detail but not of principle).

The second improvement in the process is to make it less computation intensive [3]. This can be achieved by using local edge orientation information to arrange that a *single* vote is placed in parameter space for each edge point rather than a whole line (or other locus) of votes. This is possible because the value of θ is equal to the orientation of the edge normal, so $\theta = \arctan(g_y/g_x)$, g_x and g_y being the intensity gradient components obtained from the Sobel or a similar operator (see ➲ Sect. 18.3); hence a unique value of ρ can be deduced from ➲ Eq. 18.8.

18.5.1 Alternative Parametrisations

We have already seen two parametrisations that have been employed when the Hough transform is used for line detection. A number of others have also been developed for special reasons. In particular, the "foot-of-normal" transform was designed to save computation, in particular to eliminate the need for repeated evaluation of the arctan function [4]. In this parametrisation, the coordinates of the foot of the normal from the origin O to the line being detected are used as parameters. The method also conveys the advantage that the Hough transform peak position appears in a recognisable position when plotted in the original image, thereby confirming exactly what evidence the transform is finding. Perhaps oddly, the peak sometimes appears on an extension of the real line rather than on the actual straight boundary of an object (➲ *Fig. 18.2*). To calculate the foot of normal position F (x_f, y_f), it is first noted that the direction OF is identical to that of the edge normal vector g, so that:

$$g_y/g_x = y_f/x_f \tag{18.9}$$

In addition, the line is normal to OF, so its equation has to be:

$$(x - x_f)x_f + (y - y_f)y_f = 0 \tag{18.10}$$

Solving these two equations now yields the values of x_f and y_f:

$$x_f = \gamma g_x \tag{18.11}$$

$$y_f = \gamma g_y \tag{18.12}$$

where:

$$\gamma = \frac{x g_x + y g_y}{g_x^2 + g_y^2} \tag{18.13}$$

Clearly, these formulae lead to no calculation more complicated than division, thus saving computation.

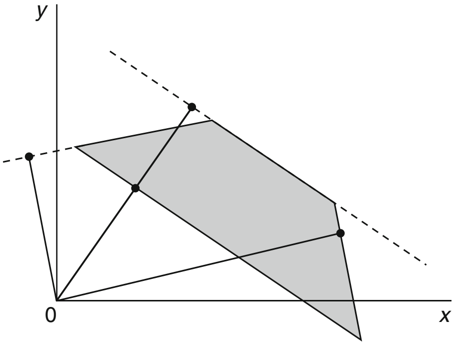

Fig. 18.2
Foot of normal parametrisation. Here the points at which the foot of normal Hough transform peaks appear are indicated by dots for the four sides of a trapezium shape (similar to that of a lino cutter blade). Note that in two cases these appear on extended sections of the object sides (see *dotted lines*)

An even more unusual parametrisation is the "muff" transform [5], which involves producing (In this chapter we use the term "producing" in the elementary geometry sense of extending a straight line in either or both directions to achieve some goal) every line segment that is located by an edge detector to the boundaries of the image, and accumulating the resulting crossing points in a set of four 1D histograms, which can be considered as simplified forms of Hough transform. Searching for peaks in four 1D histograms is many times faster than searching through a whole image (over 100 times faster for a 256 × 256 pixel image). Hence this parametrisation offers much faster search times. However, voting is twice as slow, and inferring the presence of lines from the histogram peaks can lead to significant ambiguities if many lines are present in the image. In fact, when choosing the most appropriate parametrisation, it is necessary to have a lot of information on the particular types of image data that will arise in practice.

18.5.2 Longitudinal Line Localisation

We have demonstrated the value of the Hough transform for locating straight lines in digital images, but it will be noted that each line is located in the form of an infinite straight line, whether or not the original line passed from one end to the other of the image. This is perhaps inevitable for a transform that is intended not to be confused by occlusions or breakages. Yet it demonstrates a weakness of the approach in situations where object boundaries are to be demarcated and no such distortions are expected. What is needed is a way of finding the longitudinal profile of any line, and in particular the locations of its ends and a measure of its length. This is quite straightforward to achieve [6]. All that is required is to re-run the Hough transform, and to plot an x or y projection of the edge points (depending on the orientation of the line) each time an edge point contributes to a known peak: examining the connectivity of the projection will then permit any end points to be determined – though small

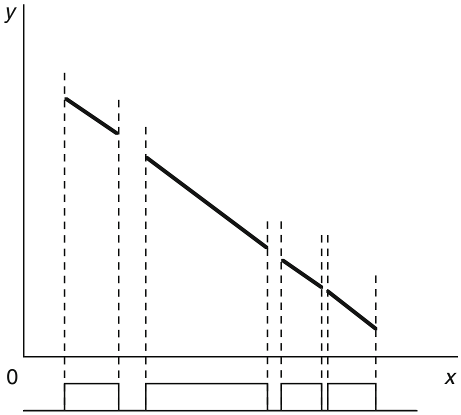

Fig. 18.3
Longitudinal line localisation. The parts of a straight line that have been located by a Hough transform are projected to form a histogram, from which connectivity can be ascertained. Typically, gaps smaller than a threshold distance are ignored, so that noise cannot confuse any following line interpretation algorithm

discontinuities may have to be disregarded as due to noise rather than gross occlusion or breakage (*Fig. 18.3*).

18.5.3 Final Line Fitting

Another factor in the design of a complete algorithm for line location is the optimisation of accuracy. In general the Hough transform itself is optimised for search capability in the presence of noise and other artefacts, i.e. it is an optimal detector rather than an optimal locator. To improve matters, a final line fitting stage based on least squares analysis is called for [6]. It is well known that least squares analysis is subject to inaccuracy if outliers are present (Inliers and outliers are defined as follows: when managing datasets it is usual to try to improve accuracy by averaging the data points; however, some points can have such extreme values that they introduce undue inaccuracy in the averaging process; these points are called outliers, and it is beneficial to remove them before averaging commences; the remaining points are called inliers). However, it is the function of the Hough transform to locate the line and to eliminate false data, so outliers should not be present at the final, accurate line fitting stage.

Overall, we now have an algorithm that operates in a number of stages:

1. Initialisation of parameter space
2. Edge detection in image space
3. Voting for peaks in parameter space
4. Locating significant peaks in parameter space
5. Transferring line information back to image space
6. Locating the ends of any lines in image space
7. Obtaining best fit line segments in image space

Occasionally, the peaks that are found in parameter space are noisy: in that case it is necessary to perform some smoothing before accurate estimates of peak position can be made. Other processes may be needed to suppress minor peaks, particularly if these arise from shadows in the original image. However, ad hoc suppression of this sort is not desirable, as it can destroy real data: if shadows are a problem, it is often better to eliminate them by more careful setup of the illumination, as described elsewhere in this handbook.

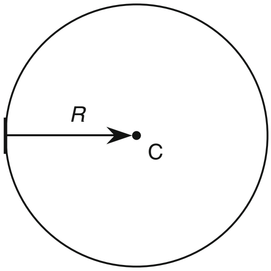
18.6 Circle Detection

Circle detection follows much the same pattern as line detection, but with a different object model, as appropriate to the situation. Clearly, any edge point could arise from a whole array of circles of different centre positions and sizes. It is convenient to consider first only circles of a given size – of radius *R*. In that case, the locus of circle centres is itself a circle of radius *R* centred at the given edge point. These observations lead to a Hough transform for circle detection in which votes are accumulated at a circle of points a distance *R* from each edge point found in the original image.

At this stage we again have the opportunity to save computation by making use of local edge orientation information [7]. Specifically, we move a distance *R* along the local edge normal and accumulate a single vote in parameter space (➲ *Fig. 18.4*). This means that for each edge point that is found in the original image we accumulate just one vote in parameter space. This procedure leads to a much greater relative concentration of votes in parameter space at the peaks corresponding to circle centres. In most other respects the Hough transform procedure is the same as for line detection, the stages in the detection algorithm now being the following:

1. Initialisation of parameter space
2. Edge detection in image space
3. Voting for peaks in parameter space
4. Locating significant peaks in parameter space
5. Transferring circle information back to image space
6. Obtaining best fit circles in image space

Note, however, that the need to locate ends that arose for lines is no longer relevant – though an adaptation of it would still be needed if semicircular objects were being located in place of circles.



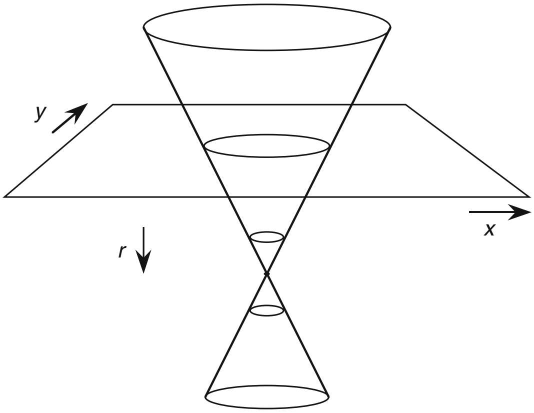
◘ Fig. 18.4
Circle detection by the Hough transform. Here an edge point on the left leads to a vote being accumulated at the centre C of a circular object

There are two more subtleties and differences relative to the case of line detection. The first is that the parameter space for circle detection is congruent to (i.e. of the same parametrisation as) that of the original image: this did not apply to the standard line detection Hough transform, though it did apply for the foot-of-normal Hough transform. The second difference is that circles have size, so there is an additional parameter to be determined. This problem will be discussed in the following section.

18.6.1 Case of Unknown Circle Size

The case of unknown circle size may be tackled by the simple expedient of applying a different version of the Hough transform for every distinguishable circle radius. Note that in the context of inspection, only a limited number of circle radii would be expected: e.g. for detecting and sorting coins, washers or ball bearings, only half a dozen sizes would be expected on a given product line or in a given application; similarly, on a biscuit line, only a small range of values – differing at most by ±10% from a standard product – would have to be coped with. Thus very little additional computation would be needed in such situations.

Nevertheless, it should be asked how the information from these various Hough transforms, each with its own 2D parameter space, should be combined. In fact, the answer is very simple: we interrogate each parameter space and select the one with the highest local peak; each such peak gives information not only on location, but also, though the value of the radius R that was used to construct it, it provides radius information as well. Interestingly, we can regard the complete set of Hough transforms used here as a single 3D (x, y, r) Hough transform, providing information on the three relevant circle parameter values, x_c, y_c, R (➲ *Fig. 18.5*). Indeed, for any application, we should first ask how many parameters p are needed to define the relevant curve: then we should design a Hough transform with p parameters to span the



◘ Fig. 18.5
Voting for circles in a 3D parameter space. This diagram shows the topmost circle being detected in a 3D parameter space. In any section of the parameter space a circle of reduced size appears. For one lower section the circle becomes a dot: at this location the density of votes accumulated is the highest in the whole 3D parameter space, indicating that this point gives the correct position and radius value of the original circle

relevant p-dimensional parameter space. This rationalisation makes the method described less ad hoc and part of a proper formalisation of the Hough transform, as originally outlined in ➲ Sect. 18.4.

A further subtlety is that, even in the case of unknown radius, circle location may still be carried out in a 2D parameter space [8]. This is achieved by tracing out a whole line of votes along the local edge normal, for whatever range of radius values is appropriate in the given application. This procedure places a great many votes in the 2D parameter space, and could in the end be extremely confusing for the peak location algorithm to negotiate. However, it has been found that in many situations good results can be achieved in this way. (Specifically, there must not be too much background clutter in the images, leading to too many votes arising in the same localities of parameter space.) The particular gains from this approach are the reduction in size of the parameter space (for a spatial resolution of 256 × 256 the effect is a very substantial reduction from ∼16 million to ∼64,000), and the consequent reduction in the computational effort, and time, needed to search it for peaks. The disadvantage of this approach is that the radii of the circles are not determined. However, once each centre has been located, a quick re-run of the transform can determine which points gave rise to it: then a separate 1D transform can be constructed showing for each peak what the distribution of radius values was, and leading to an accurate value for it. In this way we have replaced the original 3D Hough transform by a 2D plus a 1D Hough transform (The fact that this is a 1D Hough transform means that it does not merely average the radius values but can lead to identification and evaluation of radii for several concentric circles [as in the case of a set of washers].): as the computational complexity of the latter is rather small, the overall amount of computation is still close to that of a 2D transform. As remarked in ➲ Sect. 18.5.1, when choosing the most appropriate parametrisation, it is necessary to have a lot of information on the particular types of image data that will arise in practice, and this is definitely the case here too: in fact, the critical factor in this case is the amount of background clutter that appears in the image.

Finally, note that we have isolated one of the main characteristics of the Hough transform: its capability for efficient search for objects in images. Once a search has been carried out and objects have been characterised in any way, the problem has essentially been "cracked." Any remanent lack of information is far less relevant as the difficult part – the search through huge numbers of pixels for relevant information – has already been done, and the remaining part tends to be relatively trivial.

18.6.2 Overcoming the Speed Problem

In this chapter speed of processing has been alluded to a number of times, as it can be very important in real-time applications. It can be highly relevant in the case of circle detection. Two approaches aimed at speeding up the process of circle detection will now be outlined, the first involving simplified forms of edge detection and the second involving sampling.

Edge detection normally requires the application of at least two masks, as in the cases of the Sobel and Prewitt operators. Indeed, using two masks is necessary if local edge orientation is to be determined, and in turn this seemed to be necessary if the Hough transform is to be applied in such a way as to reduce the numbers of votes. However, if we try to use vertical edges – or rather, edges which have a substantial value of g_x – to detect circles, and couple the results for pairs of edges appearing on the same horizontal scan lines, we can efficiently obtain mid-points of horizontal circle chords. We can achieve similar results for vertical chords. We can then search for *x* and *y* values of circle centre locations, and obtain candidate centre locations. The process can be highly efficient because reduced size (e.g. 3 × 1 or 1 × 3) edge detection masks can be used. This means that if the image does not contain too many objects, and in particular *circular* objects, speedup factors of at least three may be attained [9].

The method outlined above requires two 1D search spaces to be used for estimating *x* and *y* coordinates, though these then need to be correlated with each other before circles can be identified. However, if the circle radius *R* is known, the circle centre (x_c, y_c) can be deduced and a normal 2D Hough transform vote can be accumulated [10]. For a horizontal chord with ends P (x_1, y) and Q (x_2, y), this is achieved (➋ *Fig. 18.6*) by noting that:

$$x_c = \frac{x_2 + x_1}{2} \tag{18.14}$$

$$(y_c - y)^2 + \frac{(x_2 - x_1)^2}{4} = R^2 \tag{18.15}$$

$$y_c = y \pm \left[R^2 - \frac{(x_2 - x_1)^2}{4} \right]^{1/2} \tag{18.16}$$

Note that there is a sign ambiguity, which necessitates double voting (In fact, each redundant vote can be eliminated by checking for an edge point at two suitable locations vertically above and below P or Q: this amounts to using triples of edge points as composite features): however, the Hough transform is able to cope with this, as the accumulation of votes will lead to only one peak of any size for any given circle.

For either of the two chord bisection methods given so far, considerable further speed improvements can be obtained by reducing the number of chords examined. In fact, we can sample the image on every *n*th horizontal and every *n*th vertical line, and thus speed up the processing by a factor close to *n*. The potential savings can be substantial, both in principle and in practice: e.g. in biscuit inspection, the combined speedup factor from simplified edge detection and sampling can be as high as a 25 [9].

