Watershed and thickening. (a) Original image, generated by smoothing and thresholding an image created by a pseudo-random number source. (b) Watershed. (c) Watershed superimposed into the original. (d) Thickening by a limited number of pixels. (e) Thickening until there are no further changes. Notice the presence of 'spurs', which are not generated by the watershed operator. Also, notice that the 'cells' are not quite the same shape by watershed. All pixels within a given cell surrounding an input blob B see a member of B as closer than any white pixel not in B. (f) Thickened image superimposed on the original

miss this opportunity of using SEs of the same shape but slightly different sizes for erosion and dilation. It is important that a vision engineer remain mentally free to improvise, so that he can devise novel combinations. Some of these, such as erosion with a circle SE and dilation with a cross SE might be entirely novel.

19.8.1 Optical Character Recognition (OCR)

OCR cannot be solved by a simple algorithm! There are many different and interacting design aspects that must all be considered when building a practical machine to read text. It is not possible in the space available here to do more than outline a few of the concepts. The obvious way to read printed text, that is *self-evident* to every lay person, is to compare each printed symbol to a series of masks exemplifying every possible member of the character set (letter, digit, punctuation mark, arithmetic symbol, etc.). Finding the 'best fit' mask effectively identifies the character. Easy? Wrong! Practical experience, by many researchers, over many years, has show repeatedly that this 'obvious' technique for OCR does not work with sufficient accuracy. It is far too sensitive to print imperfections.

Figure 19.27 illustrates one possible alternative, which is clearly akin to the 'obvious' method just dismissed. A thinned version (skeleton) of a 'good' character defines the

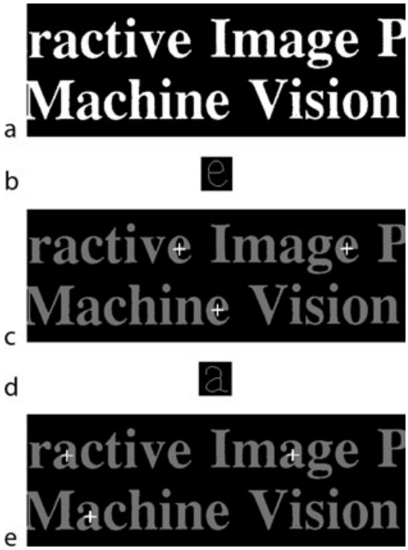

Fig. 19.27

Using erosion to detect characters in printed text. This technique is not normally robust enough for use in practice, since it is very sensitive to character size, orientation, font and print quality. (a) Original binary image. The upper case '*M*' is 84 × 67 pixels. Notice how 'clean' the printed characters are. This would not normally be the case in a practical OCR application. (b) The structuring element for detecting 'e' is the complete skeleton of that letter. (c) Erosion results in an image containing just three small white blobs. The centre of each of these blobs is indicated here by a cross. (d) The structuring element for detecting 'a' is the skeleton of that letter. (e) Erosion correctly identifies each occurrence of 'a'

structuring element, which is then used for erosion. Clearly, the skeleton retains the overall shape of the character but is not so demanding in requiring an exact fit around the edges, which always appear ragged when viewed under high magnification. While it looked promising initially, this second approach to OCR is still not reliable enough.

Figure 19.28 suggests that using a simpler SE might be effective. In this case, features such as skeleton limb ends, joints, simple curves, ɜ and (, etc. could be identified. Of course, the smaller SE is not as selective as we might like. So, it will probably be necessary to combine the decisions of two or more smaller erosion processes using different SEs. We might, for example, combine the results from five different SEs to identify an upper-case letter 'A': apex, left-T, right-T, left-limb-end, right-limb-end. If we obtain a 'hit' for each (or most) of these on the same character, then we can reasonably deduce that the character is an upper case letter 'A'. This approach is likely to be more tolerant than using the complete skeleton as an SE, because two small SEs used separately might fit in slightly different relative positions on different occasions. When they form part of a larger SE their relative positions are fixed. *Figure 19.28* clearly represents nothing more than a promising start. The complex process of reading English text requires our working with a character set containing 70 members, or more. We may be able to 'reuse' some SEs to identify different characters but it is clear that OCR is far from straightforward for even a single type font, style (*italics*, **bold** and regular) and size.

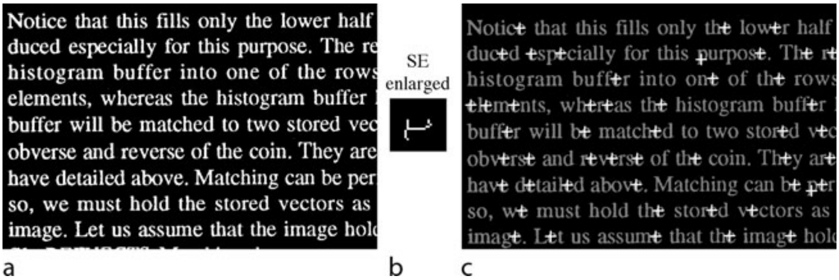

Fig. 19.28

Using erosion to detect specific features rather than whole characters. (a) Original binary image. The upper case '*M*' is 27 × 23 pixels. (b) The structuring element is shown enlarged (4x) for clarity. (c) The centre of each blob remaining after erosion is indicated by a cross. Erosion has identified each occurrence of 'e' but mistakenly detected '*p*' twice

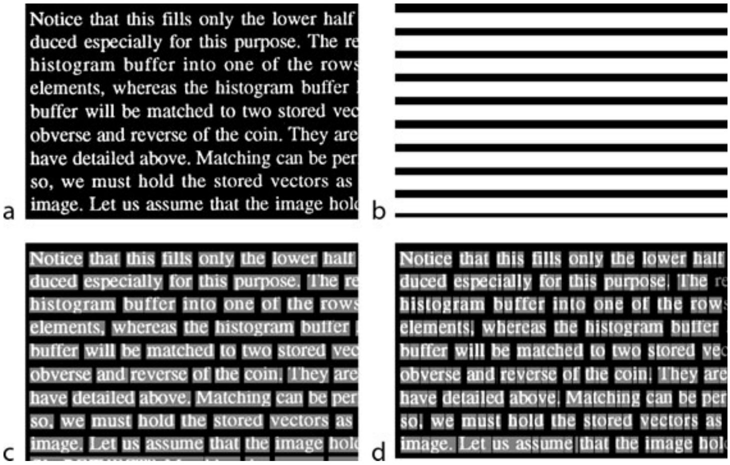

Fig. 19.29

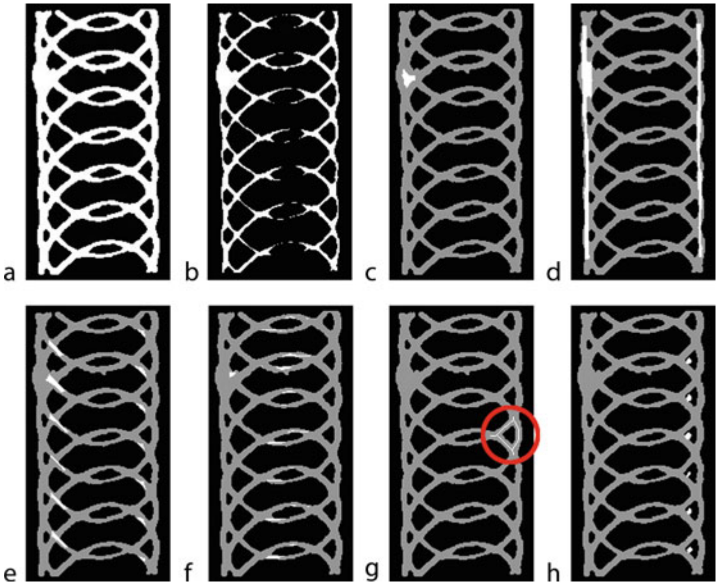
Segmenting text. (a) Original image. (b) Identifying lines using row integration. Row maximum is more sensitive to isolated white pixels originating from noise, or dirt on the printed page. [QT: *rin, csh, thr, dil(7), wri(1)*] Another possibility it to use a procedure based on erosion, with an SE in the form of a long horizontal straight line. This will work better than row integration [QT: *rin*], if the printed text is not aligned exactly with the image axes (i.e., camera axes). (c) Isolating words, using dilation. [QT: *rei, x = cse(1,5); gbd(x); y = cse(2,30); gbd(y), rei(1), mni; gbd(y), rei(1), mni*] Image file (1) is the image saved in (b). (d) Isolating letters, again using dilation. [QT: *rei, y = cse(2,30); gbd(y), rei(1), mni; gbd(y),rei(1), mni*]

Figure 19.29 shows that lines of text, words and individual characters can all be recognised. These are useful prerequisites for successful OCR, as is the early identification of the font, size and style. Although character separation is not perfect in *Fig. 19.29d*, the 'errors' seem to be reasonable, as closer examination shows that they occur where adjacent letters are connected. (Errors in the bottom line of text are due to edge effects.)

19.8.2 Inspecting Cake Decoration Patterns

The cakes illustrated in ➋ *Figs. 19.30* and ➋ *19.31* are sections of indefinitely-long strips that are cut transversely into fingers, and fed in large quantities to lucky little monsters, called children. Clearly, cake inspection does not require the level of precision needed for machine parts; general trends in the constantly-varying appearance are all that is needed. Thinning and thickening of the icing (frosting) pattern are important issues, as are major discontinuities and the misplacement of the pattern relative to the cake body. These two figures show that useful information about factors such as these can be obtained through the use of simple morphological preprocessing. Remember that, at any given moment, the nature of the particular product being made is known, so the ideal form of the decoration pattern is too. The ability to look for specific features, such as the 'ellipses' in ➋ *Fig. 19.30* or the 'tear-drops' in ➋ *Fig. 19.31*, is valuable. Simply counting 'tear-drops' or 'cross-overs' (X) (➋ *Fig. 19.31*) in a given length of cake strip is a useful inspection function but would probably need to be augmented by imposing other criteria.



◘ Fig. 19.30

Erosion applied to a cake decoration pattern. Erosion, plus basic measurements, such as the Euler number [QT: *eul*], or the number of distinct white objects [QT: cbl], may suffice as the basis for a simple inspection algorithm. (a) Original image. Euler number = -30. Blob count = 1. (b) SE is a square of 5 × 5 pixels. [QT: *ero(2)*] Euler number = 0. Blob count = 17. (c) SE is a circular disc of diameter 13. [QT: *rei, x = cse(14,7); gbe(x), adi*] (d) SE is a vertical line of length 30. [QT: *rei, x = cse (2,30); gbe(x), adi*] (e) SE is a diagonal line of length 25. [QT: *rei, x = cse(3,25); gbe(x), adi*] (f) SE is a horizontal line of length 30. [QT: *rei, x = cse(1,30); gbe(x), adi*] (g) SE (white object, circled in red) defined by manually selecting part of the 1-pixel wide 'skeleton'. [QT: *thn*] (h) Erosion using the SE in (g)

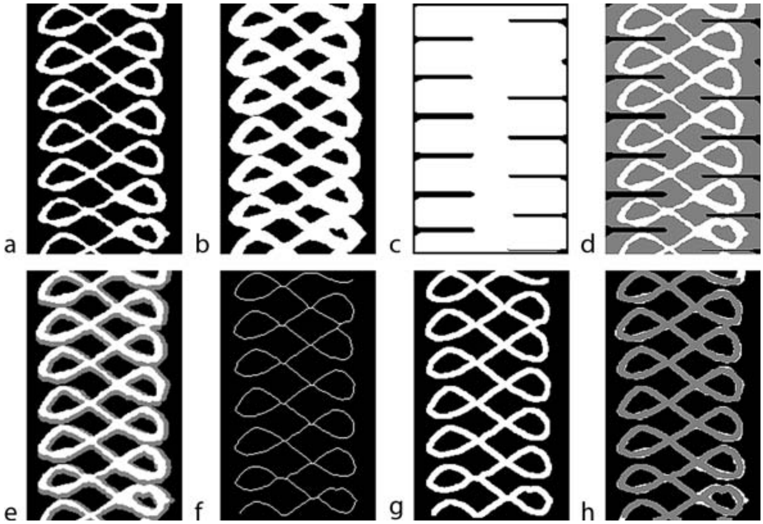


Fig. 19.31
Dilation applied to another cake decoration pattern. (a) Original image. (b) The SE was a solid disc. Notice that the number of lakes and the Euler number have changed. (c) The SE was a long horizontal line. (d) Original image superimposed on the previous image. Notice that this can be used to detect the closure of the gap near the top-right corner. (e) SE was an inverted L. The output consists of the union of the grey and white regions. Notice that dilation with this SE is non-isotropic; it extends the white regions only to the right and downwards. This has no obvious use in this particular application. (f) Thinned version of (a) with spurs removed. (g) Dilation of the previous image using an SE in the form of a circular disc. (h) The previous image compared to the original. This emphasizes the regions where the pattern is too thick

19.8.3 Counting the Teeth on a Gear

Three methods are demonstrated in ➲ *Fig. 19.32*:

- Top-hat
- Erosion, followed by a second stage of erosion. Then apply exclusive OR
- Bottom-hat

On the evidence presented in ➲ *Fig. 19.32*, all three appear to offer viable solutions. Further experimental investigation is needed to select the best one. ➲ *Figure 19.32d*, *f* and ➲ *i* each contains an array of spots, which can be counted rapidly using the Euler number, since they do not contain any lakes.

The author developed these algorithms interactively using the QT system. During this process, the conceptual units coming into his mind were simple *erosion* and *dilation*, rather than the higher level functions, *opening*, *closing*, *top-hat* and *bottom-hat*. This experience has been observed repeatedly during the preparation of this chapter. It is certainly easier to estimate appropriate parameter values and assess the results for the simpler functions when they are considered one at a time.

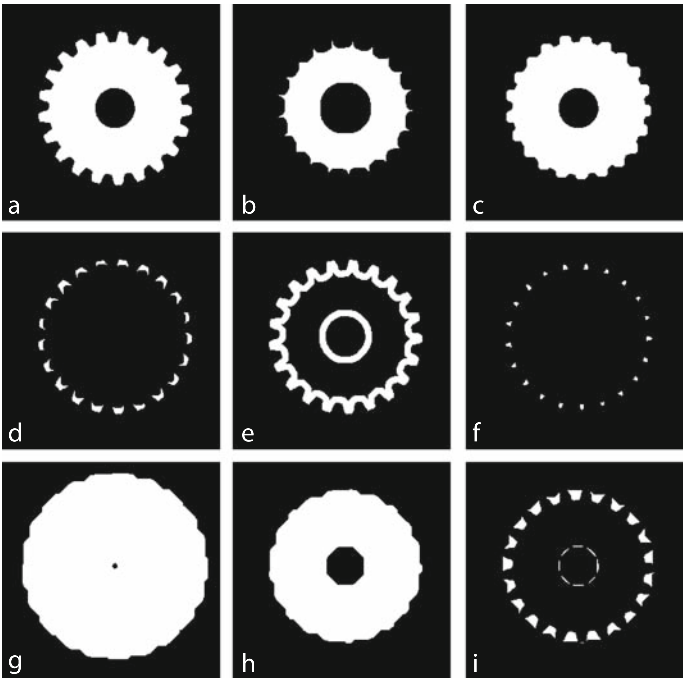

Fig. 19.32

Counting teeth on a gear. (a) Original image. (b) Erosion using an SE in the form of circular disc. (c) Dilation of the previous image using the same SE. (d) Exclusive OR of (c) and the original image. This implements the Top-hat function. To obtain a reliable result, it is probably necessary to dilate this image slightly before counting the blobs. (e) Another approach: Exclusive OR of (b) with the original. (f) Erosion of (e) with a small circular SE. (g) Dilation of the original image. (h) Erosion of the previous image using the same SE. (i) Exclusive OR of the previous image and the original. The large spots are the gaps between the teeth, not the teeth themselves. This implements the Bottom-hat function [QT: *wri, x = cse(14,19), gbd(x), wri, gbe(x), rei, exr*]

19.8.4 Inspecting Screw Threads

The principal features of a screw thread are:

- Shape of the crest
- Shape of the root
- Depth of thread
- Presence of debris
- Flank angle
- Pitch (number of threads/cm)

Morphology can be used for inspecting male (external) screw threads in several ways (➲ *Fig. 19.33*).

The crests and roots of the thread can be located using the top-hat and bottom-hat functions, respectively (➲ *Fig. 19.33b*). This task is similar to finding the tips of the teeth of

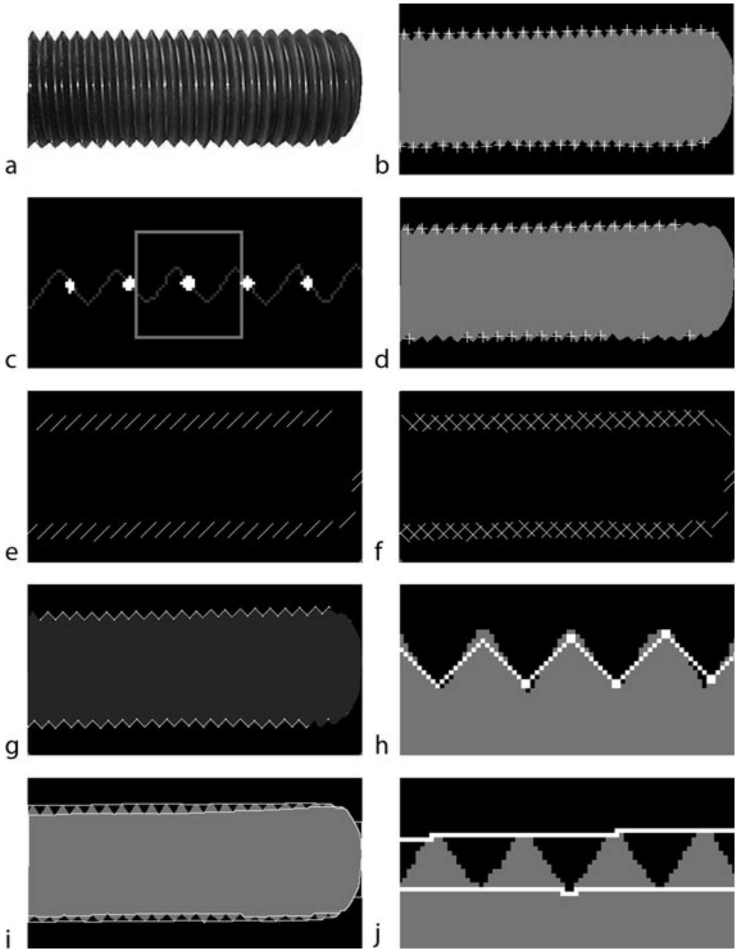

Fig. 19.33

Inspecting a male (external) screw thread. (a) Original grey-scale image. (b) Crests of the thread, detected using the top-hat function. (c) Checking thread form. (magnified view) A small part of the upper edge (1 pitch length) was selected to form the SE (grey rectangle). This was used for erosion on a slightly dilated edge. The white spots indicate the 'hits' over this small sample. [QT: *bed, dil(2), x = use; gbe(x)*] This test can be made more tolerant by increasing the parameter for the *dil* operation. (d) The centres of the spots retained after erosion are represented here by white crosses, which indicate where the thread form is *'acceptable'*. (e) Locating the '/' flanks of the thread. The QT command sequence to do this uses six different morphological operations. It was developed interactively and hence is impossible to fit it into one of the standard categories for morphological functions. [QT: *bed, u = cse(4,4), v = cse(4,5), w = cse(4,11), gbe(u), dil(2), gbd(v), shk, gbd(w)*] (f) Both flanks were detected, as just explained and the results merged. (g) The spurs in the previous image were removed and the result superimposed on the original. (h) Magnified view of the previous image. (i) The vertical positions of the crest tops and root bottoms were located using closing and opening respectively. The SE was a horizontal line whose length was just less than the pitch. (j) Magnified view of the previous image. The vertical separation of these white lines is a measure of the depth of the thread

a gear and can be accomplished using opening. Once the tips/roots have been located, it is a simple matter to count them over a known distance, to determine the pitch of the thread.

Checking the shape of the crest or root is easily accomplished using erosion with an SE derived from a ‘good’ thread. The SE was designed in the following way:

- The edge of the thread was computed. The result was a 4-connected curve 1-pixel wide.
- A small amount of dilation [QT: *dil(2)*] was applied to make the test a little more tolerant than it would be otherwise.

```
bed                   % Binary edge
dil(2)                % Dilate by a small amount. Call this image I.
x = use(0)            % Revert to a 1-pixel wide edge contour. Using the cursor, the user
                      % selects a ‘good’ section of the thread, to define the SE (x).
gbe(x)                % Erode image I (not the original) using SE defined by x.
```

The sensitivity of this method is reduced (i.e., made more tolerant of thread variations) by increasing the parameter given to the *dil* command.