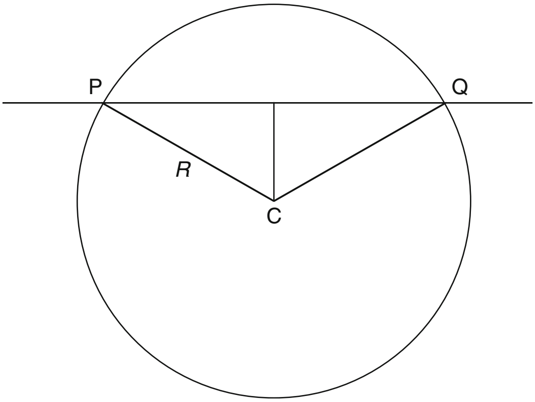


Fig. 18.6
Geometry for locating circle centres from single chords. Here the centre of a circle of known radius *R* is located from a single chord PQ. Note that there is an ambiguity in that C could be either above or below the chord PQ

The disadvantage of sampling is that circle detection becomes less robust and accurate as n increases. Reduced robustness (Although robustness is reduced, the amount it is reduced is known and controlled: it does not correspond to an arbitrary, unexpected loss of reliability.) follows since there may be insufficient evidence for the presence of the object in question and the sampling lines fail to identify sufficient numbers of whole chords – an especially important factor if the object surface is textured. Similarly, accuracy of location will fall because averaging over k data points (where $k \approx 2R/n$) results in errors being reduced by the factor $\sqrt{k}$, and hence the errors increase as n increases.

18.7 Ellipse Detection

Detection of ellipses in digital images presents an altogether more complicated problem than circle or line detection. This is because five parameters are required to define a general ellipse, compared with three for a circle and two for a line. (At first it might appear that only one more parameter – the eccentricity – would be needed to define an ellipse instead of a circle. However, the eccentricity makes the circle anisotropic and so it also acquires an additional parameter representing the direction of the major axis.) On the basis that each dimension brings with it something like a factor ∼256 more variation, the extra two dimensions are problematic. There is also a problem in deciding how exactly to parametrise the ellipse.

One approach is to make a simple modification to the Hough transform for a circle [11]. In the case of the circle, we move a given distance R along the local edge normal and accumulate a vote. However, in the case of a particular point on an ellipse we need to move a given distance R in a given direction ψ and accumulate a vote. Clearly, R and ψ will be different for different edge points. A solution to this is to ensure that at every edge point we make all possible votes corresponding to all possible positions we may be at on the ellipse boundary: in this way we are certain to vote for the ellipse centre co-ordinate, whichever edge point we are currently sitting on. We have already seen an example of this type of Hough transform, which occurred when we were searching for circles of unknown radius: we simply assume all possible values of radius in turn and make an appropriate vote for each of them. In the ellipse case, the votes will have to be made at distances from the edge point which vary between the values a and b (the semi-major and semi-minor axes lengths). It turns out that the set of votes we have to make fall on a locus which approximates to a small ellipse (➋ *Fig. 18.7*). The resulting method is effective and relatively fast, being of similar speed to that for circle location when the radius is unknown. However, to achieve optimum efficiency the locus of votes needs to be stored as a lookup table and then applied at the right position and orientation (for details see Davies [11]).

The procedure outlined above is rather complex and two alternative methods are also in common use. These are the diameter-bisection and the chord–tangent methods, which will be described next.

18.7.1 The Diameter-Bisection Method

The diameter-bisection method achieves simplicity by relying on the symmetry of the ellipse [12]. It examines all the edge points in the image and searches for pairs that are anti-parallel (oppositely orientated) so that they could lie at opposite ends of ellipse diameters; it then

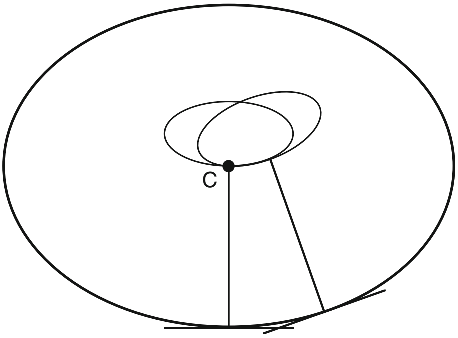

Fig. 18.7

Application of the generalised Hough transform for ellipse detection. Here a small locus of votes is accumulated for every boundary point. The diagram shows two such loci: the *straight lines* represent the tangents and normals at two boundary points, and merely serve to indicate the positions of the relevant loci

determines the mid-point of each such pair and makes a vote at this location in an image-like parameter space. Clearly, all such votes are potentially situated at ellipse centres. Thus, peak location will lead straight to ellipse detection.

To achieve this, it is first necessary to make a list of edge points for any image. Such a first stage is permissible for any of the Hough transform methods outlined so far, but in this case it is mandatory, as a systematic search through the edge points must be made. It should be noted that for E edge points, the number of pairs of edge points is quite large, namely $\binom{E}{2} = \frac{1}{2}E(E-1)$, and for $E \approx 1{,}000$ some half million pairs of points have to be considered. However, this does not mean that huge numbers of votes need be made in parameter space, the actual number being closer to $E/2$.

In general, the technique is highly effective, though it is seriously lacking in robustness. For example, if half of the ellipse is missing, no diameters will be definable and no valid votes will be cast in parameter space. Of course, if two opposite quarters of the circumference exist, there should be sufficient diameters to permit ellipse detection and location.

Another interesting characteristic of the method is that its reliance on symmetry will permit it to detect any symmetrical shape, such as a superellipse, though not an oval (egg-shape). Superellipses are defined by equations of the form:

$$\frac{x^m}{a^m} + \frac{y^m}{b^m} = 1 \tag{18.17}$$

where $m = 2$ corresponds to an ellipse, $m = 1$ corresponds to a diamond, and $m \rightarrow \infty$ corresponds to a rectangle. Thus the method is slightly non-specific regarding the shapes it is targeting (➋ *Fig. 18.8*). In some circumstances this could be advantageous. In others it may be less appropriate. However, presence of an ellipse can be confirmed by applying the test:

$$\frac{1}{(\mathrm{OP})^2} + \frac{1}{(\mathrm{OQ})^2} = \text{constant} \tag{18.18}$$

where OP and OQ are perpendicular chords of the shape. (In principle, the test must be applied to *all* pairs of perpendicular chords of the shape, but sampling will in most cases be sufficient.)

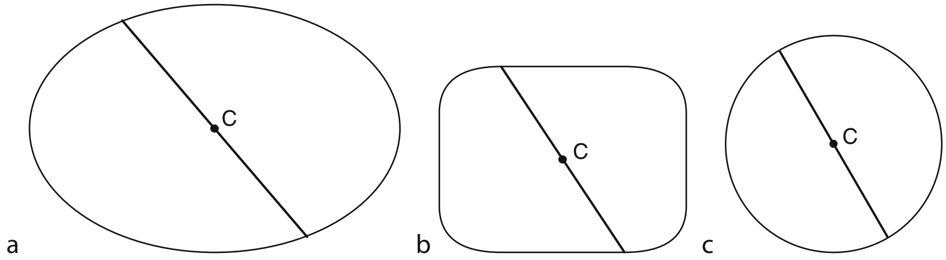

Fig. 18.8
Diameter-bisection method for ellipse detection. The examples make it clear that the technique also locates *superellipses* and *circles*, as well as a variety of other *symmetrical shapes*

Finally, it is interesting that the method will also find circles of any size: this approach can therefore be used in place of the 3D (x_c, y_c, R) circle Hough transform, though it is doubtful whether doing so would incur any additional advantage such as reduced computation. Suffice it to say that in some applications the reduced specificity of the diameter-bisection method may be an advantage, while in other applications it may constitute a serious limitation.

18.7.2 The Chord–Tangent Method

The chord–tangent method aims to make good the deficiencies of the diameter-bisection method – specifically, its distinct lack of robustness [13]. A list of edge points is again made, and pairs of these are selected in turn and used to create votes in parameter space. For any given pair of edge points, the chord joining them is constructed and the two tangents are drawn. The point T where the tangents cross is identified and this is joined to the midpoint M of the chord. Then the line TM is produced and the votes are cast along the produced section of the line. This line passes through the centre of the ellipse, so each set of votes includes one at the centre of the ellipse (➲ *Fig. 18.9*). When all pairs of edge points have been considered and all lines of votes have been cast, the parameter space is searched in the usual way for peaks, and the centres of any ellipses can be identified.

To prove that this method is valid, we note that it works for a circle: i.e. the line TM produced passes through the centre of the circle. This is clear from the symmetry of the situation. Next, we project the circle diagram so that it is viewed obliquely: this can always be done in such a way that an ellipse of any eccentricity can be produced. In orthographic projection, points project into points, chords project into chords, tangents project into tangents, and mid-points project into mid-points. Hence the property transfers validly from the case of a circle to the case for any ellipse, which proves that this form of the Hough transform does detect ellipses.

The next factor to consider is that of computational complexity. Again we have E edge points and $\binom{E}{2}$ pairs of edge points. However, this time we have to accumulate a line of votes for all of them. This means that the amount of computation scales as $O(E^3)$. Thus the method is extremely wasteful in accumulating unwanted votes – a factor to be balanced against the high level of robustness it offers. To keep computation within reasonable limits, votes should only be cast along the produced section of each line TM; they should only be cast over a distance of at

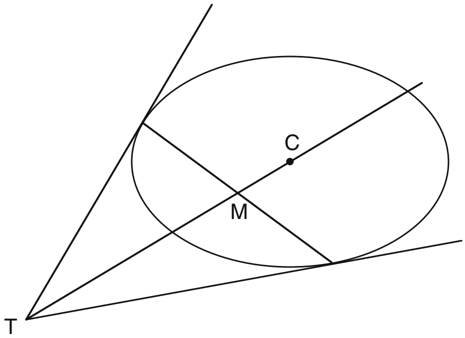

Fig. 18.9
Chord–tangent method for ellipse detection. Points on the line TM are accumulated in parameter space: note that there is no gain from accumulating votes between T and M, or beyond a certain point on the extended line

most the longest diameter ($2a$) of the expected types of ellipse; they should not be cast where the two edge points under consideration are more than a distance $2a$ apart. If necessary, various conditions on the directions of the edges and those of the line TM could be imposed, but such techniques could impose greater computational penalty than they save.

Overall, this method is robust, and is fairly computation intensive. However, it is specific to ellipses and will not detect superellipses or other symmetric shapes. Hence no special tests need be applied to confirm that the shapes being detected are actually ellipses.

18.7.3 Ultra-Fast Ellipse Location

Ellipse location is especially important because ellipses arise not only in their own right but also as projections of circles, which are themselves ubiquitous in manufactured products. Indeed, a purist could argue that in general one never sees circles – only ellipses. In any case, it is often the case that rapidly operating means must be found for locating ellipses. In recent work aimed at achieving the most rapid possible means of ellipse location, the "triple bisection algorithm" was developed [14]. This involved taking two parallel chords of the ellipse, bisecting them, joining the two bisectors, producing the resulting line to determine its ends, and then bisecting the resulting chord (➜ *Fig. 18.10*). The final chord bisector will be at the centre of the ellipse, if indeed the object found is an ellipse. In applications such as wheat grain location, when the wheat grains are on a moving conveyor, there are no other objects present, and the wheat grains appear as ellipses with an approximately 2:1 aspect ratio (i.e. $a/b \approx 2$).

The triple bisection algorithm generally works well, but may fail if two objects are touching (in which case one of the chords may pass from one object into the other). If that is a possibility, the method needs to be adapted to a more robust Hough transform format. (Strictly, the triple bisection algorithm is not a Hough transform, as votes are not accumulated, but a minimal computation alternative to it. However, in the present context, it does help to rehearse the idea of what is and what is not a Hough transform, and what the gains and losses are.) The resulting "eight-chord algorithm" has the merit of being sensitive to errors and of being able to revert progressively to a more reliable approach, as necessary to solve the problem [15].

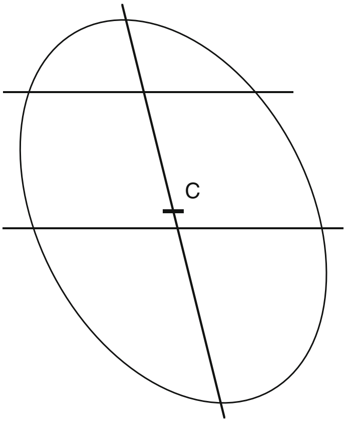

Fig. 18.10
Triple bisection algorithm. Here two parallel chords are bisected, and the bisector of the *line* joining the midpoints is taken to be the centre C of the ellipse

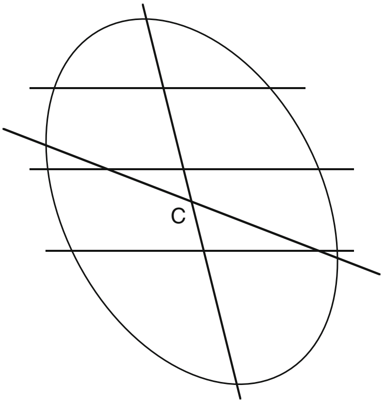

Fig. 18.11
Eight-chord algorithm. Here three parallel chords are bisected, and it is confirmed that a single line passes through the three bisectors. The centre C is located as the crossing point of two *lines* obtained from parallel chords of two different orientations. For clarity only one set of parallel chords is shown

In this method three parallel chords are used and it is checked that their midpoints lie on a straight line. Then another three parallel chords of different orientation are used and a similar check is made. Finally, the crossing point of the two bisecting straight lines is taken to be the centre of the ellipse (➲ *Fig. 18.11*). However, if the midpoints for either orientation do not lie on a straight line, further parallel chords are taken until sufficient midpoints do identify a unique line. (For this algorithm there is a build-up of voting evidence from the bisecting chords, so it may be classed as a genuine, albeit minimal, Hough transform.)

Both of these algorithms rely on the bisectors of sets of parallel chords lying on straight lines which pass through the centre of the ellipse. We have already seen that this property is valid for a circle. The proof that the property is valid for an ellipse follows the same type of projective proof as for the chord–tangent method (a suitable orthographic projection of the circular case can be selected to demonstrate the situation for any ellipse).

18.8 More Advanced Aspects of the Hough Transform

In the foregoing sections, it may seem that the Hough transform is suited to the location of a very restricted number of shapes, specifically circles, ellipses and those such as rectangles that are bounded by straight lines. However, this is by no means the case. Methods have been devised for detecting other specific shapes such as parabolas, and also for more general shapes which may be described either analytically or as lookup tables. This leads to the first of three advanced aspects of the Hough transform.

18.8.1 The Generalised Hough Transform

The generalised Hough transform [16] is in principle a straightforward generalisation of the circle Hough transform. Instead of proceeding a distance *R* directly along the edge normal at a boundary point *E*, we move an adjustable distance *R* along an adjustable direction ψ, and cast a vote at that location (➋ *Fig. 18.12*); more simply, we can describe this location as lying at a vector distance **R** from *E*. In fact, **R** is taken as a function $\mathbf{R}(\theta)$ of the local edge orientation θ. In many cases the function $\mathbf{R}(\theta)$ would be specified analytically, but in complicated cases, or when the computer is trained to cope with arbitrary shapes, it is specified as a lookup table. In either case it is commonly referred to in the literature as the *R*-table.

It is unfortunate that circles are the only isotropic shapes, so the *R*-table for more general shapes will vary with object orientation φ. Hence in reality the *R*-table will have to contain all

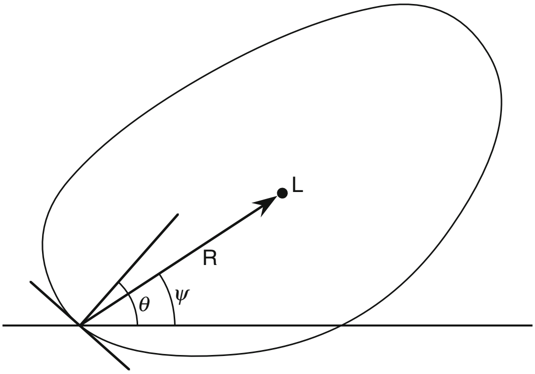

Fig. 18.12
The generalised Hough transform. The point L is taken as a reference point for the basic shape. To detect the shape, a vote is accumulated at the position of L that is estimated for each boundary point: L is assumed to lie at a vector location R relative to the boundary point, where R is a function R(θ) of the local edge orientation θ

the information needed to cope with variable object orientation. However, this is not an insurmountable problem. Indeed, the first method given in ➔ Sect. 18.7 for locating ellipses was a form of generalised Hough transform; and the Hough transform used for point pattern matching (➔ Sect. 18.9.1) can also be classified as an appropriately adapted form of generalised Hough transform.