Locating the flanks of the thread is performed in two stages. First, we locate the ‘/’ and ‘\’ flanks separately. The following algorithm was devised while working with the QT interactive image processing system.

```
bed             % Binary edge detector, produces a 4-connected edge contour
u = cse(4,4)    % First line SE (‘/’), length 4 pixels
v = cse(4,5)    % Second line SE (‘/’), length 5 pixels
w = cse(4,21)   % Third line SE (‘/’), length 21 pixels
gbe(u)          % Erosion, 1st SE. Detects the ‘/’ flank.
dil(2)          % Dilation, 3*3 square SE. Joins ‘broken’ flank edge contours, stage 1
gbd(v)          % Dilation, second SE. Joins ‘broken’ flank edge contours, stage 2
shk             % Shrink to single point
gbd(w)          % Dilation, third SE. Approximates flank with line at 45°. (Ideally, should
                % be the same as the nominal flank angle, which is known for each
                % thread type.)
```

The result is shown in *Fig. 19.33e–h*, while *Fig. 19.33i–j* demonstrates that closing with a horizontal line SE can be used to generate a polygonal contour spanning the tops of the crests. Similarly, opening can be used to draw an arc spanning the bottoms of the roots. The gap between these curves indicates the depth of thread.

19.8.5 Locating Holes and Other Features

Figure 19.34 shows how erosion with a ‘hollow’ circle SE can be used to locate holes of a certain size, while ignoring other features. Among the options for the initial processing are the grey-scale morphological edge detectors described later (Sect. 19.12). Notice that the binary image resulting from the edge detector plus thresholding is first dilated, to make the edges slightly thicker before erosion is applied. This makes the operation more robust in the presence of noise. Clearly, once the centres of the holes have been located, a robotic device can be

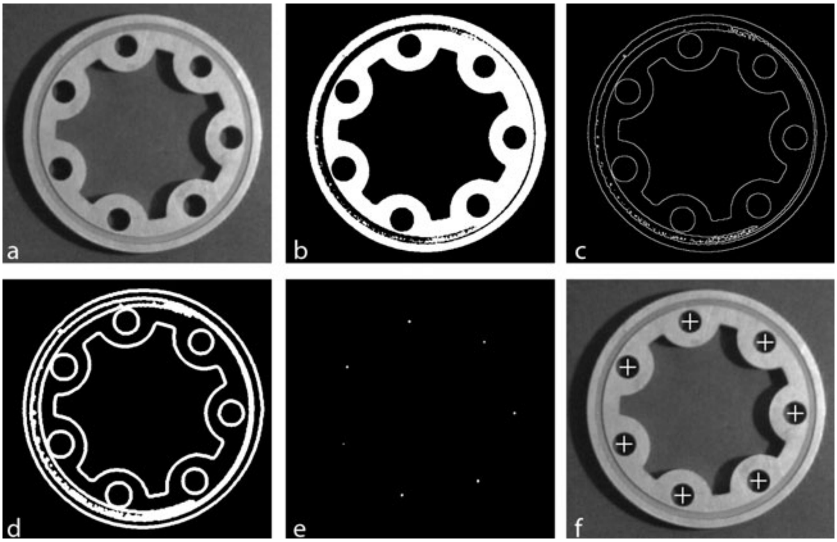

Fig. 19.34
Locating holes in a part of a Wankel engine. (a) Original image. (b) After thresholding. Deliberately, no attempt was made to make the lighting more uniform. (c) Binary edge detection, based on dilation and subtraction. (d) Small amount of dilation applied to make the edges thicker. This operation makes the procedure more robust. (e) Erosion using an open circle SE of about the same diameter as the round holes. (f) The spots in (e) were shrunk to single pixels and then dilated to form crosses. It is clear that these are close to the centers of the holes

directed to process the component in some way: pick up the component, tap its holes, fit an insert in each hole, etc. Here, as in many applications, the morphological operator is just one step amongst several others. Perhaps, it may be regarded the key *concept* but it must be seen as part of the overall solution, not as the whole solution. Hence, it is no more and no less important than the other parts of the algorithm.

➋ *Figure 19.35* is also concerned with locating holes, this time on an electrical power socket. In this instance, the solution involves a combination of operators and, once again, does not fit into any of the standard morphology categories.

As we have already seen, feature location is a key issue in many Machine Vision applications and we will pursue this topic a little further. ➋ *Figure 19.36* shows a thick-film circuit, which presents a complex binary pattern. In order to examine, or machine, a component like this, we must find some 'anchor points'. A frequently-used inspection technique involves comparing the test image to an image from a 'golden sample', or a model derived from one. These are then matched in some way, the details of which need not concern us here. The important task that we will address is that of feature location. As we have done before, the SE was derived from the image. A small sample may be taken directly from the 'golden sample' image, or as in this case, from a processed version of it. The vision engineer should use his best judgement to select a small region of interest with the cursor. In this application, it was necessary to apply a bit of judicious 'touching up', using PhotoShop™, to generate a 'clean' SE. This is totally appropriate, for example, when we know that the object under inspection is constructed with straight edges and 90° corners. In such a situation, it would not be justified to use a 'ragged' SE to search for

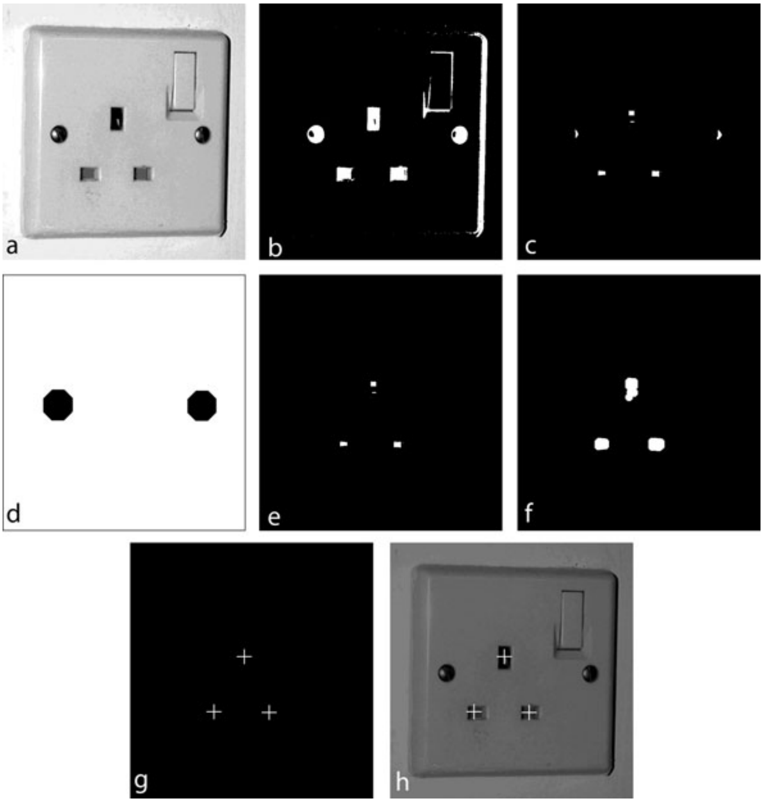

Fig. 19.35

Application requiring a combination of morphological operators. (a) Original image, British 240V/13A electrical power socket. (b) Threshold applied. (c) Erosion with solid square SE. (d) Erosion of (b) with open circle SE. The resulting image was negated, dilated using a solid circle SE and then negated. (e) Previous image was used to mask (c). (f) Dilation with solid square SE. (g) Shrunk to single pixel and then dilated with '+' shaped SE. (h) Result superimposed on the original. The following sequence of operations was disovered using QT. (There were a few short 'blind alleys' in the search tree and these have been removed for the sake of clarity.) [QT: *rni(original); enc; thr; type cse; neg; pxv; wri; x = cse(7,20), gbe(x); wri(1); x = cse(14,40), gbe(x); rei; x = cse(13,40), gbe(x); x = cse(14,40), gbd(x); neg; rei(1); mni; dil(3); swi; dil(7); swi; dil(11); shk; dil; crs(20); rni(original); swi; adi; mxi*]

features like these. The points indicated by crosses in *Fig. 19.36c* and *e* (not the crosses themselves) effectively form 'star maps'. The combined set of coordinate pairs representing points in these two images would form an ideal input for a Prolog program (Chap. 23). Such a program would align each test image with an image derived from a 'golden sample'. To do this, two 'star maps' should be matched. In some cases, when there is some noise or dirt, two such maps might contain different numbers of 'stars'. This is exactly the kind of situation in which Prolog excels. Feature detection using morphology and Prolog reasoning are ideal companions in the kind of application that we have just described.

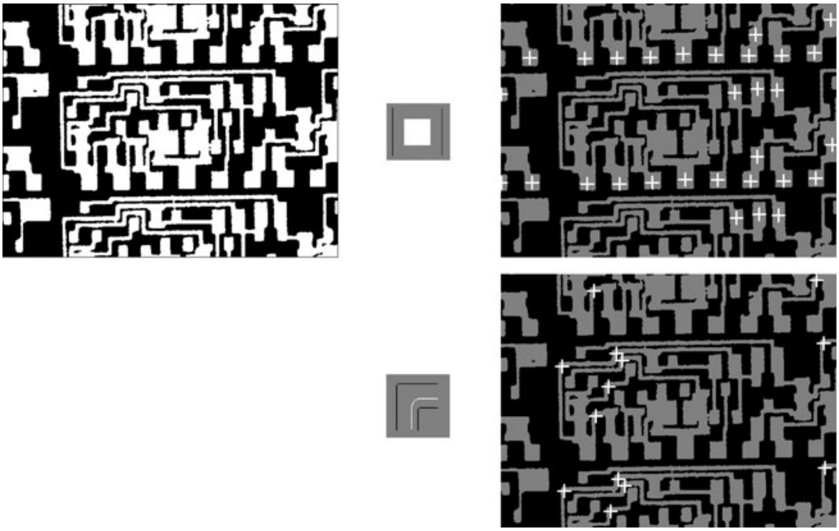

Fig. 19.36

Hit-or-miss. (a) Original image, thick film circuit. (b) Hit-or-miss requires two structuring elements: black: *se_x*; white: *se_y*. These refer to the SEs used in the QT command sequence given below and are designed to detect white rectangles that have no white pixels along two vertical lines beside it. (c) Hit-or-miss produced a set of small white blobs but these are not easily displayed at this resolution. For clarity, the centre of each of these blobs is represented by a cross. (d) Another pair of structuring elements, designed to detect the corners of thin vertical conductors as they 'turn right'. (e) Result. [QT: *rei('se_y'), y = strel(current); rei('se_x'); x = strel(current); rei, current = bwhitmiss(current,y,x), thr(1), shk, dil(2), crs(25), rei(original'), swi, adi, mxi*. Both *strel* and *bwhitormiss* are MATLAB functions]

Figure 19.37 demonstrates feature location on a bare printed circuit board. In 1978, J.A.G. Halle and P. Saraga [3] used morphology for this task, although this method of processing images did not yet have that name.

19.8.6 Colour Recognition

This topic cannot be covered in detail here and the reader is referred to Chap. 16 for further explanation and examples. *Figure 19.38a* shows the so-called *Colour Scattergram* and was derived from *Fig. 19.37a*. The details of how this is done are not needed here; *Figure 19.38a* is the starting point for what follows. Various morphological functions have been used in the preparation of the colour map:

- Dilation, to join disjointed spots that form a cluster
- Opening, to remove small white spots in the thresholded colour scattergram
- Closing, to join disjointed spots that form a cluster
- Majority filter, to eliminate very small spots
- Thickening, for limited colour generalisation
- Watershed, for extreme colour generalisation

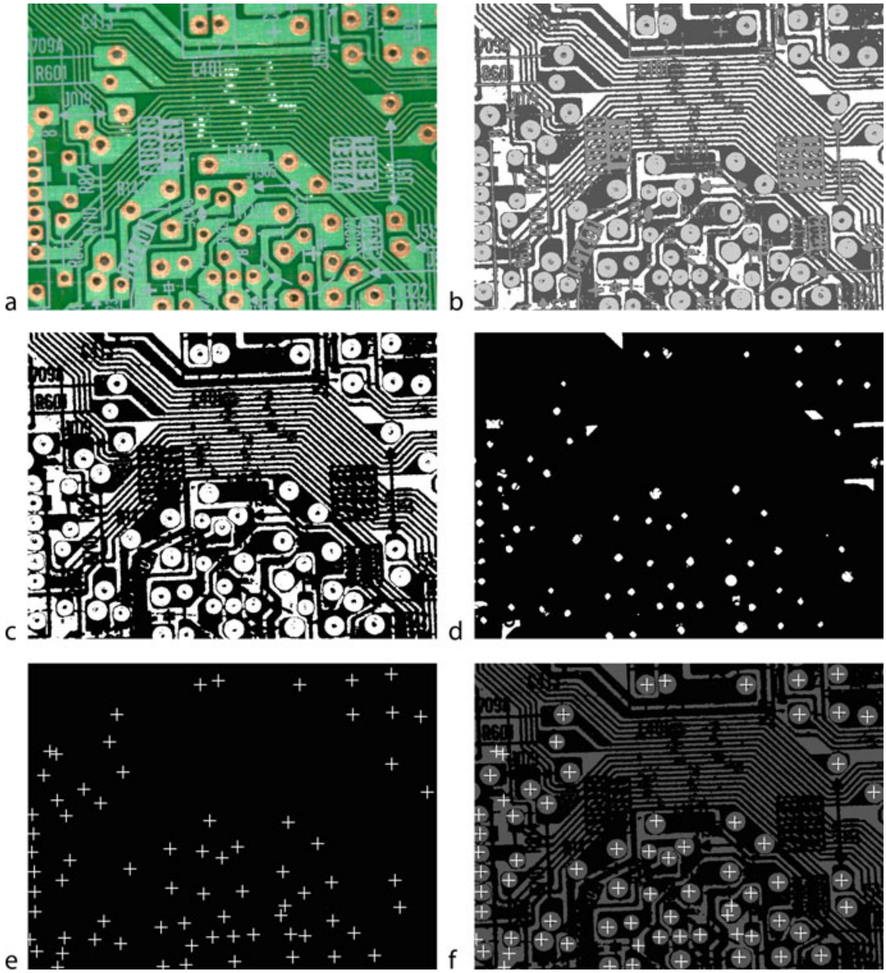

Fig. 19.37

Locating pads on a printed circuit board. (a) Original image. (b) Image segmented using a programmable color filter (*Fig. 19.38e*) and Chap. 16 (c) Thesholding of (b) distinguishes the copper conductors from the substrate. (d) Erosion with an open-circle SE was applied first. The size was about 80% of the diameter of the pads. The result was then ANDed with the negative of (c). Finally, a small amount of dilation was applied to merge small nearby blobs. (e) The blobs in (d) were shrunk to single pixels. Their positions are indicated here by the crosses. (f) Results superimposed on the original binary image, (c)

19.8.7 Texture Analysis of Binary Images

Texture analysis is a vexed subject, despite its importance in a wide range of applications, including automobile (paintwork), white goods (paintwork), ceramics (microstructure), timber (grain), food (cell matrix structure), etc. The reason is that *'acceptable'*, or *'normal'*, texture in a given application cannot be defined satisfactorily by rule, or formula. So, it is necessary to

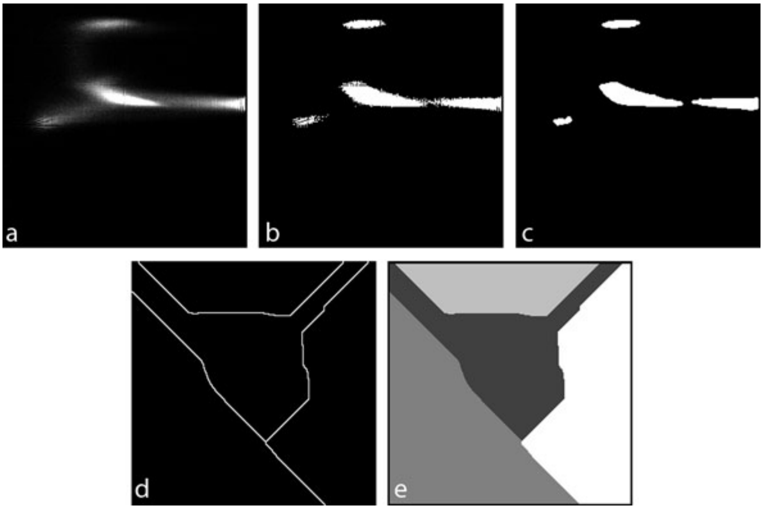

Fig. 19.38

Colour recognition using morphology for preprocessing. (a) Color scattergram of Fig. 19.38a. (See Chap. 16.) (b) Thesholding. Notice the ragged edges of the blobs and the small spots. (c) Majority voting filter. (d) Watershed. (e) Region labeling. This is the colour map which, when applied to Fig. 19.38a, produces the image in Fig. 19.37b (see Chap. 16 for details of the Programmabale Colour Filter)

learn from samples what a person labels as '*acceptable*', or otherwise. It may not be possible to collect a representative sample of '*not acceptable*' textures but it is usually possible to obtain a set of '*acceptable*' textures that is large enough to allow statistical, or Pattern Recognition, methods of analysis to be used (Chap. 24). In this brief section, we have a very specific objective: showing how morphological operators can be used to generate a multi-variate (vector) description of binary texture. Once such a data representation has been obtained, it can be applied to a Pattern Recognition system. *Figure 19.39* shows several examples of binary texture being transformed using different morphological operators. Simple measurements on the resulting images, such as blob count and number of white pixels, are affected in different ways by these operators (*Table 19.2*). The important points to note are

1. While it is easy to suggest a wide variety of texture measurements, the vision engineer should be prepared to invent novel combinations of erosion and/or dilation. Many morphological operators are quite fast in operation and several functions can often be performed together, with very little increase in computational effort. (See Chap. 19.)
2. Selecting which measurements are most useful is always difficult. So, aiming for a 'sufficient solution' is probably better than fretting about not being able to find the very best one.
3. Pattern Recognition, statistical and other data analysis programs can probably help in choosing a good set of texture descriptors but there is no point in ignoring human intuition and common sense.
4. If there is a strong directional component in the texture, then exploit it by using structuring elements that are aligned and others that are orthogonal to it.

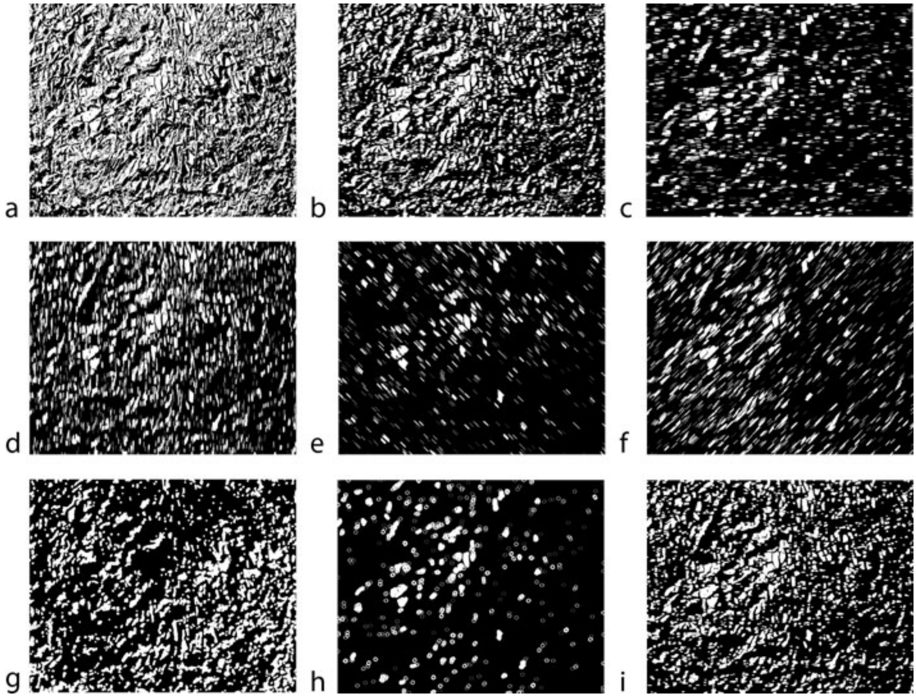

Fig. 19.39
Analyzing the texture of binary images using morphological operators. (a) Original image, thresholded so that 50% of the pixels are white. (b–i) Processing with eight different SEs. The details are given in *Table 19.2*

19.9 Recursion and Speed of Operation

In the discussion above, morphological functions have several times been described as recursive. We need to consider the implications of this, since the very mention of the word ‘recursion’ suggests that execution time is unpredictable. However, we can place some limits on the execution time. We will not, however, claim in absolute terms such as ‘*Function* $\mathbf{F}$ *with structuring element* S *can be performed in* T *seconds on an image containing* P *pixels*’. Instead, we shall show, in functional form, how T depends upon P and the size of S. First, however, we shall show why recursion is necessary.