18.8.2 Relation to Spatial Matched Filtering and Gradient Weighting

The idea of voting that the Hough transform embodies may seem a little strange from a signal processing point of view. However, it has its origins in matched filtering, which is known to be an optimal means of detection in a signal-to-noise sense [17]. In fact, matched filtering is of supreme importance in radar, where it is crucial to optimise the detection of aircraft, because, with the inverse square law operating twice, the amount of reflected energy arriving back at the radar system will typically be 10^{12} times smaller than the energy originally transmitted. In image analysis applications the signal is 2D and we should be talking about spatial matched filtering rather than matched filtering [1, 16].

The way of designing an optimal matched detector is to convolve the received signal with an idealised but reversed form of the expected signal [17]. However, image analysis differs from the situation for radar, not merely in replacing the time variable by two spatial dimensions, but also in that the level of background brightness tends to be arbitrary, so a zero-mean template is required for matching. (This is illustrated by the template masks given in ➔ Sect. 18.3). In addition, the brightness will tend to vary gradually but unpredictably over the whole image, so it is better to examine all parts of the image separately for evidence of the existence of objects, and then to accumulate the signal in sections (one contribution for each part of the image examined). This leads us to a basic understanding of why votes have to be accumulated for all the image features found.

However, there is another consequence of this analysis. The number of votes, or their amplitudes, ought to be proportional to the response received at each feature point. Specifically, features should not be regarded as either present or absent at different locations in an image – as a result of an arbitrary threshold being set: they should be regarded as present to a specific degree, and the votes cast in proportion to the strength of the evidence they embody. It has been shown that this model does produce a significant improvement in performance of the Hough transform when applied to noisy images, and is generally worth the additional computation that it involves [18]. On the other hand, in many cases the amount of clutter in images can be the real problem that limits object detection, and elimination of outliers will then be more important than correct weighting of inliers to obtain optimal signals.

In fact, there is a final twist in the story of how matched filtering gave rise to the Hough transform. In a matched filter the weight given to the final signal is in proportion not only, as stated above, to the received signal but also to the size of the expected signal [18]. This means that votes should be accumulated in proportion to the magnitude of the signal that is expected at a particular point in any object. While this criterion is somewhat difficult to apply in general (as it is not known what part of an object a feature may come from), if it can be applied it is beneficial to do so. Likely cases when it could be applied are when some edges are low contrast and some high contrast, and can be identified as such: in that case an additional weighting proportional to the expected contrast should be applied.

18.8.3 The Particular Value of the Hough Transform

At this point there may be some confusion over the real value and purpose of the Hough transform. It may seem that its value resides in shape analysis and recognition. However, this is one aspect of its value. More properly, it should be viewed as a method for searching for required objects amongst a clutter of other objects and noise. (Note also that other examples of the required type of object amount to clutter when a particular object is under consideration.)

In general, search is a highly computation intensive task, and special methods are needed to perform it efficiently. However, if an image contained only a single object, search would still be required to find it, but this type of search could probably be carried out by a rather basic method such as thresholding; in such a case, shape recognition could then be carried out using the centroidal profile approach. However, when the situation is not so straightforward, and neither thresholding nor centroidal profiles will work well or even at all, the Hough transform comes into its own, both searching for and recognising the shapes it is tuned to. It is best used when both of these tasks have to proceed in tandem: when either has to be done on its own, there may be other methods that work better. A further point will illuminate the situation. If the location of an object is known approximately, there will be little point in using the Hough transform to locate it accurately: it will be better to employ a method such as least squares analysis to refine the accuracy. Least squares analysis is unable to eliminate outliers but is excellent at averaging to reduce the error from inliers: the Hough transform is excellent at eliminating outliers (including irrelevant objects) but is relatively poor at averaging to reduce the error from inliers.

18.9 Point Pattern Matching Techniques

As pointed out in ➲ Sect. 18.3, there are four particularly important types of feature by which objects may be recognised and located, namely edge segments, line segments, small holes and corners. The first two of these are extended features and are commonly used for locating objects by their boundaries or internal divisions; on the other hand the last two are point features which are accurately locatable in two dimensions, being characterised by a specific pair of (x, y) coordinates. We have already seen how the Hough transform may be used with good effect with the extended type of feature. We shall now see how point pattern matching techniques may be used to locate objects from their point features.

At first sight point pattern matching would appear to be especially simple: first locate the object from a single point feature; then use a second feature to uniquely orientate it. Unfortunately, in many cases features may be missing from the image, and extra features may appear that are not due to the type of object being sought. In detail, the problems are (Essentially the same list applies whatever types of features are used to recognise objects, or whether Hough transforms or point pattern matching are used for analysing the feature point placements):

1. Noise or image clutter may give rise to additional features.
2. Noise may eliminate some features.
3. Poor lighting or shadows may reduce contrast so much that some features may not be visible.
4. Partial occlusion by other objects may cause some features to disappear.
5. Slight perspective distortions may shift features from their ideal locations.

6. Lens distortions (including barrel distortion) may shift features from their ideal locations.
7. Camera to object distances may be shifted so that features may not be at their ideal locations.
8. The objects themselves may be defective or distorted, again shifting features or preventing them from being found.

In case 8, it may be part of an inspection task to identify objects in spite of their being defective or distorted, or to identify the non-defective or non-distorted sections so that the defective or distorted sections may be highlighted.

All these effects mean that the object location software may not receive complete, ideal data, so it will have to do the best it can with non-ideal data. Thus it must embody robust algorithms. Note also that it will have to be capable of distinguishing features on one object from those on another. To achieve all this, the algorithms used must be able to cope successfully with the redundancy arising from a number of features.

To proceed, we consider the input image as a graph G, and the template of an ideal object as another graph T (A *graph* is defined as a diagram containing a set of points (sometimes called *vertices*), some of which may be joined by lines (sometimes called *edges*)). We now need an algorithm which searches for instances of possibly incomplete parts of T within G. We can re-express the requirement as the identification of subgraphs of T in subgraphs of G: this is often called the subgraph–subgraph isomorphism problem. Note that, to be optimally useful, the method needs to identify maximal subgraphs of T which appear in G.

To carry out this task, we need some criterion to assess the match between the template and image subgraphs. Perhaps the simplest criterion is when the distances between corresponding point features are the same (within a suitable practical tolerance limit) in the two subgraphs. First take separation distance as D_{ij} in the image and D_{pq} in the template, for some i, j, p, q; then if $D_{ij} = D_{pq}$, we can deduce a possible compatibility between i, j in the image and p, q in the template, such that $i = p$ and $j = q$, or else $i = q$ and $j = p$: the alternative arises because the proper ordering of the points in the image will not be known before the analysis, and separation distance will not immediately distinguish between the two possibilities.

We now take a five-point image (1, 2, 3, 4, 5) and a four-point template (A, B, C, D) as example (➋ *Fig. 18.13*): in this case the valid feature compatibilities are given by 1 = A, 2 = B, 3 = C, 4 = D. However, this needs to be inferred by a computer algorithm. The base information that the computer algorithm will receive as input is that $D_{12} = D_{\mathrm{AB}}$, etc. We next get the computer to build a "match graph" showing the compatibilities between pairs of feature assignments. Thus $D_{12} = D_{\mathrm{AB}}$ means that A1 (the assertion that feature 1 is in class (A) is compatible with B2, though A2 must also be compatible with B1). Hence these two compatibility lines are included in the match graph (➋ *Fig. 18.13c*). For an object with four points, all of which appear in the image, there will be a total of $\binom{4}{2} = 6$ pairs of features, each of which will produce two compatibility lines. In addition, the image shown in ➋ *Fig. 18.13c* contains feature 5, which is in such a position that $D_{35} = D_{\mathrm{CD}}$ and $D_{45} = D_{\mathrm{BD}}$. If there had been no such equalities, the match graph would not have needed to use the label 5 at all, and the feature point could have been totally ignored (It is easy to say this with hindsight from our percipient human perspective. However, in the computer algorithm there is no option other than to include label 5 in the initial match graph); but with these equalities, four additional compatibility lines are included in the match graph. At this point all 16 compatibility lines are marked in the match graph, and it is possible to start inferring the presence of objects in the image.

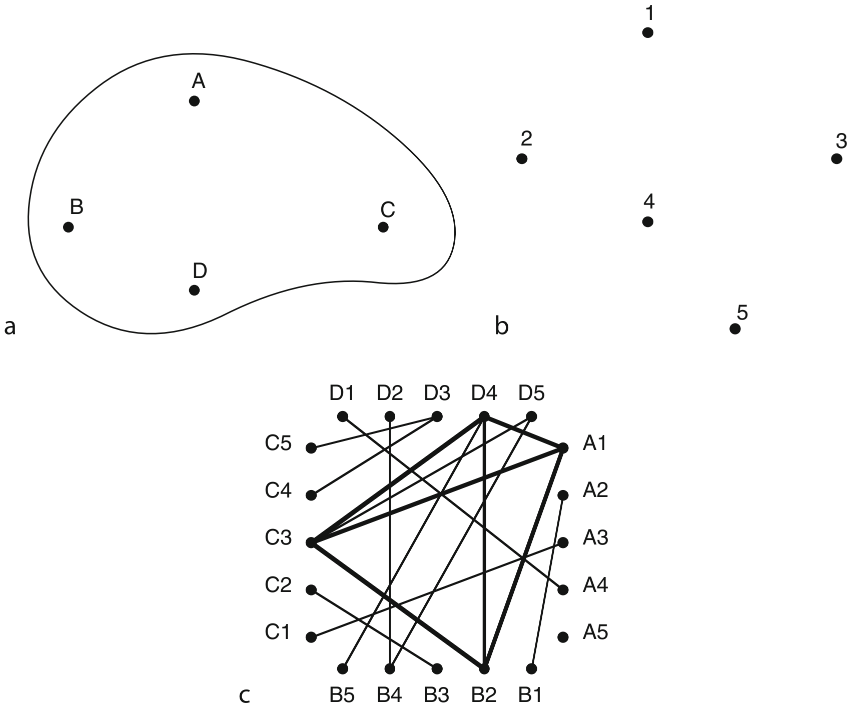

Fig. 18.13
The maximal clique approach to object location. (a) shows the template of an idealized object with point features A, B, C, D; (b) shows the point features 1,2,3,4,5 actually observed in an image; (c) shows the match graph for this image, the most likely interpretation of the data being represented by the largest maximal clique, in this case the quadrilateral A1–B2–C3–D4, which is indicated by *thicker compatibility lines*

To do this, the initial discussion showed that we need to look for maximal subgraphs of *T* within *G*. To achieve this we can search for maximal completely connected subgraphs (or "maximal cliques") within the match graph, as these represent complete agreement between the subgraphs (Completely connected subgraphs are called cliques: this reflects the fact that people in a "clique" all know each other, and thus in the present sense are compatible with each other. Here, however, we take the concept of a clique further and look for maximal cliques – which are those cliques that are not completely contained in any larger clique). In the match graph of *Fig. 18.13c*, there are 11 maximal cliques, A1–B2–C3–D4, A2–B1, B3–C2, C4–D3, D1–A4, B4–D2, C1–A3, B4–D5, B5–D4, C3–D5, C5–D3. Compatibility lines such as B4–D5 form two-element maximal cliques: these often (as here) have to be interpreted as due to chance distance equalities arising from noise features. However, two-element maximal cliques can also mean that there is an instance of an object which is oppositely orientated and for which there are only two support features. Clearly, it is far more likely that the four-element maximal clique A1–B2–C3–D4 (shown in thicker lines in *Fig. 18.13c*), which incorporates these same image features, is the most likely interpretation.

We now see that we are not just looking for maximal cliques: we are looking for the *largest* maximal cliques as these represent the *most likely* interpretations of the image features [19]. Of course, just stating that the largest maximal cliques are the most likely solutions could be invalid if the same set of features appeared in two large maximal cliques. However, such circumstances are rare. Specifically, it is unlikely that noise or image clutter will give rise to large maximal cliques. Nevertheless, to eliminate such problems, the match graph should probably be interpreted sequentially, by looking for the largest maximal clique; then eliminating from the match graph all the compatibilities between its features; then proceeding to the largest remaining maximal clique; and so on. In *Fig. 18.13*, eliminating clique A1–B2–C3–D4 and its features will mean also eliminating all the two-element cliques. Thus feature 5 will be seen to have no support from any other features and may be disregarded as due to noise. It is as well to note that these procedures for making sense of the match graph are somewhat ad hoc, and the solutions obtained should be regarded as hypotheses to be checked by further analysis of the image data. In fact, the same cautions apply as for the Hough transform, where the highest peaks in the parameter space are most likely, but not certain, to represent correct solutions. In both cases, the number of votes or the number of compatibility lines in a clique represent the amount of support for the solution in question, and thereby increase the probability that it represents the correct solution.

Unfortunately, graph matching algorithms based on finding maximal cliques take a long time to run because of the need to check all the possible pairs of elements that might form part of a clique. Indeed, this type of algorithm is "NP-complete," in that it runs in exponential time rather than polynomial time, relative to the number of image features involved. While the maximal clique approach has itself been speeded up [20], it has also proved possible to perform the graph matching task described above in an analogous way using the generalised Hough transform, as we shall see below.

18.9.1 Using the Hough Transform to Save Computation

The generalised Hough transform approach was described earlier in the context of ellipse detection, and again later in its full generality. In fact, it has a particularly neat form when applied to the location of objects from point features. All that is needed is to define a reference point within an object, and use pairs of features a specific distance apart to vote for the existence of the object at its reference point [21]. *Figure 18.14a* shows the same object as in *Fig. 18.13a*, with the reference point indicated as a small circle. If the topmost and leftmost feature points are used to vote for this reference point, the algorithm will not (as in the graph matching case) know which is which of the two feature points, so two votes will have to be cast – as indicated by the two small circles in *Fig. 18.14b*. When all the voting has been carried out for the image of *Fig. 18.13c*, the result is as shown in *Fig. 18.14c*: here, the small circles correspond to single votes, and the bold circle at the reference point corresponds to six votes. Interestingly, the total number of votes is the same as the number of compatibility lines in *Fig. 18.13c*, and the breakdown 16 = 6 + 10 is also the same. Thus there is a great synergy between the methods: the important difference is that the analysis of the parameter space is far easier and less computation intensive than for the match graph, and takes place in polynomial time: the execution time is actually proportional to the square of the number of feature points in the image, because all pairs of feature points have to be considered [21].