Consider the task of thinning to generate a skeleton. It is clear throughout this chapter, beginning with *Fig. 19.12*, that erosion with a large SE eliminates thin white streaks, while retaining wide ones but leaves them slimmer than before. In order to generate a skeleton, fine control of the erosion process is needed. Let us now apply erosion repeatedly, using a small SE that on each cycle removes a 1-pixel wide object boundary (*Fig. 19.40*). Again, thin white streaks are lost, so we do not appear to be any closer to our objective. However, let us now modify erosion by adding a rule that acts locally to stop the process when the *next* erosion cycle would break the blob into pieces.

Table 19.2

Measuring texture using morphology. Notice that different sizes and shapes of structuring element produce varying blob count and white area values. We can combine these to generate a multi-variate description of the texture that can then be applied to a pattern classifier

Operation	Fig. 19.39	Structuring element (SE)	Size of SE (pixels)	No. of blobs	No. of white pixels
None (original)	(a)	Not applicable	–	2,614	7,40,341
Closing	–	Horizontal line (–)	5	2,467	6,64,893
Closing	(b)	Horizontal line (–)	10	2,557	4,85,489
Closing	–	Horizontal line (–)	15	1,952	3,24,627
Closing	(c)	Horizontal line (–)	20	1,365	2,07,498
Closing	(d)	Horizontal line (–)	25	8,59	1,29,194
Closing	(e)	Vertical line (–)	20	1,595	3,57,155
Closing	(f)	Diagonal line (\)	20	6,83	1,00,582
Closing	(g)	Diagonal line (/)	20	1,013	2,10,168
Closing + negation	(h)	Solid circle (●)	5	8,17	4,09,526
Closing + negation	(i)	Open circle (○)	20	1,465	1,22,150
Closing	–	Rectangle (✺)	10 × 5	965	4,16,043
Opening	–	Rectangle (✺)	10 × 5	1,364	38,580

Many papers have been written about skeletonisation. Here, we will state only that the desired result cannot be achieved using only the information from a 3 × 3 neighbourhood of the current pixel (➲ *Fig. 19.41*). The 3 × 3 neighborhood does not allow 2- and 3-pixel wide arcs to be distinguished, whereas the 4 × 4 neighbourhood does. Hence, they can be treated differently. Repeating this kind of analysis for stripes of all widths and orientations shows that the 4 × 4 neighbourhood, with the upper-left corner omitted, is sufficient to avoid fracturing, in all cases.

Floeder [4–6] showed that a single pass using the information from a 4 × 4 neighborhood is sufficient. ➲ *Figure 19.42* shows the seventy-eight 4 × 4 templates required by the Floeder algorithm, which performs one thinning stage in each pass. These templates distinguish between pixels that can and cannot be removed without 'breaking' the resulting skeleton. The Floeder thinning algorithm is simply stated thus:

- If the pixel is white and its neighbourhood matches one of the templates, then it is set to black.
- Otherwise, the pixel remains unchanged in the output image.

Various approaches and implementations are used for thinning and other high-level morphological functions by different researchers and equipment vendors. The SKIPSM implementation (➲ Chap. 20) [7–9] allows all seventy-eight of the Floeder templates to be tested in no more time than it takes to test one of them. (This remarkable fact is explained in ➲ Chap. 20.) For this reason, SKIPSM is likely to be one of the fastest implementations, when compared to others running on computers of comparable speed.

Now that we have established what each cycle of the thinning process requires, we can return to the calculation of timing the complete skeletonisation process. This can only be

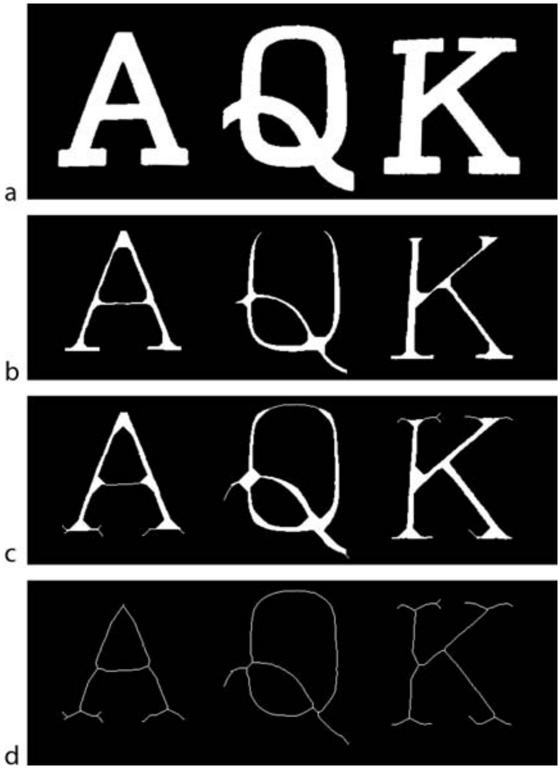

Fig. 19.40
Iterated erosion and thinning. (a) Original image. (b) Erosion after several cycles has already broken some of the white streaks. (c) Thinning has not broken any streaks. Thinning is not yet complete. (d) Skeleton is 1 pixel wide. Thinning this has no effect

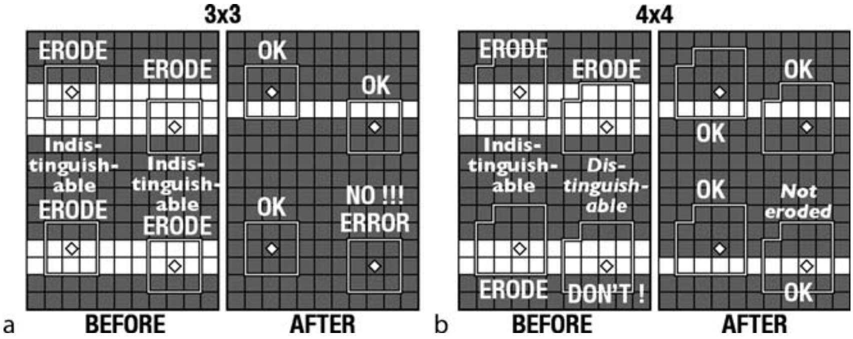

Fig. 19.41
Skeletonisation is impossible using a 3 × 3 pixel SE because there is no way to sense when to terminate recursion (a) SE: 3 × 3 pixels. (b) SE: 4 × 4 pixels with the top-left pixel omitted. Erosion is performed by scanning from left to right, top to bottom

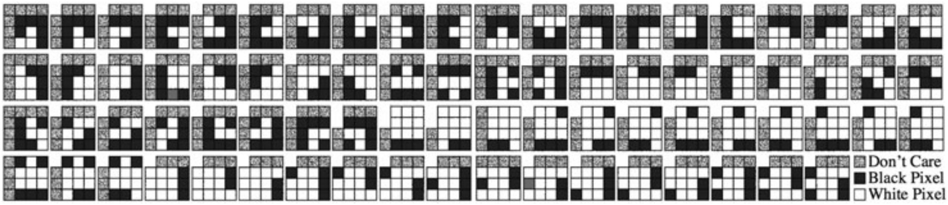

Fig. 19.42
The seventy-eight 4 × 4 templates used in the Floeder skeletonisation algorithm

answered by finding out how many thinning passes are required. On each cycle, a 1-pixel curve is removed all around the border of each blob. This will require *G* passes, where *G* is the maximum intensity in the grass-fire transform, to generate the skeleton. This is immediately apparent when we realise that these two functions are both built on erosion. (Notice that measuring G is a very simple task.) Let the image resolution be *M* × *N* pixels. For the SKIPSM implementation, the time to process each pixel is almost independent of the size of the structuring element. (Another remarkable feature of SKIPSM!) Denote this by L. Then, the time to reduce the image to its skeleton is G.M.N.L. For a square image, this simplifies to G.N^2. L. Notice that, for the SKIPSM implementation, thinning takes almost exactly the same time as erosion to process each pixel. So we are able to conclude that skeletonisation takes *G* times as long as a single erosion cycle. This parameter is measurable, using a simple test: the grass-fire transform. Notice that 'fat' blobs take longer to thin than 'thin' ones. The execution time depends on the square of the number of image rows/columns but is linearly dependent on G. If we study the same skeletonisation task at different resolution levels we must take note of the fact that *G* is proportional to *N*. So, the time to perform skeletonisation varies as N^3. This cubic dependence on resolution can make thinning, skeletonisation, thickening and watershed quite slow, so any speed increase that can be achieved by any means is welcome. SKIPSM greatly reduces the time spent processing each pixel (L) but the execution time is still proportional to N^3.

19.10 Hit-and-Miss Function

Structuring elements defined for erosion and dilation require only that some pixels be *white.* Any pixels in the processing rectangle but not in the SE are referred to as *'don't care'* pixels. It is an obvious conceptual extension to binary morphology to use structuring elements that contain *white*, *don't care* and *black* elements. An appropriate name for this is *Binary Template Matching*, but it is usually called the *Hit-and-Miss* function. The SE 'fits' the image at a particular position if and only if all of the white pixels *and* all of the black pixels in the SE are matched by corresponding image pixels. In that case, the output image is set to white. Otherwise, it is set to black.

Mathematical Definition: Let the K elements of the SE be denoted by $S_1, S_2, \ldots, S_K$. The values of the S_i are restricted to be either Boolean 1 (*white*), or Boolean 0 (*black*). (*Don't care* elements are not allowed as values for any of the S_i. They have no role in the definition of the algorithm. They are only defined so that the SE can be represented graphically, which is

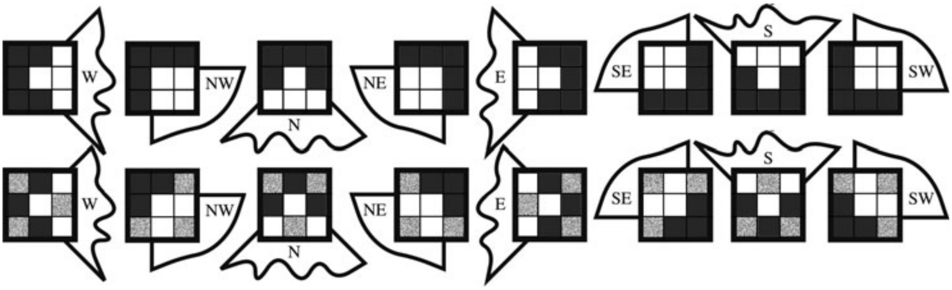

Fig. 19.43

The upper row shows 'exact' templates, and the lower row shows comparable templates with *don't care* pixels (speckled). The templates in the lower row are preferred as they produce a more robust corner detector when image noise is present. Structuring elements for detecting corners. (a) Allowing only white and black elements. (b) Allowing *'Don't care'* elements. These SEs produce a more robust corner detector in the presence of image noise

a significant conceptual aid.) As usual, let the K pixels of the input image covered by the SE be denoted by $a_1, a_2, \ldots, a_K$. Then, the Hit-or-Miss function is defined by

$$Output\_Image(i,j) = \{(a_1\ \ XNOR\, S_1)\&(a_2\ \ XNOR\, S_2)\&\ldots\&(a_K\ \ XNOR\, S_K)\}.$$

where XNOR (Exclusive NOR) is the logical operation with output Boolean 1 if its two arguments are the *same* and Boolean 0 if they are not the same. The above expression therefore gives a *white* output if all the image pixels match the corresponding SE elements, and *black* otherwise.

Noise template matching of any kind is susceptible to noise. As a result, some of the desired features may be missed. Performance in the presence of noise can often be improved by incorporating 'don't care' pixels. *Figures 19.43* shows 'exact' and 'don't care' versions of eight 3 × 3 SEs used to detect corners. *Figure 19.44* shows 'exact' and 'don't care' versions of four other larger (9 × 9 or 9 × 18) SEs that have successfully been implemented as fast, one-pass operations in SKIPSM [7].

19.11 Grey-Scale Morphology

Grey-scale morphology extends the ideas already discussed to grey-scale images. Familiarity with binary morphology will help in understanding grey-scale morphology. We will begin by looking at binary morphology in a different way. This far, our conceptual approach to processing binary images was as if we were looking at a map, in plan view. Images can also be considered as three-dimensional objects: the pixel locations define coordinates in the horizontal XY plane, while the image intensity determines the Z dimension. *Figure 19.45* shows a binary image and a grey-scale image represented in this way. The binary image has only two levels (0 and 1), so it looks like a 'mountain range' with sheer cliffs and flat plateau(s). A grey-scale image can take on intermediate values, normally with gently sloping 'hills and valleys'. In both cases, assume that the 'mountains' are hollow and that their surfaces are impenetrable by the SE, which is pushed up (for erosion) or down (for dilation). That is, the SEs can touch the surfaces but not pass through them.

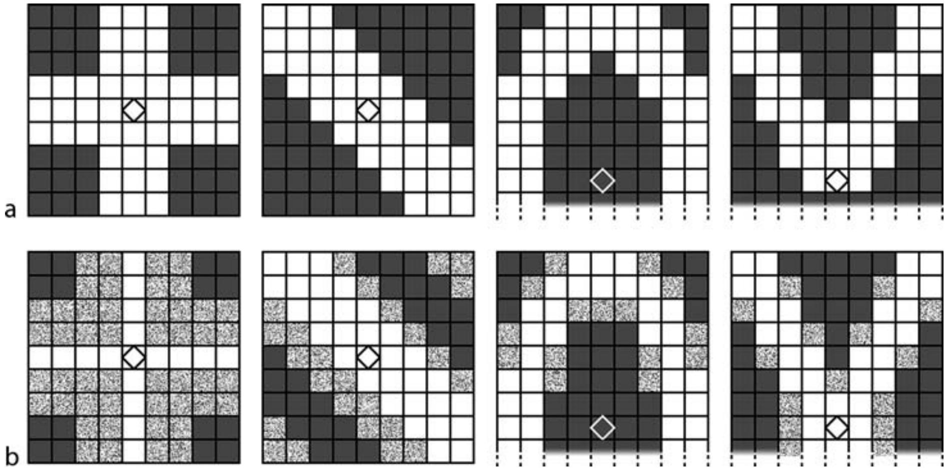

Fig. 19.44

Larger SEs. These have been implemented as fast one-pass operations in SKIPSM. (a) Allowing only white and black elements. (b) Allowing *'Don't care'* elements

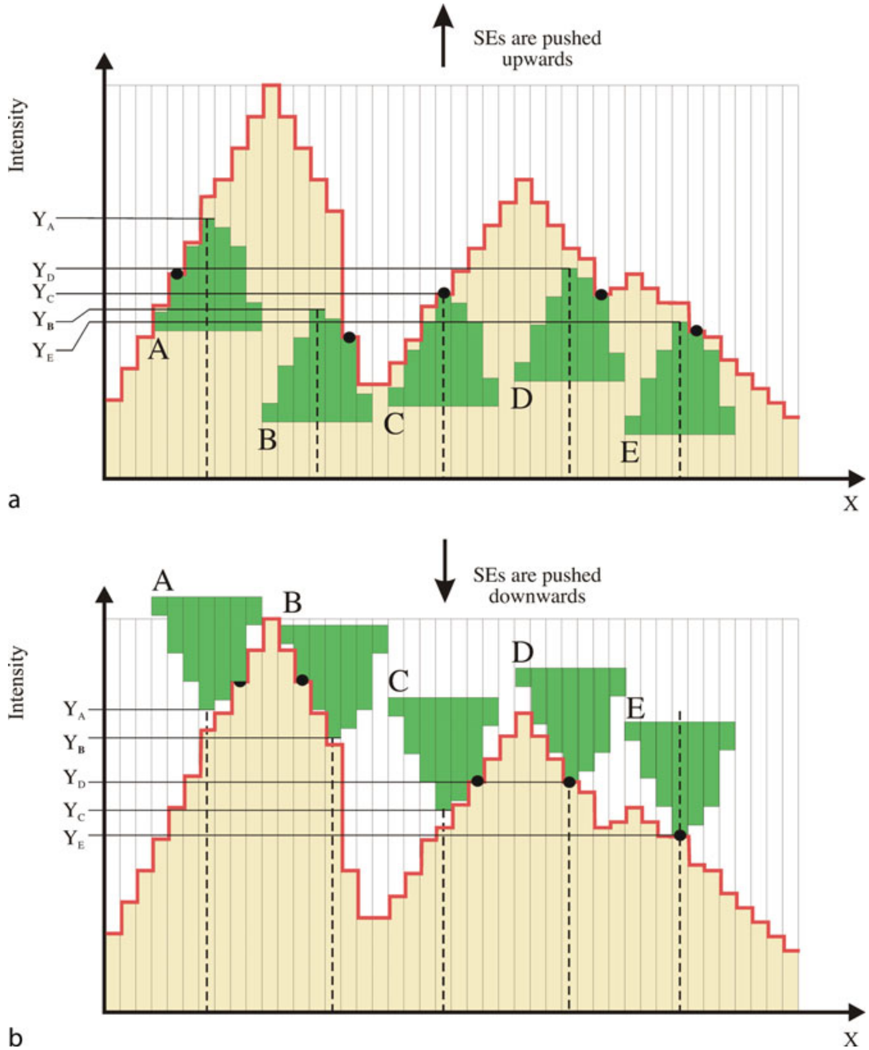
Fig. 19.45

Representing erosion and dilation as operations in three-dimensional space. For erosion the SE is pushed up. For dilation it is pushed down. (a) Binary morphology. The large grey cylinder (or mountain), representing a white blob on a black background, is hollow and has an impenetrable top for the SEs. (b) Grey-scale morphology. The sloping surface representing the intensity function of a grey-scale image is impenetrable for the SEs

Figure 19.46a shows that grey-scale erosion represented as pushing the SE up from the bottom, until it 'crashes' into the intensity surface, while *Fig. 19.46b* shows dilation as pushing the SE downwards. With this in mind, we see that grey-scale and binary erosion are similar, except that in the former case, the SE hits the intensity surface and usually stops somewhere between black and white. Notice, that grey-scale SEs may have flat or contoured tops. The output grey level of the morphological operation is defined by the height of the center pixel of the SE as it crashes into the intensity surface.



◘ Fig. 19.46

Grey-scale morphology represented in one dimension. (a) Erosion. At each position, X, the SE (green polygon) is pushed up as far as it will go, without any part of it crossing the intensity surface, represented here by the red line. At position A, the SE can be pushed up to height Y_A. Similarly, at position B, the SE can be pushed up to height Y_B and so on. The output is given by the sequence of Y values generated in this way. The small black circles indicate where the SE 'crashes' into the intensity profile. (b) Dilation. The SEs are pushed downwards

In regions of gradual intensity change and with these round-top SEs, the outputs for both erosion and dilation follow the input quite closely. Where the intensity gradient is larger, the differences between the outputs and the original are greater. Note that, for grey-scale erosion, the output value can never be higher than the intensity at the centre-pixel location in the original image but it can be lower. As we might expect from duality, the output from grey-scale dilation can never be lower than the original value.

As an alternative to this graphical way of visualising grey-scale erosion, we now present a mathematical expression for this operation and grey-scale dilation. It is similar in form to those for binary morphology, except that the function $\mathbf{F}$ is more complex.