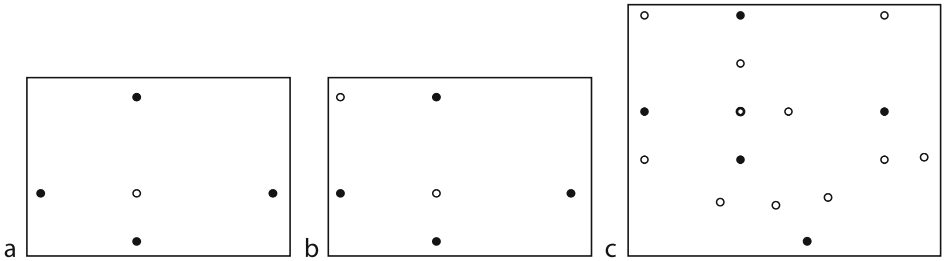

Fig. 18.14

Use of the generalised Hough transform for locating objects from point features. (a) shows the template of an idealized object, as in *Fig. 18.13a*, but with the reference point marked by a *small circle*. (b) shows the voting positions for the reference point when the topmost and leftmost point features are examined. (c) shows all the voting positions for the image of *Fig. 18.13b*: six votes are accumulated at the true position of the reference point, and are marked with a *small bold circle*

18.10 Perspective on the Development and Use of the Hough Transform

The Hough transform (HT) was developed in 1962 as an aid to the location of straight line high-energy particle tracks [2], and was introduced to the wider image processing literature only in 1969 [22]. Duda and Hart (1972) were the first to use it for circle detection [23]. In the mid-1970s, it was shown how to use edge orientation information to make line and circle detection more efficient [3, 7]. Dudani and Luk's classic (1978) paper was the first to give a definitive account of line localisation using the HT [6]. Gerig and Klein's key (1986) paper on circle detection used a two-stage approach to achieve greater robustness in the presence of clutter [24]. Subsequently, a series of papers demonstrated that the HT was formally equivalent to both template matching [25] and spatial matched filtering [26], and extended these results to the generalised Hough transform (GHT) [16]. One of the most important ideas since then has been the development of the randomised HT, which involves casting votes only until specific peaks in parameter space become evident, thereby saving unnecessary computation [27]. The diameter bisection, chord–tangent and GHT speedup techniques for ellipse detection, described in this chapter, originate respectively from papers by Tsuji and Matsumoto [12], Tsukune and Goto [28], and Davies [11]. The idea of saving dimensionality in the implementation of the GHT was an increasingly important theme in the late 1980s [8, 13]. Gradient weighting of votes for improving detection sensitivity also became an important topic around this time [18], and is still of decided interest [29].

Graph matching and clique finding algorithms started to appear in the literature around 1970. Bolles (1979) applied the maximal clique technique to engineering applications [30], and Bolles and Cain [19] extended the approach in a number of ways, including use of the symmetry-reduced match graph. Kasif et al. [31] showed how a modified GHT (the "relational HT") could be used for graph matching, although their paper gave few practical details. Subsequently, Davies [21, 32, 33] applied the GHT to point pattern matching to improve speed and accuracy.

Remarkably, considering the simplicity and importance of ellipses, new ellipse detection schemes are being developed even in the 2000s. Xie and Ji [34] developed an efficient ellipse detection technique, while Lei and Wong [35] employed a method which was based on symmetry: the latter was found to be able to detect parabolas and hyperbolas as well as ellipses.

Something of the power of the HT can be seen from the range of applications for which it is nowadays being used. These include the following:

- Toennies et al. [36] showed how the HT can be used to localise the irises of human eyes for real-time applications, one advantage of the transform being its capability for coping with partial occlusion – a factor that is often quite serious with irises.
- Wang and Sung [37] applied the HT not only to iris location but also to eye gaze determination: they found that the method had to be refined sufficiently to detect the irises as ellipses, not only because of iris orientation but also because the shape of the eye is far from spherical and the horizontal diameter is larger than the vertical diameter.
- Wu et al. [38] extended the 3-D possibilities further by using a 3-D HT to find glasses: sets of features that lie on the same plane are interpreted as the glasses rim plane. The technique allows the glasses to be separated from the face, and then they can thus be identified and located in their entirety.
- Schaffalitsky and Zisserman [39] extended earlier ideas on vanishing lines by considering the case of repeated lines such as those occurring on fences and brick buildings.
- Tuytelaars et al. [40] described how invariant-based matching and HTs can be used to identify periodicities in planes appearing within 3D scenes in spite of perspective skew.

Finally, a useful set of papers on projection-based transforms (as some of the developments of the HT are called) appears in [41].

18.11 Concluding Remarks

In this chapter we have seen something of the power of the Hough transform in performing the inference tasks required to locate objects efficiently and robustly in digital images. Remarkably, the method is able to overcome a great variety of potentially lethal interfering factors, including noise and background clutter, and problems with the objects being detected – such as distortions, breakages or partial occlusions. The method is very readily applied to the detection and location of circles, ellipses and objects bounded by straight edges, and there are a number of variants of the technique that may be used in these cases, offering differing degrees of specificity, robustness, accuracy and speed. In addition, the generalised Hough transform will recognise a good many other shapes, and indeed is completely general in this respect, though it may require more computation to cope with the additional shape parameters and complexity.

The need for the Hough transform arose because applying the obvious template matching technique is normally impracticable for objects of any substantial size – especially if their orientation is unconstrained. However, template matching is still suitable for locating small features, and the Hough transform extends this to whole-object detection by using an inference approach, which is also responsible for the method's robustness. The Hough transform has long been used when the features in question are edge and line features. However, when point features such as small holes and corners are chosen, it used to be usual for graph matching techniques such as the maximum clique approach to be employed. More recently, it has been demonstrated that a suitably adapted form of the generalised Hough transform gives essentially the same solutions, but is also much faster in operation.

The Hough transform has been seen to embody both search, recognition and location capabilities in a single approach. However, if there is only a single object in an image, simpler, more efficient search methods can often be applied to find it – as for example in the case of the triple bisection algorithm. Thus the real value of the Hough transform resides in its capability for effective search in a cluttered, noisy background. Similarly, it is less good at especially accurate object location, as it is optimised for outlier rejection rather than averaging inlier data. This means that it is often useful to apply a least squares fitting procedure once the Hough transform has completed its search for relevant data.

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_19,

Abstract: Morphology applies certain simple rules and shapes, such as squares, circles, diamonds, cubes and spheres, to process images. The objective is usually to identify features of interest in images as a prelude to performing high-level inspection, or machining, functions. Navigating around complex objects is facilitated using ‘anchor point’ features detected by morphology. The chapter begins by defining four basic morphology operations for binary images: erosion, dilation, opening, and closing. The application of these operations to analysing images from real-world vision tasks is discussed, as are techniques for fast implementation. Further operations akin to morphology are also described, including skeletonisation, hit-and-miss transform, and binary template matching. The extension of binary morphology into grey-scale morphology is also described and illustrated.

19.1 Introduction

The linguistic root *of morphology* is a classical Greek word (μορφή) meaning *form* or *shape*. The word is used in biology, to refer to the study of plant/animal shape and structure and is used in linguistics, to refer to the identification, analysis and description of units of meaning in a language. Our subject, is properly called *Mathematical Morphology* but we shall refer to it simply as *Morphology*. It too is concerned with recognising elemental shapes, this time in digital images. Morphology uses simple rules to process images and employs two- or three-dimensional templates, such as lines, (e.g. I, –, / and \), crosses (+ and X), composites (V, T, L and II), squares (open and closed), circles (open and closed), diamonds, etc. The templates may be derived instead from a ‘golden sample’ image. Erosion and dilation are two of the simplest morphology operations. The former makes binary objects (blobs) smaller, while dilation increases their size. The blobs may be shrunk or extended non-isotropically in certain directions, defined by the shape of the template. Identifying image features that match the given template is a particular benefit of morphology. Another possible function of morphology is preprocessing to enhance feature contrast, prior to local or global measurement of the image. While morphology sometimes improves the visual appearance of an image, such results are usually incidental to the primary goal, which is to facilitate recognition and/or location of features in images, or to measure them.

There are two principal ways to learn about morphology: by the study of mathematic theory, or experimentally. In this chapter, the authors strongly advocate the latter, as it provides a convenient way to gain intuitive insight into the functions that morphology can perform. In this essay, we shall draw on examples from several different application areas to explain the underlying concepts and to demonstrate the use of morphology in practice. It is important to realise that different template shapes, when used with the same processing rules, can produce widely differing effects. These can often be anticipated by an experienced vision engineer, without recourse to a lot of deep mathematics. Visual examination of an image will often suggest the appropriate means of processing it, at least in broad conceptual terms. However, this needs to be tried and tested thoroughly. An interactive image processor is ideal for this purpose. The engineer’s skill in working with morphological operators is also developed effectively in this way. For this reason, we have provided practical examples that can be repeated by the reader, using the QT system described in ❯ Chaps. 21 and ❯ 41. (Where appropriate, QT command sequences are given below, so that the reader can try these ideas for himself.)

Mathematical Morphology can be traced back to 1964, with the collaboration between Georges Matheron and Jean Serra in Paris, France. Morphological image processing techniques were formalised and named by Serra's book in 1982 [1]. Many of them were known earlier than that and were invented independently by other workers. One of the authors (BGB) independently 'discovered' several binary and grey-scale morphological operators in the 1970s, while he was experimenting with an early precursor of QT. This is mentioned here simply to emphasise the value of experimentation using an interactive processing system.

Morphology is defined in formal mathematical terms using set-theoretic notation. For example, the erosion of a binary image may be expressed thus:

$$A \ \Theta \ B = \left\{ z \in E | B_{\approx} \subseteq A \right\}$$

The notation is defined in the appendix to this chapter [2]. The precise details need not concern us for the moment. The point is that an equation like this does not yield the immediate intuitive insight that other less formal methods of expression can do. To demonstrate this, let us now describe erosion verbally: *it is the result of trying to fit a defined binary template to a given binary image. The output image consists of the set of pixels indicating where this is possible.*

There are four obvious ways to describe erosion, dilation and the other functions derived from them:

1. Mathematically
2. Verbally
3. Graphically
4. Program listing

The concept of erosion can be explained in a few words or a simple diagram. The authors of this chapter contend that morphology consists of fundamentally *very* simple concepts and that the powerful machinery of set theory is unnecessary for our present purposes. Indeed, they maintain that set-theoretic notation actually obscures the underlying simplicity. For this reason, they have chosen to rely on a graphical/pictorial approach to define and describe the various morphological operations. Notwithstanding this, formal definitions are given in the appendix to this chapter.

By definition, morphological operations are *neighbourhood operations*. That is, they base their calculations on more than one image pixel at a time. In keeping with the established terminology of this field, we will refer to the shapes used in these neighbourhood operations as *Structuring Elements*, often abbreviated to *SEs*. However, this term contributes very little to understanding what they actually do. Alternative names for an SE are *template,* or *mask.* However, in keeping with customary practice, the term structuring element will be used throughout the remainder of this chapter.

19.2 Definitions: Images and Structuring Elements

This chapter will consider primarily two types of images: binary and grey-scale. Initially, we will concentrate on the former and will extend those ideas later to describe grey-scale morphology.

Binary images have two intensity levels, usually called *black* and *white.* Black pixels will be represented here by the numerical value 0 when arithmetic is being performed, or the Boolean value 0 when logic operations are being performed. White pixels will be represented by Boolean 1 when logic operations are being performed. Sometimes, arithmetic is to be performed, in

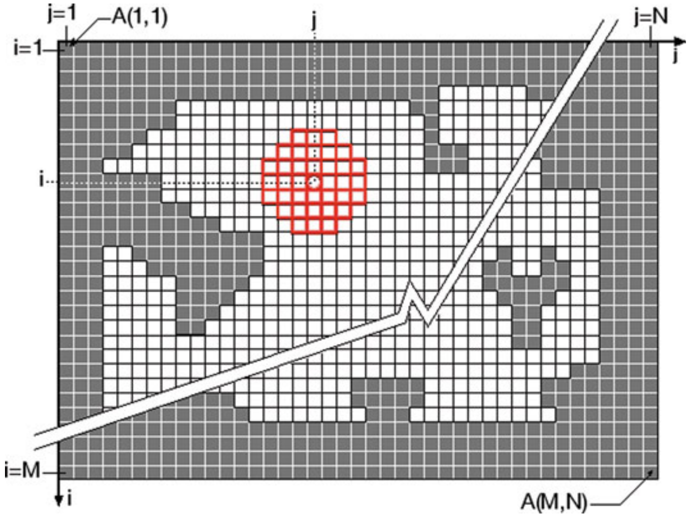

Fig. 19.1

Notation for binary images. The region outlined in red represents a 'circle' structuring element centred on the point (*i,j*), which is called the reference (or centre) pixel for that SE. The result of the calculation based on his neighborhood defines the new value for the centre pixel

which case, the numerical value 1 may be used to represent white. (In some image processing systems, any non-zero value denotes 'binary white'. In 8-bit systems, 255 is sometimes used instead. The context should make clear which representation is being discussed.) For convenience of discussion, the black pixels will usually be called 'background' pixels and the white pixels will usually be called 'object' pixels. Binary images will be denoted as arrays of binary numbers of the form *A(i,j), i* = 1,2,. . .,*M*; *j* = 1,2,. . .,*N* (*Fig. 19.1*). Each square is 1 pixel.

Grey-scale images, typically with 256 intensity levels (8-bit images). In these, the level 0 will be referred to as *black* and the level 255 as *white*. All other levels will be referred to as *grey*, although subdivisions of the grey range (e.g. light grey, dark grey) are sometimes useful. In addition, there is sometimes a need for 16-bit images (to avoid rounding errors when summations over regions with many pixels are involved, for example). When the need for such images arises, this will be noted. Grey-scale images will be denoted as arrays of *positive integers* of the form *A(i,j), i* = 1,2,. . .,*M*; *j* = 1,2,. . .,*N* (*Fig. 19.2*).

A binary SE *specifies a neighbourhood* relative to a *reference* pixel, usually called the *centre pixel*. This is usually, but not necessarily, located close to the centre of the neighbourhood. However, it is not necessary for the centre pixel to be included in the SE. The SEs in *Figs. 19.3* and *19.4* have various numbers of pixels, ranging from 1 to 69. These diagrams illustrate one of the conventions for representing SEs: small white squares represent pixels that are part of the SE and small grey or black squares represent pixels that are *not* part of the SE. The SEs in *Fig. 19.4* are shown using a different convention: non-SE pixels are omitted completely and the reference pixel is marked with a circle. Many SEs define neighbourhoods in which the pixels are arranged contiguously, symmetrically, and forming a convex shape. However, none of these is necessary; the SE may be disconnected, asymmetric, concave, and have

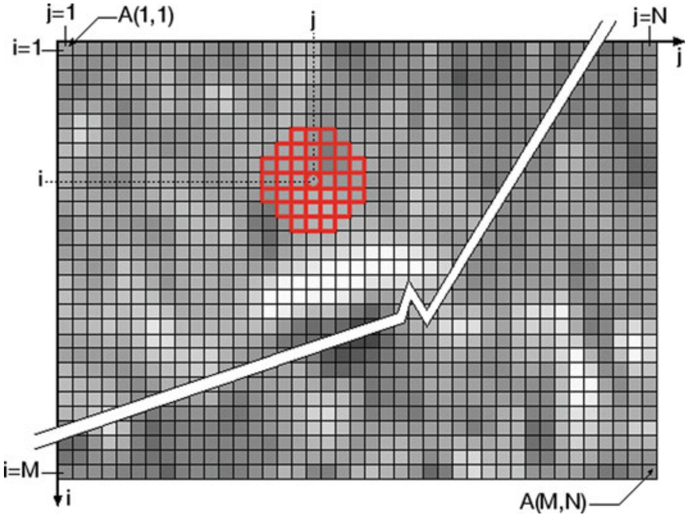

Fig. 19.2

Notation for grey-scale images. The region outlined in red represents a ‘circle’ structuring element centred on the point (*i,j*), which is called the reference (or *centre*) pixel for that SE. The result of the calculation based on his neighborhood defines the new value for the centre pixel

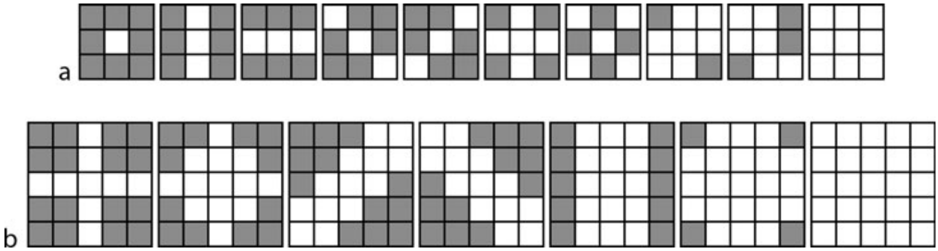

Fig. 19.3

Sample structuring elements (a) 3 × 3 pixel SEs. The left-most SE, the *identity operator*. Its sole use is for testing erosion or dilation programs; the input image remains unchanged. (b) 5 × 5 pixel SEs

‘holes’ such as a disc (O), or 8. *Figure 19.4* shows the rather limited range of SEs available in Photoshop™.

Another important concept is that of *connectedness* in digital images (see *Fig. 19.5*). Apart from pixels around the border of the image, each one has four *4-neighbours,* adjacent to it and arranged around it in the four principal directions: above, below, left, and right. All points within a blob that can be traversed by moving from pixel to pixel by visiting only 4-neighbours are said to be *4-connected.* Similarly, we can define *8-neighbours* and *8-connectivity.* Notice that the term 8-neighbour refers to all 8 pixels surrounding the central pixel’s 3 × 3 pixel neighbourhood. Notice further that an 8-connected arc does not divide the image into two distinct parts, in the way that a line normally segments a plane. Two 8-connected arcs can cross one another, creating the so-called *Connectivity Paradox.*

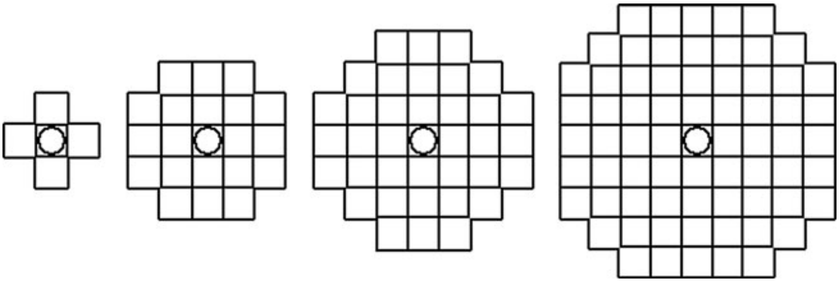

Fig. 19.4

SEs used by Photoshop® (CS3 and CS4) for erosion ('Contraction. . .') or dilation (*Expand*. . .). Photoshop® provides the four structuring elements shown here

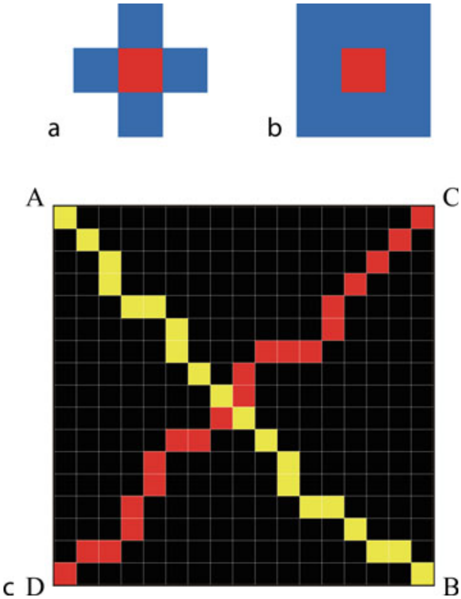

Fig. 19.5

Connectedness in digital images. (a) 4-neighbours (*blue*) of the red pixel and are said to be 4-connected to it. (b) 8-neighbours (*blue*) of the red pixel are 8-connected to it. (c) Connectivity paradox. A and B are 8-connected (*yellow line*), while C and D are also 8-connected to each other (*red line*). Neither of these lines divides the grid into separate regions (i.e., that are not 8-connected to each other)

19.2.1 General Morphological Procedure

Morphological image processing (both binary and grey-scale) proceeds as follows:

1. Place the reference pixel of the SE at some position on the input image. Computationally, the process usually begins with the pixel in the first row and first column of the input image, and proceeds in raster-scan order. However, any convenient scan sequence could be used.

2. Let the number of pixels in the SE be denoted by K. (For example, in the third SE shown in ➋ *Fig. 19.4*, $K = 37$.) Extract from the input image the K values of the pixels in the neighbourhood defined by the SE. Denote these by $\{a_1, a_2, \ldots, a_K\}$.
3. From these K values and the rules to be defined in later sections, calculate the value to be written into the output image buffer at that location. In general terms, this may be represented thus:

$$\text{Output\_Image}(i, j) = \mathbf{F}\{a_1, a_2, \ldots, a_K\}$$

   where $\mathbf{F}$ is a logical function specifying the operation being performed.
4. Repeat for all other positions in the input image (Depending on the application requirements, some of the input image pixel positions might be skipped, thereby saving computation time).

19.3 Binary Erosion

Consider a binary image containing both black pixels ('background') and white pixels ('object'). Binary erosion is a process by which some of the white pixels in the image are 'removed' i.e., converted to black pixels. The choice of which white pixels to keep and which white pixels to erode is determined by the SE. In terms of a physical analogy, the binary erosion operation finds all the places where the SE 'fits' completely inside a blob in the image (➋ *Fig. 19.6*). The SE is said to 'fit' at a certain position if the input image has 'white' pixels at all positions in the neighbourhood defined by the SE. An image may have one or many blobs. The erosion operation is position-invariant, in that it treats all blobs in the same way, irrespective of where they are.

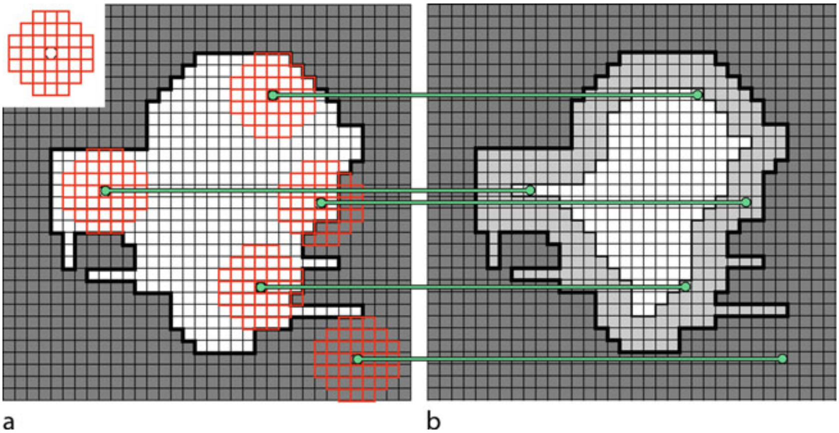

Fig. 19.6

Erosion using a 'circle' SE. (a) Original image. Inset: SE consisting of a 7 × 7 pixel representation of a circle. (b) Result of erosion (*white blob*). The grey pixels were originally white and are set to black by erosion. The SE is shown in several positions and the green lines indicate the corresponding pixels affected

19.3.1 Mathematical Definition

For binary erosion, the function $\mathbf{F}$ is the *logical* AND (&) of the K binary pixel values, which are, by definition, either Boolean 0 (black) or Boolean 1 (white). Thus, for binary erosion,

$$\text{Output\_Image}(i, j) = \{a_1 \& a_2 \& \ldots \& a_K\}.$$

This is equivalent to saying that the centre pixel is white if and only if all of the pixels in the neighbourhood are white.

19.3.2 Examples of Erosion

Erosion is illustrated with reference to a circular SE of diameter 7 pixels applied to a simple blob (➲ *Fig. 19.6*). This shows two of the many positions at which the SE 'fits'. That is, all image pixels within the neighbourhood of (*i,j*) defined by the SE are white. In addition, three SE neighbourhoods (shown in red) at which the SE does *not* fit, are also shown. At these points the output value is Boolean 0.

Notice the following points which are generally valid for erosion:

- Thin 'hairs' are removed.
- Very small blobs are removed (not shown in ➲ *Fig. 19.6*).
- Larger blobs become smaller.

We have established the general concept of erosion and an understanding of its actions without recourse to abstruse mathematics. The precise function of erosion depends upon the size and shape of the SE, as well as the particular blob features: size, shape, and orientation. This will be illustrated several times later.

19.4 Binary Dilation

Binary dilation is a process by which white regions in the input image are augmented by adding white pixels around the edges, or in holes ('lakes') in the interiors of blobs. That is, some of the black background pixels are converted to white object pixels. The choice of which black pixels to leave unchanged and which to change to white pixels is determined by the particular SE being applied. ➲ *Figure 19.7* shows dilation applied to the same simple blob that we previously used for erosion.

19.4.1 Mathematical Definition

The function $\mathbf{F}$ used to define binary dilation is the logical OR of the K binary pixel values covered by the SE. Thus, for binary dilation,

$$\text{Output\_Image}(i, j) = \{a_1 \textbf{ OR } a_2 \textbf{ OR} \ldots \textbf{OR } a_K\}$$

This is equivalent to saying that the output is *white* if at least one of the pixels in the neighbourhood covered by the SE is *white*.

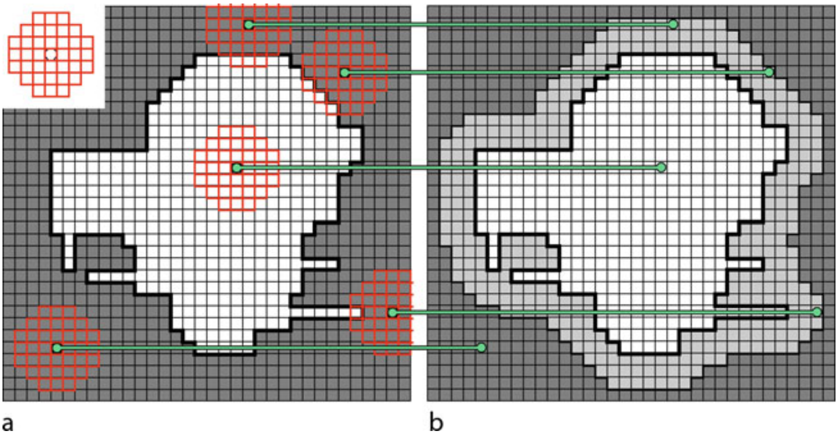

Fig. 19.7

Dilation using a 'circle' SE. (a) Original image. Inset: SE consisting of a 7 × 7 pixel representation of a circle. (b) Result of dilation. The grey pixels were originally black and are set to white by dilation. In two instances shown here, the SE overlaps the border of the image. This often gives rise to anomalies, called edge *effects*, which will be described later

19.4.2 Duality

Dilation is, in some ways, the 'opposite' of erosion, in that it *expands* white areas, while erosion reduces them. However, dilation is *not* the true *inverse* of erosion; dilation followed by erosion does not restore the image to its original state and vice versa. Morphological operations, like most other neighbourhood operations, in general, do not have inverses. This lack of an inverse operation is, in fact, a particular benefit of morphological operations and we shall see later how we can take advantage of this.

Ignoring 'edge effects'(defined below), *dilating* the white pixels of the *object* is identical to *eroding* the black pixels of the *background*, and vice versa. This relationship is referred to as the *duality* between erosion and dilation (see Supplement). Hence, duality is a particular case of *de Morgan's Rule.* (Recall that erosion is defined in terms of ANDing and dilation using ORing.) Duality allows us to define an *indirect* method of performing dilation:

1. Negate the image.
2. Erode the now-white pixels (which were originally the background pixels) with the appropriate SE.
3. Negate the output image, so that the original black-white relationship between object pixels and background pixels is restored.

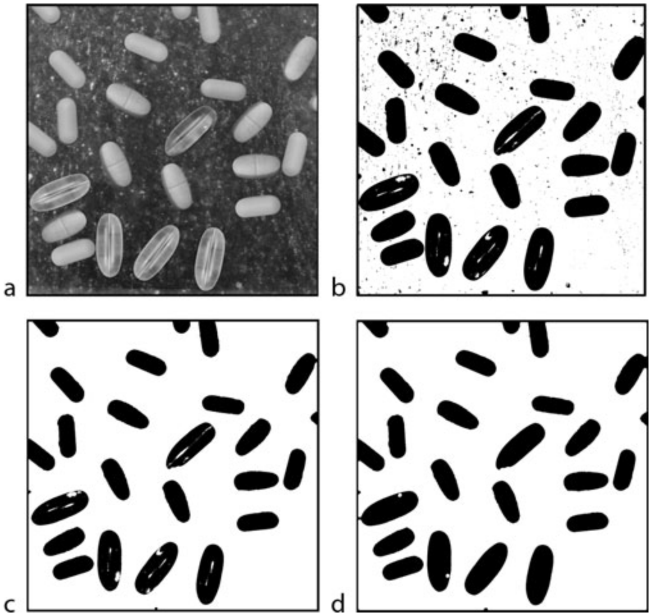
By simply interchanging the representations of black and white (equating black with Boolean 1 and Boolean 0 with white), we see that there is no need to incur any time penalty for performing dilation by the inverse method. In QT, *gbd(SE)* produces exactly the same result as [*neg, gbe(SE), neg*], for any structuring element, (*SE*), which of course is slower.

Dilation is useful for removing black streaks and spots. It also makes large blobs even larger. This is to be expected from duality. (Recall that erosion removes white streaks and spots and makes large white blobs smaller.)

The definition of duality given above holds for structuring elements that are rotationally symmetrical about some line. If this is not the case, the SE must be flipped, by rotating it through 180°. That is, dilation with structuring element $S = \{[i_1,j_1],[i_2,j_2], [i_3,j_3],\ldots\}$ is the dual of erosion with structuring element S', where $S' = \{[-i_1,-j_1], [-i_2,-j_2], [-i_3,-j_3], \ldots\}$ and vice versa.

19.4.3 Examples of Erosion and Dilation

➲ *Figure 19.8* shows a grey-scale image of tablets and capsules lying on a mottled background. Suppose the goal is to isolate and count the pills of the various types. Since all of the pills are larger than the speckles of the background, dilation with an SE *smaller* than the pills but *larger* than the speckles can be used to discriminate between them. It is not immediately apparent from ➲ *Fig. 19.8c* that the pills have become slightly smaller. Shrinkage is not important if our task is to count, rather than measure pills. ➲ *Figure 19.8d* shows that dilation can have a beneficial effect by removing white spots within the pills. Erosion and dilation are illustrated again in ➲ *Fig. 19.9*, where the change of blob size is more obvious.



◘ Fig. 19.8

Erosion and dilation. (a) Original image, pills lying on a mottled background. (b) Thresholded and inverted binary image. (c) Dilation result. Notice the absence of small black spots, except around the edges of the image. (d) Erosion of the previous image. Notice that there are fewer white blobs within the pill borders

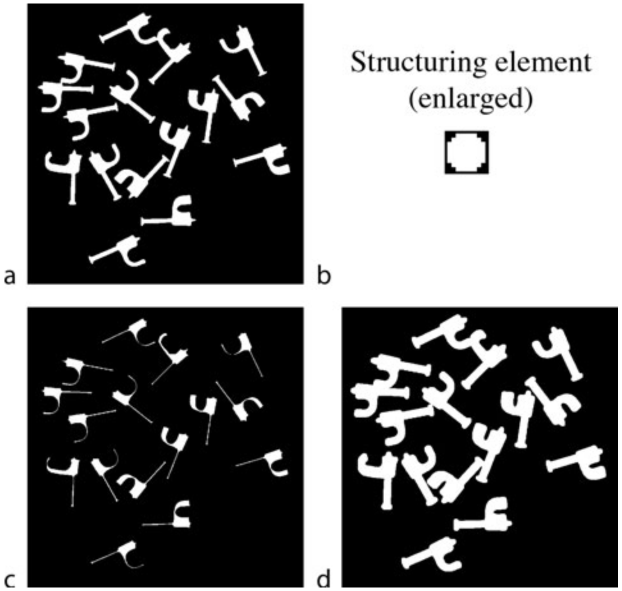


Fig. 19.9
Another example of erosion and dilation. (a) Original image, cable fasteners. (b) Structuring element, 9 × 9 'circle'. (c) Erosion. (d) Dilation

19.5 Opening and Closing

Opening and closing are combinations of erosion and dilation. The reader will already appreciate that erosion *reduces* the sizes of white regions in a binary image, while dilation does the opposite. With this in mind, it is reasonable to ask whether eroding an image and the dilating the result returns it to its original state. The answer is '*No!*' but the effects of combining them can be very useful.