As before, a_1, a_2, . . ., a_K are the values of the K input-image pixels in the neighbourhood defined by the SE at position (*i, j*). In the following definitions, g_1, g_2, . . ., g_K are positive offset values for the corresponding SE elements. These often span only a very small part of the available intensity range, [*black,white*]. Let

$$g_{max} = MAX(g_1, g_2, \ldots, g_K)$$

$$g_{min} = MIN(g_1, g_2, \ldots, g_K)$$

Then, erosion is defined thus

$$\text{Output\_Image}(i, j) = MIN((a_1 - g_1), (a_2 - g_2), \ldots, (a_K - g_K)) + g_{max}$$

and dilation as

$$\text{Output\_Image}(i, j) = MAX((a_1 + g_1), (a_2 + g_2), \ldots, (a_K + g_K)) - g_{min}$$

The higher-level functions for grey-scale morphology are defined in a similar way to binary morphology:

- Grey scale opening: dilation followed by erosion
- Grey-scale closing: erosion by dilation
- Grey scale top-hat: erosion followed by subtraction of the original
- Grey scale bottom-hat: dilated followed by subtraction of the original

We have not included grey scale hit-or-miss in this list because the concept of ‘don’t know’ has no meaning when dealing with grey-scale images. Instead, use the term ‘*ignored*’, which applies to all of the other grey-scale operations as well.

19.11.1 Building Grey-Scale SEs

Suppose we wish to ‘borrow’ a segment of a real image in order to construct a grey-scale SE for erosion (or dilation). One simple way to do this is to copy a small area of that image to define the SE’s values directly. To do this, it would normally be convenient to take a rectangular sample S of the image to define the SE. That is, we use the intensity values of pixels within S to define $\{a_i \, | i \in S\}$. However, we might be interested in using only a subset of *S* to define a smaller SE. We can adjust some of the offset terms, {g1, g2, . . .} so that they will be ignored by the MIN function. Let $S' \subset S$ denote the set of pixels we wish to use in the SE and $S'' = (S \sim S')$ those that we wish to ignore. An SE using all members of S will produce exactly the same result as one using only members of S' if we choose the values for the gi as follows:

```
for $i$ = 1:K
    if $i \in S'$
            $g_i = 0$    % Pixel $i$ is ‘wanted’ & will be not be ignored
    else
            $g_i = -W$    % W = white level. Pixel $i$ is ‘unwanted’ & will be ignored
end
```

Rather than using S' to define the SE, we use S and give the offset parameters for 'unwanted' pixels (i.e., $\{g_i \mid i \in S''\}$) some large negative value. Terms such as $(a_i - g_i)$ where $i \in S''$ will then be ignored by the MIN function.

Why should we deliberately make the SE larger? It is easy to select a rectangular region of an image to define the set S. We can then 'switch off' certain elements by setting the gi appropriately. This can all be done interactively, using only the computer mouse and hence readily lends itself to experimentation. Of course, more computational effort is involved using S rather than S', so the SE would have to be redesigned for a target (factory floor) system. While this is not difficult, it can be tedious.

One word of warning is required: designing an SE by sampling an image allows its parameter values to become 'frozen' noise. For this reason, it may be necessary to make some manual adjustments. For example, pixels within a region of nominally constant intensity should generate equal a_i and g_i values.

SE terms can be ignored in grey-scale dilation by giving the appropriate g_i offset parameters large positive values.

19.11.2 Examples and Uses of Grey-Scale Morphology

➲ *Figure 19.47* shows how grey-scale erosion can be used to detect objects of a given orientation.

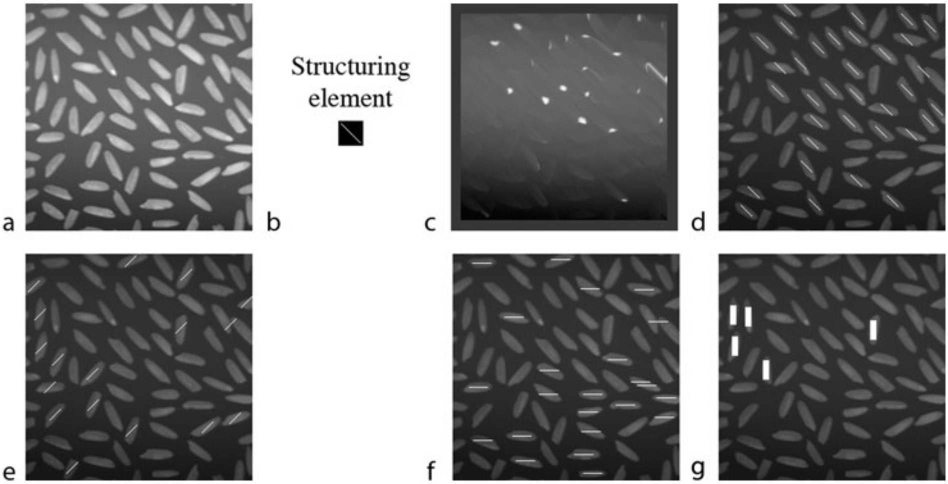


Fig. 19.47

Using grey-scale morphology to detect objects of a given orientation. (a) Original image, rice grains. (b) Diagonal line structuring element, 1 × 13 pixels. (c) Erosion. [QT: *x = gsk(3,13); gse(x)*] (d) The previous image was thresholded. The resulting white blobs were then shrunk to single pixels and (binary) dilated, using the same SE. Finally, the result was superimposed on the original. [QT: *thr(110), shk, gbd(se), rei(original), swi, adi, mxi*] (e) Same processing with the orthogonal diagonal line structuring element. (1 × 13 pixels) (f) Same processing, again. The structuring element was a longer horizontal line. (1 × 22 pixels) (g) Similar processing but with a rectangular structuring element (9 × 24 pixels)

➤ *Figure 19.48* shows that grey-scale erosion or dilation, followed by subtraction of the original, produces a very effective edge detector. The size of the SE determines the width of the edge produced. Line SEs can be used to detect edges at a given orientation. The point made in relation to ➤ *Fig. 19.20d* applies here: dilation produces an outer edge and erosion an inner edge.

The ability to detect cracks and other image features appearing as thin dark streaks using bottom-hat has been known for many years and predates the formalised approach now encompassed by Mathematical Morphology (➤ *Figs. 19.49* and ➤ *19.50*. Also see ➤ Chap. 27. The author discovered the 'crack detector' algorithm independently, using a precursor of QT.) Thin dark streaks that are known to arise in a given orientation can be detected most effectively using a line SE, rather than a rectangle or disc. Thin bright streaks can, of course, be detected by top-hat, or by negating the image before applying bottom-hat. The crack detector has been very successful in solving a wide variety of applications not involving cracks. One such application is 3D shape measurement by triangulation, using projected light stripes (➤ *Fig. 19.51*).

➤ *Figure 19.52* shows how a combination of grey-scale morphological operators can be used to locate simple patterns, such as hollow rings (pads on a printed circuit board). It is interesting to note that the SEs were successfully selected experimentally. It would be very difficult to design the SEs without the ability to try different ideas and see the results almost immediately.

Grey-scale morphology has a significant role to play in preprocessing. For example, textured images can often be enhanced in this way (➤ *Figs. 19.53* and ➤ *19.54*).

Noise in grey-scale images can be suppressed by opening (eliminates bright spots) and closing (eliminates dark spots). Use both to eliminate dark and bright spots (➤ *Fig. 19.19*).

The grass-fire and watershed functions can be used together to isolate objects that are just touching. ➤ *Figure 19.55* illustrates this on a binary image containing four objects. (The same four objects but isolated from one another are shown in ➤ *Fig. 19.25a*.) This is an important task since many objects are delivered for inspection, handling or machining in contact with one another. ➤ *Figure 19.56* shows how grass-fire and watershed have been used to segment a grey-scale image of cut cane ends.

19.11.3 'Frequency Response' of Morphological Filters

It is common practice to measure the frequency response of filters used for analysing time series. The same concept can also be useful when discussing image filters. However, morphological filters are grossly non-linear, so there can be no precise measurement of their frequency response (➤ *Fig. 19.57*). For this reason, we can only relate their behaviour to spatial frequency in an approximate way. Nevertheless, we can gain some useful insight by discussing frequency and wavelength. Remember that what follows in this section is merely an aid to understanding; it is not precise.

➤ *Figure 19.58a* shows an image in which the intensity varies as a sine-wave whose frequency varies along the horizontal axis. Such an image can generated using an equation of the following general form:

$$f(x,y) = 127.5 * (1 + \sin(2\pi k(a + bx))), \text{for all } y$$

Here, a and b are constants. This equation has been normalised so that the intensity $f(x, y)$ always lies in the range