The process of eroding an image, and then dilating the result, with the same SE, is called *opening*, and is defined using fairly obvious terminology:

$$\text{Output\_Image}(i,j) = \text{OPEN}_{\text{SE}}[\text{A}(i,j)] = \text{DILATE}_{\text{SE}}[\text{ERODE}_{\text{SE}}\{\text{A}(i,j)\}]$$

A*(i,j)* is the input image and the subscript SE denotes the particular structuring element being used, which is the same for both erosion and dilation. Opening is a very useful operation, particularly for eliminating noise in the form of small white spots, or narrow streaks, while leaving the rest of the image almost unchanged. *Figure 19.10* shows the result of opening on a simple test images. More practical results will be seen from the examples presented later.

Similarly, dilating an image and then eroding the result with the same SE, is called *closing*, and is defined thus:

$$\text{Output\_Image}(i,j) = \text{CLOSE}_{\text{SE}}[\text{A}(i,j)] = \text{ERODE}_{\text{SE}}[\text{DILATE}_{\text{SE}}\{\text{A}(i,j)\}]$$

Closing is useful for filling small lakes and eliminating thin black streaks. Again, the remainder of the image is changed very little.

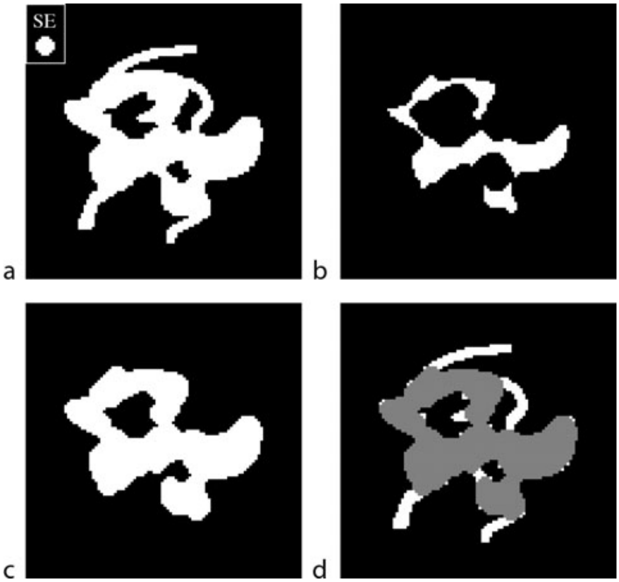

Fig. 19.10

Opening. (a) Original image. Inset: structuring element. (b) Erosion. (c) Opening. This is equivalent to the dilation of the previous image with the same structuring element. (d) Differences (*white*) between opening and the original image (*grey*). Notice that thin white streaks have been eliminated, convex corners have been smoothed slightly and a narrow 'neck' has been broken. The last mentioned effect gives this operation its name

Figure 19.11 shows the result of closing on an image containing a simple hand-drawn blob.

Figure 19.12 shows the results of applying all four binary morphological operators discussed so far, to a rather more sophisticated test image, using three different structuring elements. This test image consists of a wedge and several solid circles of different sizes, in positive and negative contrast. The reader is urged to study these results carefully, as they provide the key to understanding binary morphology. This *Fig. 19.12* also includes illustrations of the effects of two further functions:

- *Opening*. That is, erosion followed by dilation, using the same SE.
- *Closing*. That is, dilation followed by erosion, using the same SE.

19.6 Edge Effects

Blobs touching the edge of the image can result in unexpected outcomes when neighbourhood operations are performed. (This is true for other neighbourhood operations, including convolution, as well. See Chap. 15.) This follows from the fact that, when the SE is centered on a pixel on the edge of an image, part of it extends beyond the image, leaving the operation undefined. Assumptions are always built into the hardware or software implementing morphological functions that determine what will happen at the edges. Different assumptions give different results – and are always totally arbitrary!

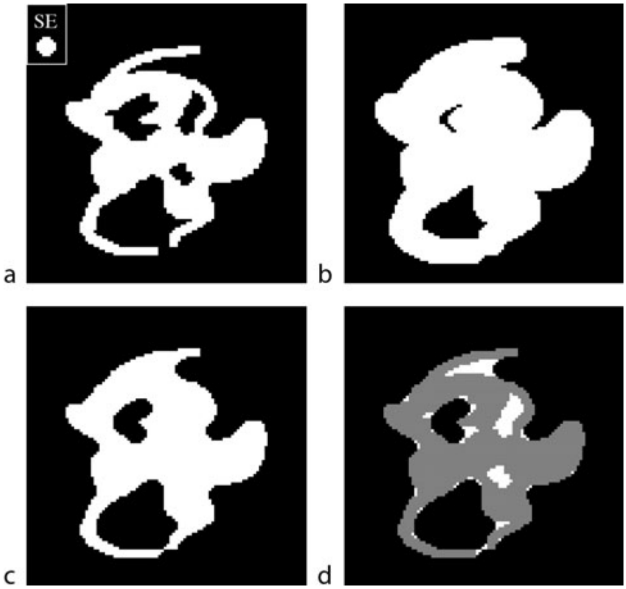

Fig. 19.11
Closing. (a) Original image. Inset: structuring element. (b) Dilation. (c) Closing. This is equivalent to the erosion of the previous image with the same structuring element. (d) Differences (white) between closing and the original image (*grey*). Notice that small black lakes have been filled, concave corners have been smoothed slightly and a narrow black 'channel' has been bridged. The last mentioned effect gives this operation its name

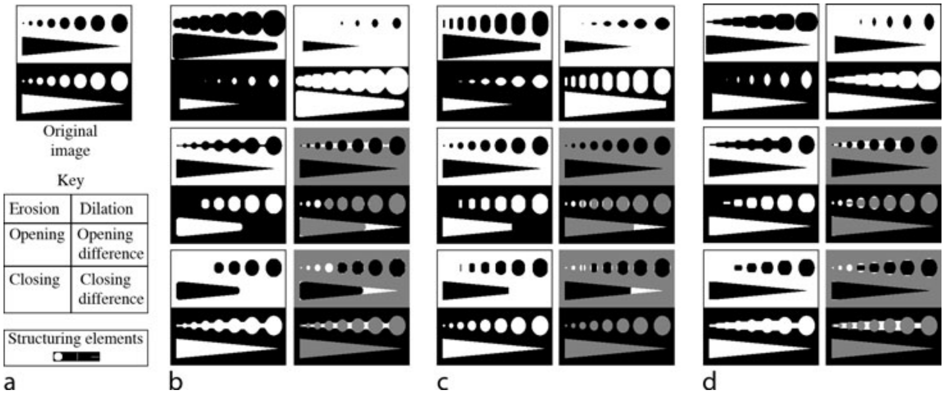

Fig. 19.12
Erosion, dilation, opening and closing applied to a simple test image. (a) Original image, the key to interpreting the results and the structuring elements. (b) Structuring element was a circle. (c) Structuring element was a vertical line. (d) Structuring element was a horizontal line

Algorithms for binary erosion, dilation, opening and closing usually handle this by assuming that there are additional 'phantom' rows and columns of pixels surrounding the image. This allows the '*inner loop*' code to run faster because it does not have to check for and handle special cases each time it moves to a new pixel. For erosion, these phantom pixels are usually set to black and therefore not part of any blobs. However, it means that all pixels are set to black, if their neighbours, as defined by the SE, lie outside the edge of the image. For a similar reason, it is customary when implementing dilation to set the phantom pixels to white. ➲ *Figure 19.13* illustrates this using erosion with a 3 × 3 4-connected SE on a very simple blob. ➲ *Figure 19.14* shows how the boundary of an object touching the image border can be distorted by edge effects.

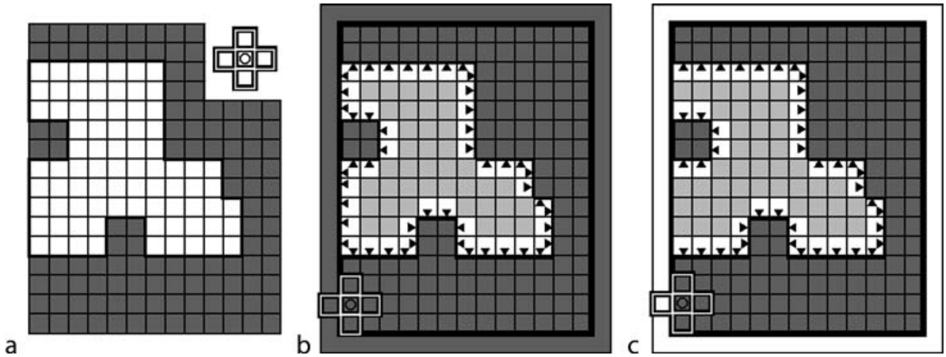

Fig. 19.13
Edge effects. (a) Original blob. (b) Erosion with black phantoms. The small arrow-heads indicate which pixels will be eroded to black, with the arrows pointing to the black pixel, or pixels, responsible for eroding them. (c) Erosion with white phantoms

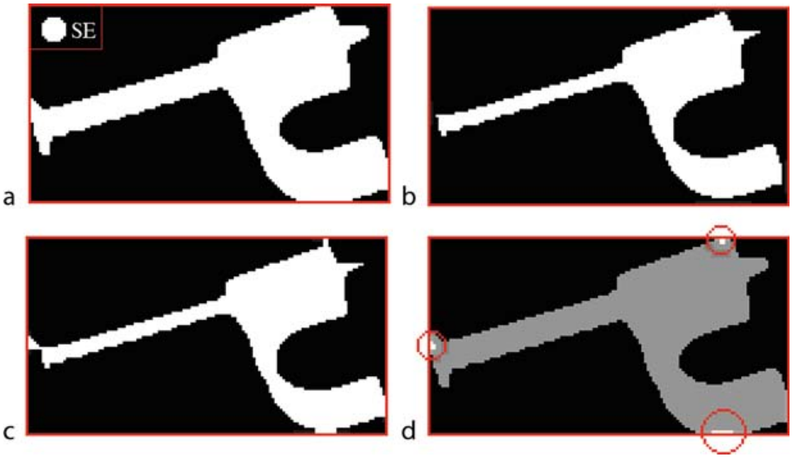

Fig. 19.14
Edge effects. (a) Original blob. (b) Erosion with black phantoms. (c) Erosion with white phantoms. (d) Differences due to change of phantoms. These are very small *white blobs circled* in *red*

Another approach to handling edge effects is simply to ignore all pixels close to the image border. This is really the only 'honest' approach, as all others are perfectly arbitrary. If the results at the edges of the image are not what is wanted, the assumption must be changed.

19.7 Extended Functions

Opening and closing are combinations of erosion and dilation. Since the last mentioned is the dual of erosion, we see that that all four of the morphological operators described so far can be expressed in terms of a single concept: erosion (or its dual, dilation). Clearly, other combinations are possible. For example, we could compare the images created by erosion (or dilation) with different structuring elements. Another possibility is to combine the four basic procedures with subtraction of the original image. All of these combinations can produce interesting and useful effects. In this section, we explore some of the options, wherever possible illustrating the operation using images drawn from practical applications. Other options are available, such as applying erosion recursively, with clever rules for deciding when to stop processing, locally and globally. Morphology is effectively a family of non-linear neighbourhood operations but it does not provide a complete tool-box for processing images. Combining morphological operations with members of the large range of non-morphological functions cannot be described effectively for the general case. The best advice we can provide is learn about morphology first, look at the image carefully, decide what operation to perform, then apply it and evaluate the results by eye and/or computer. On its own, a single morphological operator is rarely sufficient. The sequences of image-processing operations required for most practical applications do not fit neatly into simple categories. For this reason, the following examples do not follow a simple pattern.

Selecting linear features at a given angle. *Figure 19.15* shows how a straight-line structuring element can be used to select linear features within a narrow range of angles. The precision obtained depends on the length of the SE.

Checking the periodicity of a grid. *Figure 19.16* shows an array of spots. This image was generated using a standard lens which introduces barrel distortion. Since the authors wanted to exhibit the power of morphology, this warping effect was deliberately produced. (To obtain a distortion-free image, a telecentric lens should be used.) The SE was derived by sampling the original mesh-like structure after a small amount of erosion had been applied. (Actually, thinning was used but this explanation will suffice until we meet that subject later.) Generating the SE by sampling the image, optionally applying some preprocessing first, is an important adjunct to morphology. (This point will be illustrated again later, when we consider optical character recognition.) The initial erosion (*Fig. 19.16c*) leaves an array of disconnected spots, which is difficult to measure. Dilation and closing were then applied to join them together. The resulting blobs indicate where the local periodicity is 'acceptable' (*Fig. 19.16e*).

Deriving a disjoint SE from the image. *Figure 19.17* shows an example of erosion using a structuring element that consists of four separate parts. There is no theoretical limit on the number of distinct parts in an SE.

Using the largest internal circle to choose the SE. The largest internal circle operator [QT: *lic*] draws the biggest circle that can be drawn within the white regions of a binary image (*Fig. 19.18b*). It can also be applied recursively (*Fig. 19.18c*) [QT: *mic*], or to the background to measure lake diameter (*Fig. 19.18d*). Clearly, these circles only give an approximate guide to where SEs of different sizes will fit.

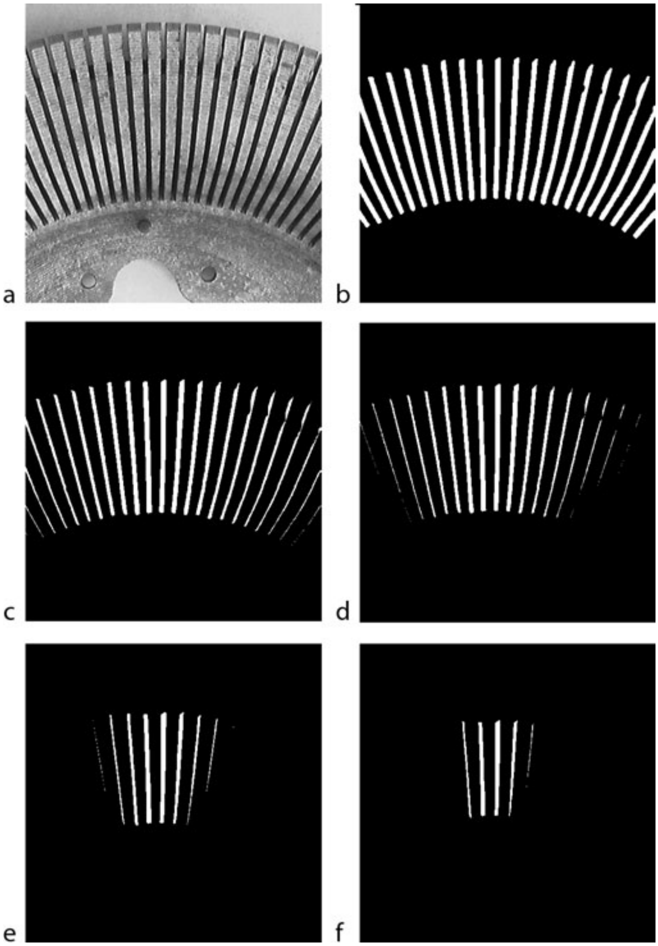

Fig. 19.15

Erosion with straight-line structuring elements of varying lengths selects linear features with variable precision. (a) Original grey-scale image (This is a die-cast alloy component, from a mechanical typewriter). (b) Binary image. Produced using thresholding and morphology, to reduce noise. (c) SE was a vertical straight line of length 15 pixels. (d) SE was a line of length 25 pixels. (e) SE was a line of length 50 pixels. (f) SE was a line of length 75 pixels

Noise reduction (➲ *Fig. 19.19*) Salt-and-pepper noise consists of white and black spots contaminating the background and foreground of a binary image, respectively. It results in bit reversal in a small proportion of the pixels. In general, noise arises in binary images as a result of a variety of physical effects, including camera noise, electrical noise, quantisation errors and actual dirt on the object being viewed. Morphology can selectively reduce the number of either white or black spots, or both. ➲ *Table 19.1* lists the general principles for selecting the method of noise reduction. For the sake of comparison, ➲ *Fig. 19.19* also shows results for other methods of filtering to remove noise. Simply removing all blobs that have a small area is often very effective but is rather slow compared to morphological operations. Taking a majority

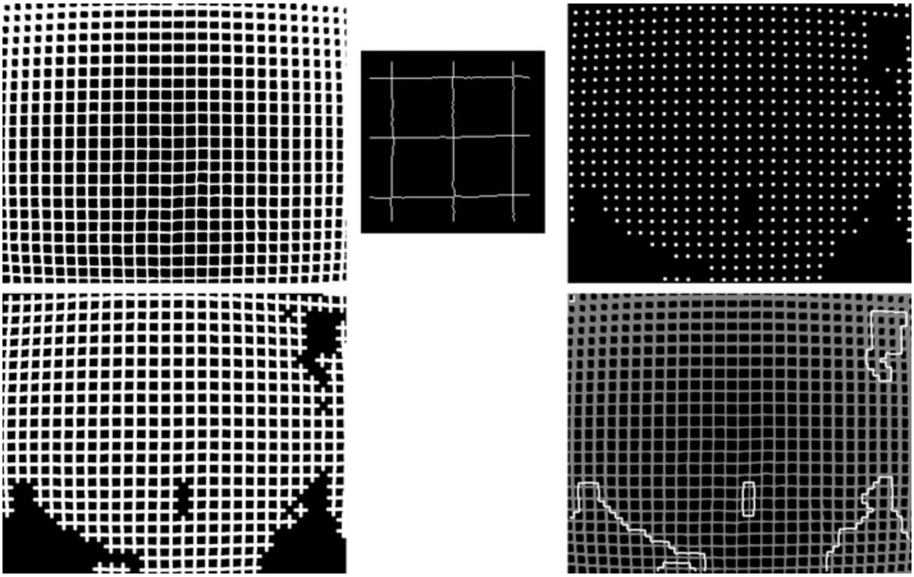

Fig. 19.16
Erosion with an SE derived from the image: checking repeated patterns. (a) Original binary image, substrate for an automobile catalytic converter. The barrel distortion is due to the lens. The warping of the geometry was deliberately tolerated here, so that we could better demonstrate the image filtering. (b) Structuring element, enlarged for clarity. This was derived from the central region of the image, after thinning. (c) Result of erosion. Each ‘hit’ is represented by a spot of uniform size. (d) Dilation using a vertical cross (+) SE ‘to join the dots’. (e) Closing of the previous image using a solid square SE produced a set of blobs, whose outlines have been superimposed on the original

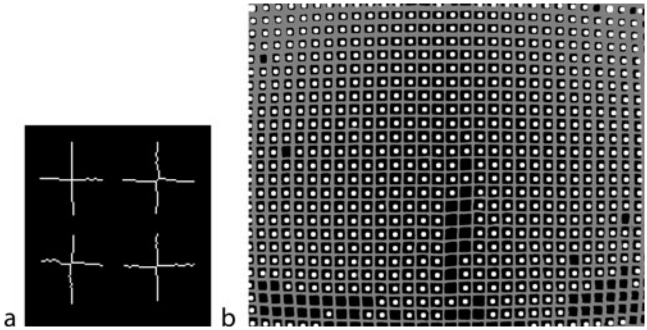

Fig. 19.17
Using a multipart SE. (a) Structuring element, selected manually from the thinned version of *Fig. 19.17*. **(b) Result of erosion. Notice the ‘holes’ are detected here, whereas the processing described in the previous figure detected the lattice-wall junctions**

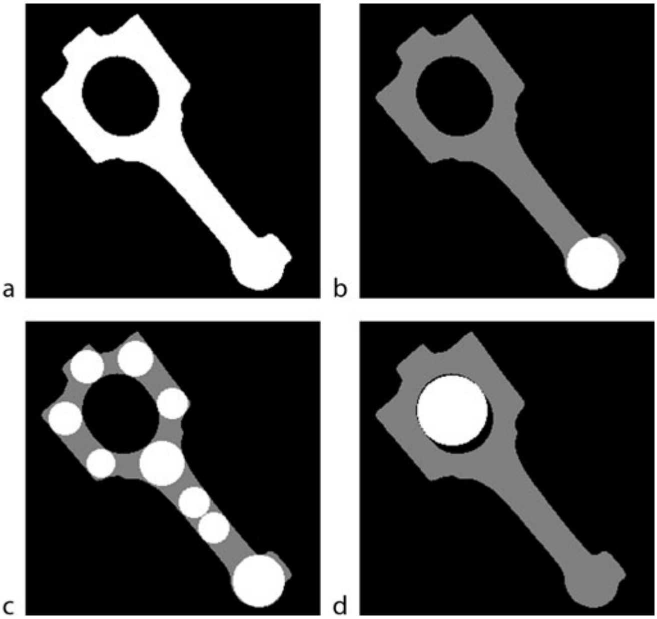

Fig. 19.18

The largest internal circle can help in choosing appropriate structuring elements for morphological operations. (a) Original binary image, automobile conrod (connecting rod). (b) Largest internal circle superimposed on the original. [QT: *lic, adi*] (c) The largest circle was found, the exclusive OR was applied. This process was repeated recursively a total of nine times. (d) Largest internal circle fitted to the lake. [QT: *blf, exr, lic*]

vote of the pixels within the neighbourhood covered by the SE provides an effective way to eliminate both black and white spots. [QT: *maj*] The majority voting function can be performed once, several times as the user chooses, or repeated recursively, until the image no longer changes. Of course, the execution time cannot be predicted for the last option, because it is data driven.

Binary edges. Erosion followed by exclusive OR with the original image, draws the edge contours (➋ *Fig. 19.20*). This operation is given the name *Top-hat.* The size and shape of the structuring element determines the exact form of the edge contour. Normally, it is desirable to produce a curve that is 1 pixel wide, in which case a 3 × 3 pixel SE is used. However, it is possible to highlight, say, top edges, or left edges; a linear SE is then used. The vision engineer must also decide whether a 4- or 8-connected curve is needed. Dilation followed by exclusive OR with the original image produces an edge contour. This is called the *Bottom-hat* operation. Top-hat produces contours that lie within the original white area, while bottom-hat places the curve in the background adjacent to the white pixels in the original image.

Searching for specific small-scale patterns. The top-hat and bottom-hat functions are, of course, able to detect any pattern that can be expressed in an SE, whether or not it is contiguous. An obvious extension of this is to look for pixels that have a given *number* of white neighbours (➋ *Fig. 19.21*). Strictly, this function does not look for a single pattern but any one of a number of patterns. Isolated white pixels (i.e. no white 8-neighbours) are detected

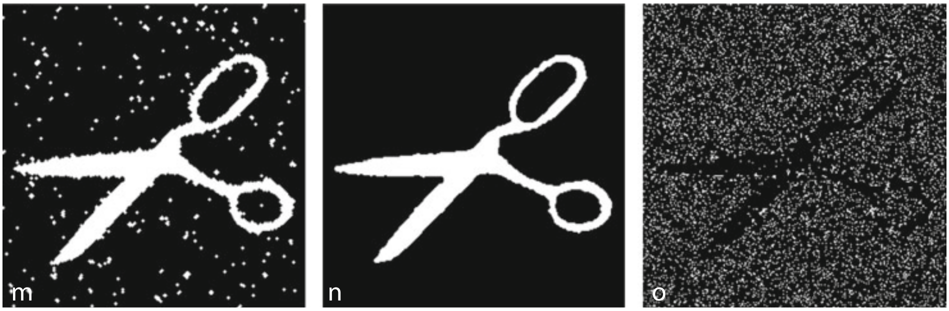

Fig. 19.19

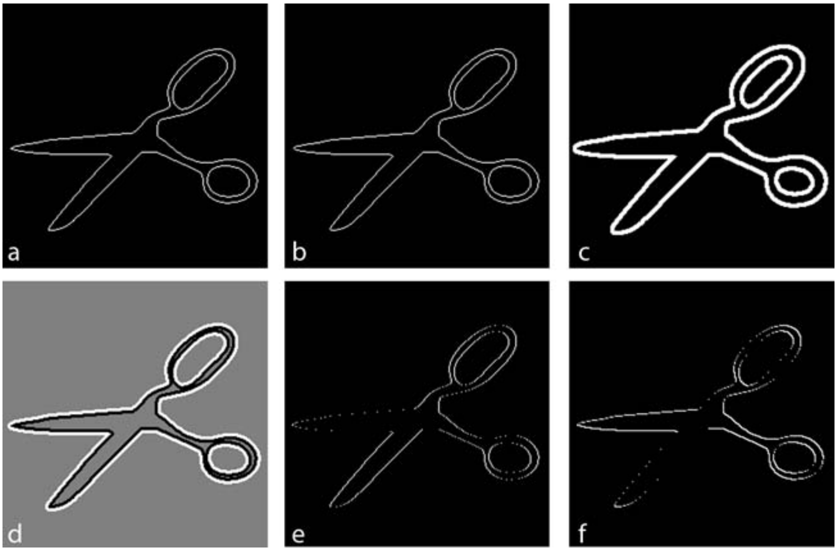
Reducing noise using morphology. Some of the operators mentioned here are described later. They are included here so that the various options can be compared. (a) Original image image, created specially for this purpose by superimposing salt-and-pepper noise on the 'scissors' image. (b) Removing isolated white pixels. [QT: *cln*] (c) Removing isolated black pixels. [QT: *neg*, *cln*, *neg*] (d) Removing small white spots, fewer than 10 pixels. [QT: *kgr*(10)] (e) Removing small black spots, fewer than 10 pixels. [QT: *neg*, *kgr*(10), *neg*] (f) Removing both white and black spots. [QT: *kgr*(10), *neg*, *kgr*(10), *neg*] (g) Majority filter applied to (f) produces a smoother edge. [QT: *kgr*(10), *neg*, *kgr*(10), *neg*, *maj*] (h) Original scissors image, before the artificial addition of noise. (i) Differences between (g) and (h), shown in white. (j) Opening [QT: *x* = *cse*(14, 1), *gbe*(*x*), *gbd*(*x*)] (k) Closing. [QT: x = *cse*(14, 1), *gbd*(*x*), *gbe*(*x*)] (l) Opening followed by closing with the same SE. [QT: *x* = *cse*(14, 1), *gbe*(*x*), *gbd*(*x*), *gbd*(*x*), *gbe*(*x*)] (m) Closing followed by opening with the same SE. [QT: *x* = *cse*(14, 1), *gbd*(*x*), *gbe*(*x*), *gbe*(*x*), *gbd*(*x*)]. (n) Majority function with a 3 × 3 pixel SE applied recursively to the original image. (o) Top-hat. [QT: *x* = *cse*(14, 1), *gbe*(*x*), *gbd*(*x*), *rei*('original'), *exr*]

Table 19.1

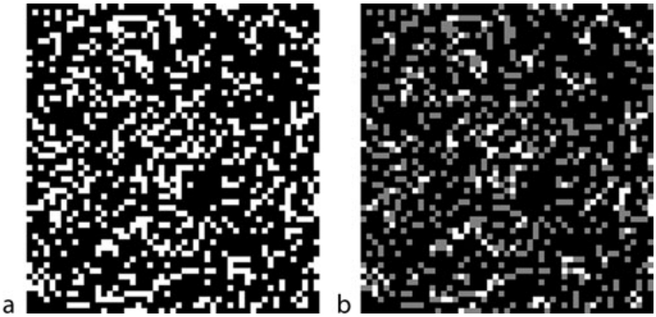
Reducing noise in binary images using morphology

Type of noise	Method	Comments
White spots	Erosion	Large blobs become smaller
White spots	Opening	Large blobs are same size
Black spots	Dilation	Large blobs become larger
Black spots	Closing	Large blobs are same size
White and black spots	Closing, dilation	Experiment
White and black spots	Dilation, closing	Large blobs are same size
White and black spots	Majority vote	See ➲ *Fig. 19.19*
White spots	Biggest blob	Non-morphological function [QT: *big*]
White spots	Retain only those blobs with a large area	Non-morphological function [QT: *kgr*]
Hair, spurs (white streaks with one 'free' end)	Erosion or opening	As white spots
Hair, spurs (white streaks with one 'free' end)	Selective erosion of the end of the spur	[QT: *spr(n), exr* repeated recursively]



■ Fig. 19.20

Binary edges. (a) Top-hat with a 3 × 3 pixel SE. [QT: *ero, exr*] (b) Bottom-hat with a 3 × 3 pixel SE. This contour is slightly larger than that in the previous image. [QT: *dil, exr*] (c) Bottom-hat with a 5 × 5 pixel circle SE. [QT: *rni(49), thr(1), x = cse(14,5), gbd(x), exr*] (d) Comparing edges found by bottom-hat (*white*) and top-hat (*black*). Both contours were generated using a 7 × 7 pixel circle. SE. (e) Top-hat with a horizontal-line SE. [QT: *x = cse(1,3),gbe(x), exr*] (f) Top-hat with a diagonal-line SE (/). [QT: *x = cse(4,3), gbe(x), exr*]



■ Fig. 19.21

Selecting white pixels that have a given number of white 8-neighbours. (a) Original image. (b) White pixels that have exactly three white 8-neighbours. White pixels that have any other number of white 8-neighbours are shaded grey. [QT: *sbc(3)*]

in this way (❯ *Fig. 19.19b*). Later, we shall see that counting white neighbours is used to identify important features on a 'match-stick' figure. In addition, note that the Euler number combines ten 8-neighbourhood counts (❯ Chap. 14) to calculate the number of blobs minus the number of lakes in the image.

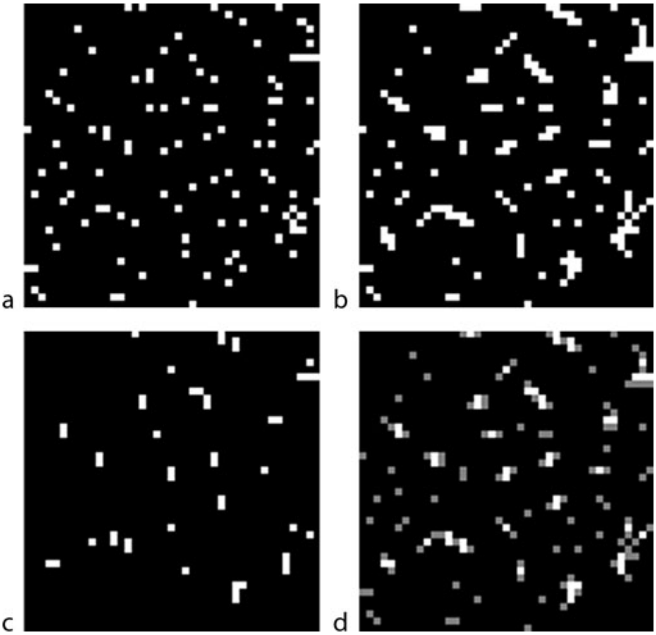


Fig. 19.22

Bridge operator. (a) Original image. (b) Result of bridge. [QT: *mbo*] (c) Exclusive OR of the original image and the result of bridge. [QT: *mbo, exr*] (d) White pixels were added by applying bridge. Original white pixels are shown here as mid-grey

Figure 19.22 shows the results of applying the so-called *Bridge function*. This detects black pixels that have two 8-neighbours that are not 8-connected to each other. Such a pixel is set to white. For example:

$$\begin{matrix} 0 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & 0 \end{matrix} \qquad \text{becomes} \qquad \begin{matrix} 0 & 0 & 1 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \end{matrix}$$

Similarly

$$\begin{matrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \end{matrix} \qquad \text{becomes} \qquad \begin{matrix} 0 & 1 & 1 \\ 0 & 1 & 0 \\ 1 & 1 & 1 \end{matrix}$$

The bridge function has limited value in filling or detecting small gaps between white regions.

The morphological operators described so far are all logical. Hence, *all* pixels covered by the SE must be white for erosion to produce a white output. This makes them rather sensitive to noise. For this reason, it is sometimes better to insist that *most* of the neighbours be white. Counting white neighbours can be achieved using linear convolution with unit weights. In QT/MATLAB, the command sequence

```
x = ones(m,n)                      % Create an m*n array of 1s
t = floor(255*p/(m*n))             % Rescale parameter p
```

```
glc(x)                               % General linear convolution with weight matrix x
thr(t)                               % Threshold at level t
```

produces the value *white* (255) for each pixel that has at least *p* white neighbours, including itself. Implementing a 'biased-voting' function like this can be convenient during experimentation but may not lend itself for use in a high-speed target (factory floor) system.

Grass-fire Transform (*Prairie Fire Transform* or *Distance Transform*) The grass-fire transform (of a binary image) is a grey-scale image, in which each white pixel is assigned an intensity indicating the distance from it to the nearest black pixel. Pixels that were black originally remain black (➲ *Fig. 19.23b* and ➲ *d*). To understand how this is related to morphology, consider the process of recursively eroding a blob by removing a 1-pixel wide layer of pixels on each cycle. Points that are far away from the blob boundary will be removed later than those close to it. The output image created by the grass-fire transform indicates how long (i.e., how many erosion steps) it takes to remove each pixel by this 'onion-peeling' process. Clearly, there must be some rules to prevent the erosion continuing when to do so would 'break' the object. These rules act locally, not globally. Local maxima in the grass-fire transform image can be useful indicators of object pose (➲ *Fig. 19.23d*).

Skeletons The skeleton of an object is easier to understand from a picture than a verbal explanation (➲ *Fig. 19.23e*). The recursive erosion process just described needs only a minor modification to generate the skeleton, rather than the grass-fire transform. Comparing these shows that the skeleton runs like a continental divide over the mountain range defined by the grass-fire transform. (Think of intensity as defining the height of each point in a 3D representation of the grass-fire transform image.) Note that the skeleton preserves the Euler number of the original image. Since they are morphological functions, the grass-fire transform and skeletonisation are applied to every blob in the image.

Two skeleton features are important: joints (➲ *Fig. 19.23f*) and limb ends (➲ *Fig. 19.23g*). These are both detected by counting white neighbours, as explained above. The tips of a skeleton's limbs, called 'spurs', may be removed by recursively removing the limb ends. Notice that all limb ends in the skeleton image are pruned pixel-by-pixel, so all spurs are removed at the same time.

Shrinking Imagine trying to place a robot gripper to pick up a horse-shoe. The centroid will not suffice to calculate the robot pose, since the gripper will try to grasp air, not metal. In this kind of situation, it is useful to know the address of just one pixel within each blob that is close to its centre. Shrinking is a useful function that does just this, provided there are no lakes (➲ *Fig. 19.23i*). A binary object with lakes shrinks to a series of inter-connected rings. Each ring is halfway between a lake and the outer boundary nearby (➲ *Fig. 19.23j*).

Thinning The skeletonisation process involves repeated erosion, with rules devised to stop the figure from breaking apart. Thinning is the same process but terminated earlier, usually by specifying beforehand how many erosion cycles are to be performed. Partial, or incomplete thinning, is shown in ➲ *Fig. 19.23k*.

Thinning, like the grass-fire transform and skeletonisation, depends upon the concept of distance. This can be measured in many ways, the usual one being Euclidean distance. To improve computation speed, it is sometimes expedient to use other distance measures and this can sometimes produce unexpected results (➲ *Fig. 19.23l*).

Removing 'Hairs' and 'Spurs' A 'hair' is thin white streak. It may be attached at one or both ends to a large blob, or not attached at all. A 'spur' is a special case of a hair; it is attached at one end only. Hairs can be removed from an image by opening. Similarly, thin black streaks

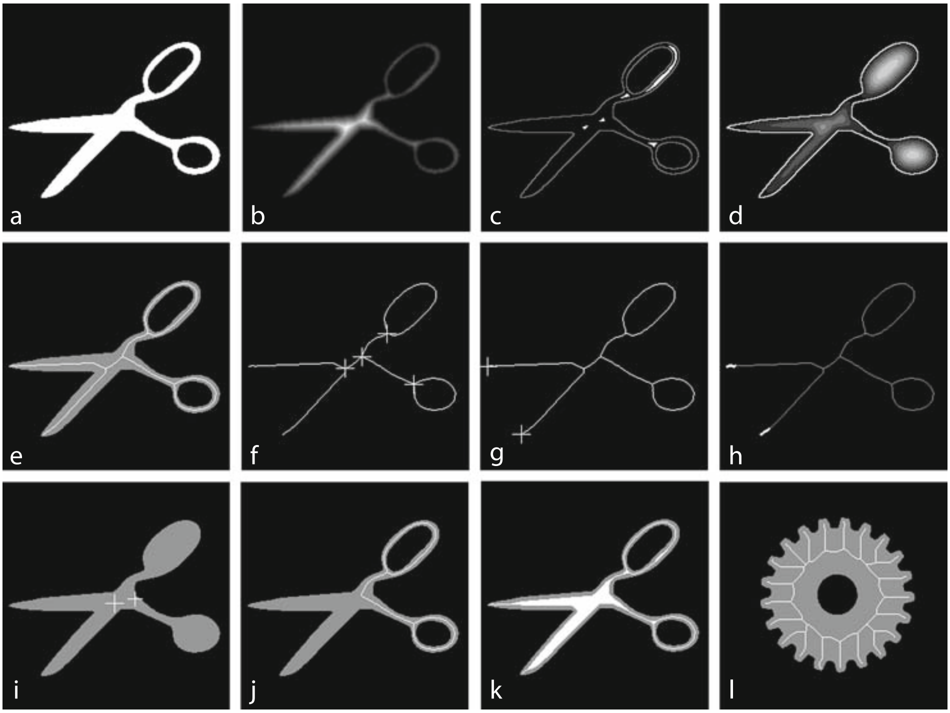

Fig. 19.23

Grass-fire, skeleton and thinning. (a) Original image. (b) Grass-fire transform after contrast enhancement. [QT: *gft, enc*] (c) Local maxima in the grassfire transform, detecte [QT: *gft, emx*] (d) The lakes have been filled in the original image. The grass-fire transform was then applied, followed by contrast enhancement and posterising. The outline after filling lakes is superimposed for illustrative purposes. [QT: *blf, bed, wri, gft, enc, sca(3), rei, mxi*] (e) Skeleton superimposed on the original scissors image. [QT: *thn*] (f) Skeletons joints [QT: *sbc(3)*. Function *jnt* incorporates skeletonisation.] (g) Skeleton limb ends. [QT: *sbc(1)* Function *lmb* incorporates skeletonisation.] (h) By repeatedly removing the limb end, the tip of the skeleton can be removed. The pixels that were removed by this process are shown in white here. This is the basis of the 'spur' removal operator. [QT: *spr*] (i) Shrinking when there are lakes present retains a single point for each blob that was part of the original blob. (*left-most* cross) [QT: *blf, shk*] The centroid (*right-hand* cross) may not lie within the original blob. (j) Shrinking when there are lakes present. A binary object with lakes shrinks to a series of inter-connected rings. Each ring is halfway between a lake and the outer boundary nearby. The Euler number remains unchanged. [QT: *shk*]. (k) Partial thinning. Skeletonisation is performed by thinning recursively, with rules to prevent 'breaking' the figure (i.e., altering the Euler number). Notice that the skeleton is already visible in places. [QT: *thin(5)*] (l) As it is currently implemented skeletonisation (MATLAB: *bwmorph* with the *'thin'* option; QT: *thn*) does not preserve Euclidean distance. Hence, the skeleton of the gear is not circularly symmetrical

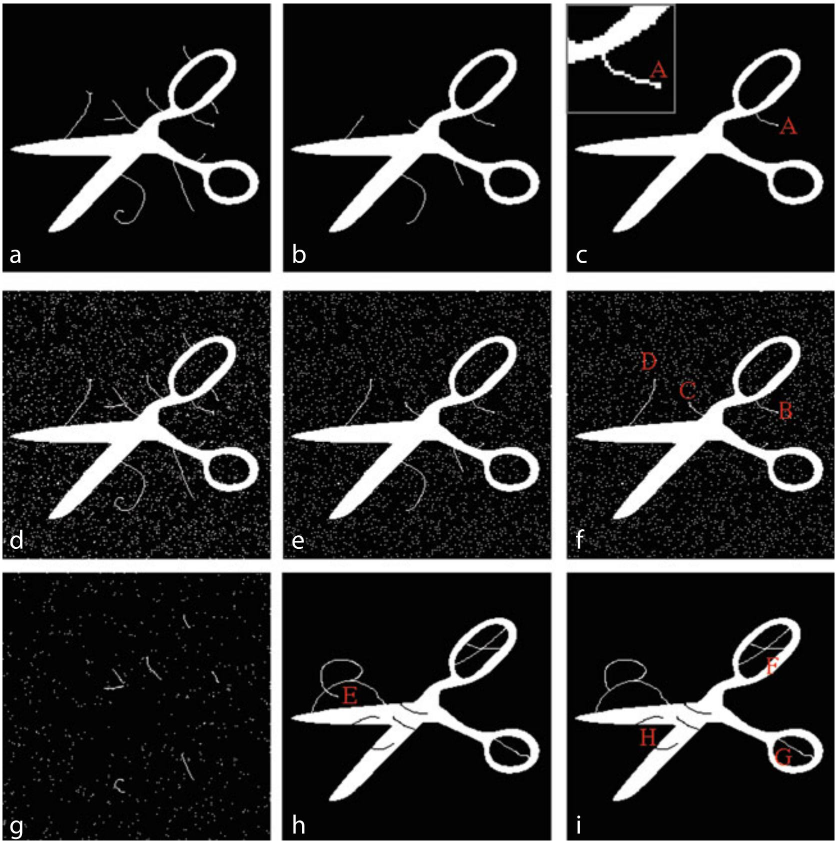

Fig. 19.24

Removing 'hair' and 'spurs'. A hair is a set of pixels forming a 1-pixel wide arc or line. (a) Original image (Hairs were drawn manually, using Photoshop®.) (b) Removing 25 pixels is insufficient to eliminate all hairs entirely. (c) All hairs have been removed. The algorithm will not remove any more pixels from this point on. Notice that one strand (A) remains because its end is not 1 pixel wide. (See inset) (d) Another original image, with noise superimposed. (e) After removing 25 pixels, some hairs remain. (f) The algorithm has terminated as in (c). Notice that B remains for the same reason as A. Removing the hair end pixels stopped prematurely at C and D because noise increased the strand width locally. (g) Differences between (d) and (f). Noise pixels have been removed where they constituted part of short hairs in the background. (h) A third original image. Notice the 'cracks'. (Hand drawn) (i) The algorithm does not affect the cracks (H) nor the loops (F, G), once the tail E has been removed

('cracks') can be eliminated by closing. Hair removal is illustrated in *Fig. 19.24*. Elimination of spurs is possible either by opening or recursive removal of limb ends.

Thickening Thickening is a recursive dilation process, with rules to stop locally when doing so would remove all evidence of a black region. Thickening is, of course, related to dilation, as thinning is to erosion. *Figure 19.25* illustrates thickening in the presence of noise.

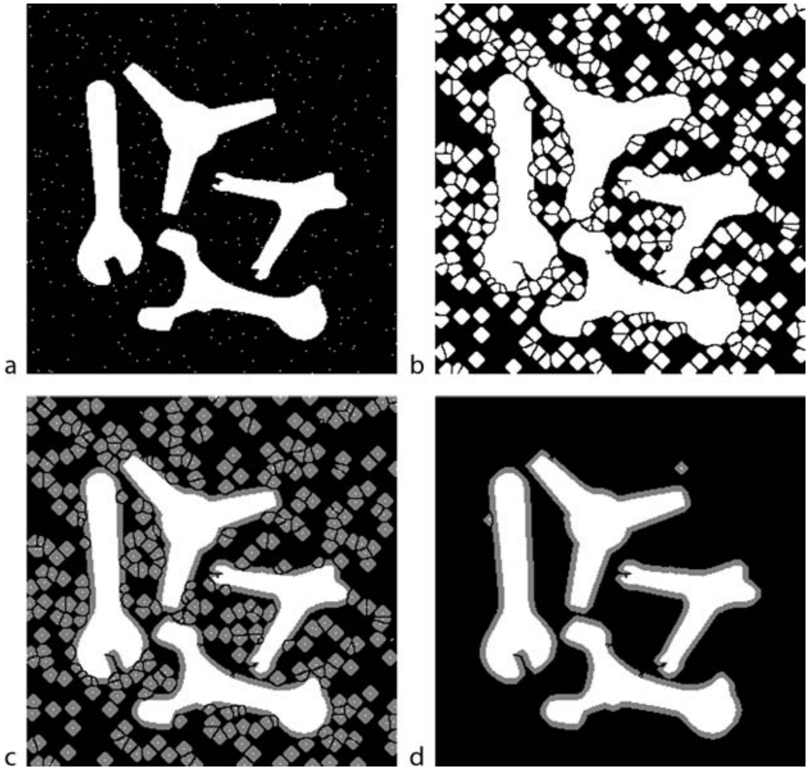

Fig. 19.25
Thickening. (a) Original image. (b) Result of thickening. (c) Thickened image superimposed on the original. (d) Most of the noise spots have been removed, by eliminating single isolated white pixels. [QT: *cln*] The result is improved but still imperfect, showing that thickening is very sensitive to background noise

Watershed Imagine a set of small white spots in a digital image. The watershed function places a 1-pixel wide mesh in the output image surrounding each blob. *Figure 19.26* illustrates this and compares the watershed with ultimate thickening, applying the function recursively until no further changes take place.

19.8 Applying Morphology to Practical Tasks

So far, we have described the binary morphological functions without discussing possible applications. It was necessary to do this because practical inspection task are rarely solved with just one key function. Now that we are properly equipped with a set of tools we can begin to consider the important question of how we use these techniques to solve useful problems. One important point emerges repeatedly: algorithms involving morphological operators cannot be designed without effective experimentation. Often, we find that the higher-level functions are best regarded as combinations of low-level functions that are selected separately. This even applies to opening and closing. If we start by thinking that we should use opening, we might

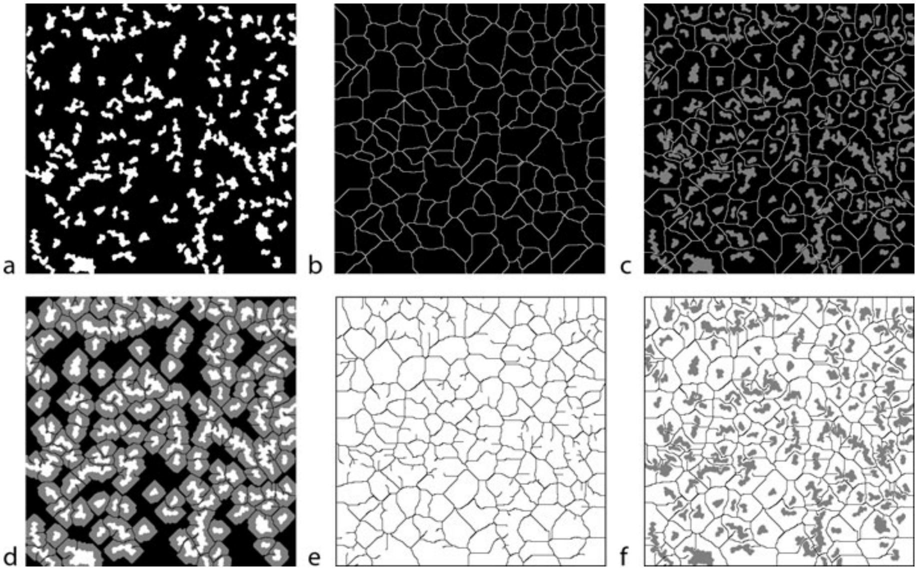

Fig. 19.26