$$0 \leq f(x,y) \leq 255$$

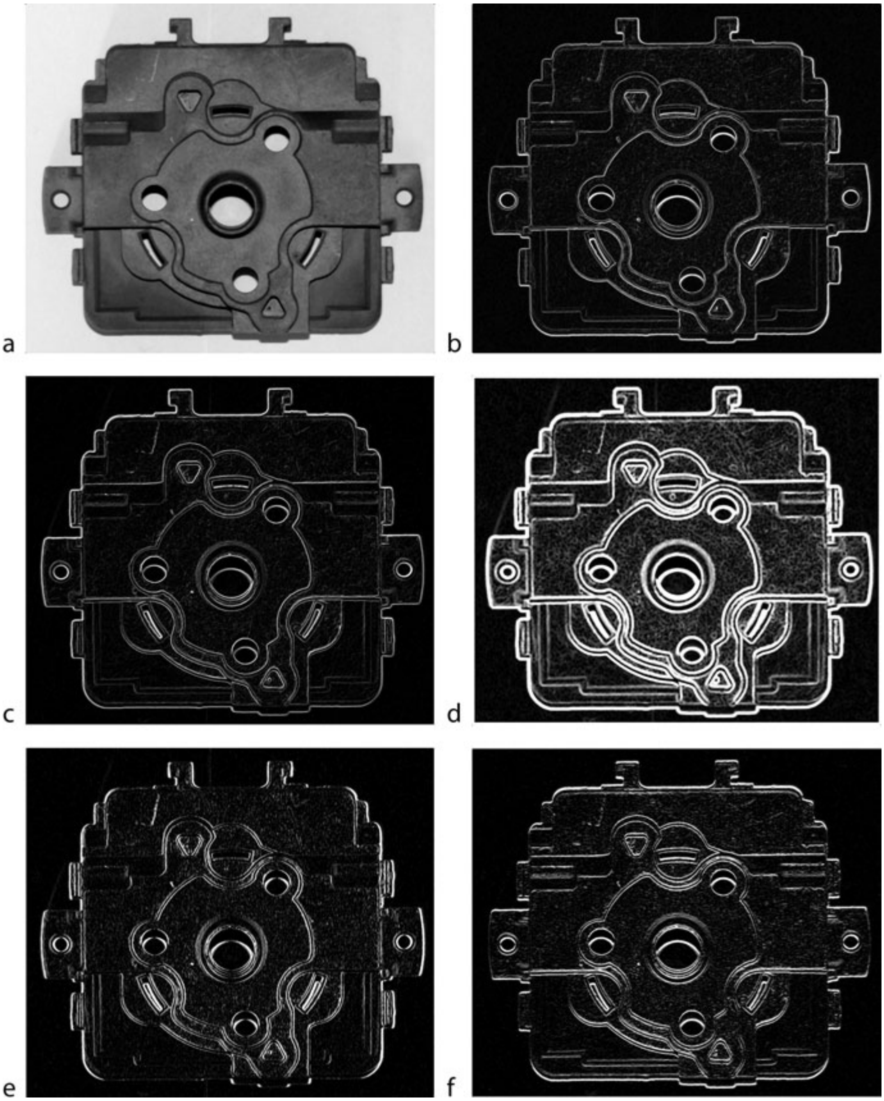

Fig. 19.48

Grey-scale edge detection. (a) Original. Zinc die-cast component. (b) Dilation, then subtract original. Circle SE. (e) Vertical line SE, length 13 pixels. (f) Vertical line SE, length 13 pixels. [QT: *wri, x = gsk(2,13); gsd(x), gse(x), rei, sub, edg(8,avg), enc*] (g) Median filter applied before closing. Vertical line SE, length 13 pixels. [QT: *mdf(7), wri, x = gsk (2,13); gsd(x), gse(x), rei, sub, edg(8,avg), enc*] (h) Previous image thresholded. Parameter selected manually. (i) Circle SE, diameter 9 pixels. (j) Circle SE, diameter 19 pixels

Applying grey-scale dilation to such an image, with a horizontal line structuring element of appropriate length, causes the stripes on the right-hand side to merge into a bright block (➋ *Fig. 19.58b*). While the bright stripes on the left do not merge, they do become narrower as a result of dilation. Applying grey-scale closing instead is not particularly helpful, since the bright block on the right remains bright (➋ *Fig. 19.58c*). Erosion creates a dark block on the right (➋ *Fig. 19.58d*). Adding the results of dilation and erosion creates a filter that approximates a low-pass filter (➋ *Fig. 19.58e*). Varying the length of the line SE alters the 'cut-off' frequency (➋ *Fig. 19.58f*).

Another way to express the same idea is that narrow streaks can be eliminated by a 'low-pass' filter, thereby differentiating them from wider ones. By subtracting the output of a 'low-pass' filter from the original image, we can produce a 'high-pass' filter. An example of this is shown in ➋ *Fig. 19.51*, where a series of light stripes have been projected onto the top surface of a loaf. Tracing the light stripes is a prelude to measuring its 3D shape. (This technique is called *Triangulation by Light Sectioning* and is described in ➋ Chaps. 14 and ➋ 41.) Notice that median filtering and majority voting are also used, for eliminating the effects of noise.

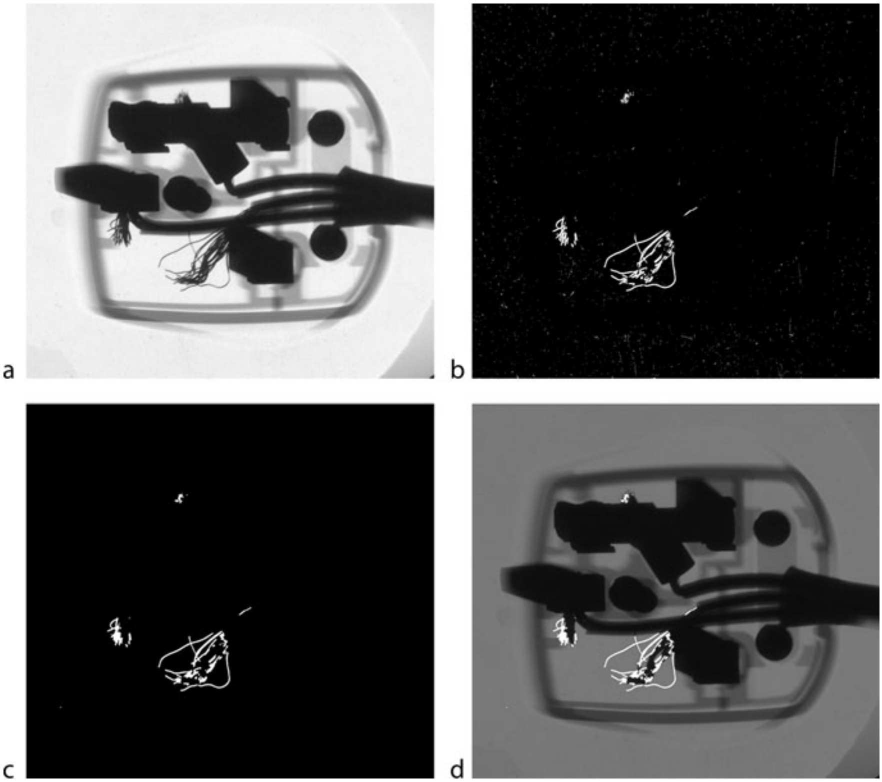

Fig. 19.50

Detecting thin dark streaks due to shadows of wires using grey-scale morphology. (a) Original image, x-ray of a domestic power plug (British design, 240V//13A). The loose strands of wire make this dangerous. Resolution: 1454 × 1336 pixels. (b) Grey-scale closing. [QT: *crk(5)*] (c) After removal of isolated white points [QT: *cln*] (d) Previous image superimposed on the original. It is not apparent in this printed image that the algorithm has correctly detected all individual loose strands and no other features

Interpreting the 1-pixel wide contours is not our concern here; let it suffice to say that some 'intelligence' is needed and may even require Prolog reasoning (Chap. 23).

So far, we have considered only 1D filtering. We can apply similar ideas to 2D patterns, perhaps filtering in quite different ways along the two image axes. We could, for example, apply a low-pass filter along one axis and high-pass filter along the orthogonal axis. To investigate the behaviour of a filter, it is helpful to devise a suitable test image. One possibility is shown in *Fig. 19.59a*. A variety of images of this general form, covering different frequency ranges along the image axes, can be generated; the reader must be prepared to exercise his imagination and judgement.

In *Fig. 19.59*, 'isotropic' 2D filters using simple rectangle and circle SEs are illustrated. *Figure 19.60* demonstrates non-isotropic filtering on the same test image. Notice the way that the various parts of the sine-wave pattern are blurred in different ways by these filters. The important lesson to be noted from these two figures is that test images can provide a valuable aid to understanding. When a rectangle SE is used (*Fig. 19.59b–h*), the two image axes can be processed independently and in either order, to obtain the same result.

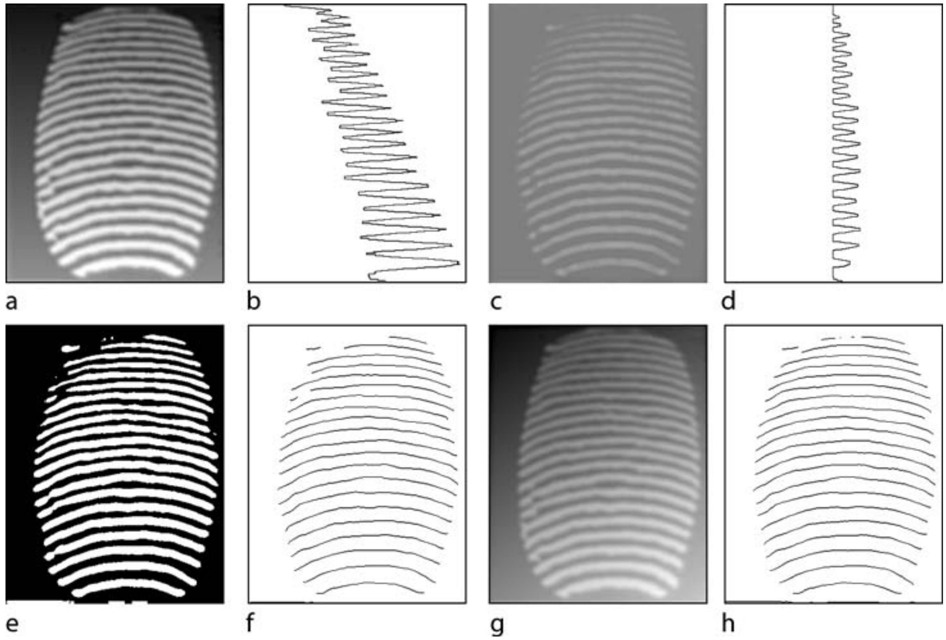

Fig. 19.51

Loaf shape analysis using grey-scale morphology. (a) Image contrived for this demonstration, using light sectioning and triangulation. A series of parallel light stripes was projected onto the top surface of a loaf. The camera viewed the loaf from a different angle. The resulting image had a high contrast and could be thresholded to produce a 'clean' binary image. However, this does not properly indicate the range of variation that can occur with other loaves that are over- or under-baked locally. In addition, variations of the intensity of the projected light stripes and ambient light make fixed-level thresholding unreliable. To demonstrate the effectiveness of the filtering better, an image whose intensity varies with vertical position was added. ('intensity wedge'; QT: *wgy*) (b) Intensity profile of (a). Notice that no fixed threshold could properly detect all of the peaks in this graph. (c) After median filtering and grey-scale closing with a vertical line structuring element of length 15 pixels. (The image has 325 × 415 pixels.) (d) Intensity profile of image (c). Although this has a low contrast, there is no variation of background intensity, so thresholding can be more effective. (e) After thresholding (c). The threshold parameter was selected manually but its value is not critical and does not depend on the light level. (f) Majority voting and thinning applied to the image in (e). (g) Another synthesised image, this time with vertical and horizontal wedges added. [QT: wgx, adi, wgy, adi]. (h) The processing just described was applied to (g). [QT: *wgx, adi, wgy, adi, mdf(7), wri; x= gsk(2,15), gse(x), gsd(x), rei, sub, neg, thr (a), maj, thn*]

This makes it easier to visualise what the filter does and to design one with characteristics that we desire. However, this is not the case for the circle and non-paraxial line SEs. Anticipating the results of some filters is less straightforward, making experimentation essential.

While it is easy to relate the behaviour of a simple morphological filter, albeit approximately, to the familiar concepts of time-series analysis, it also worthwhile remembering that

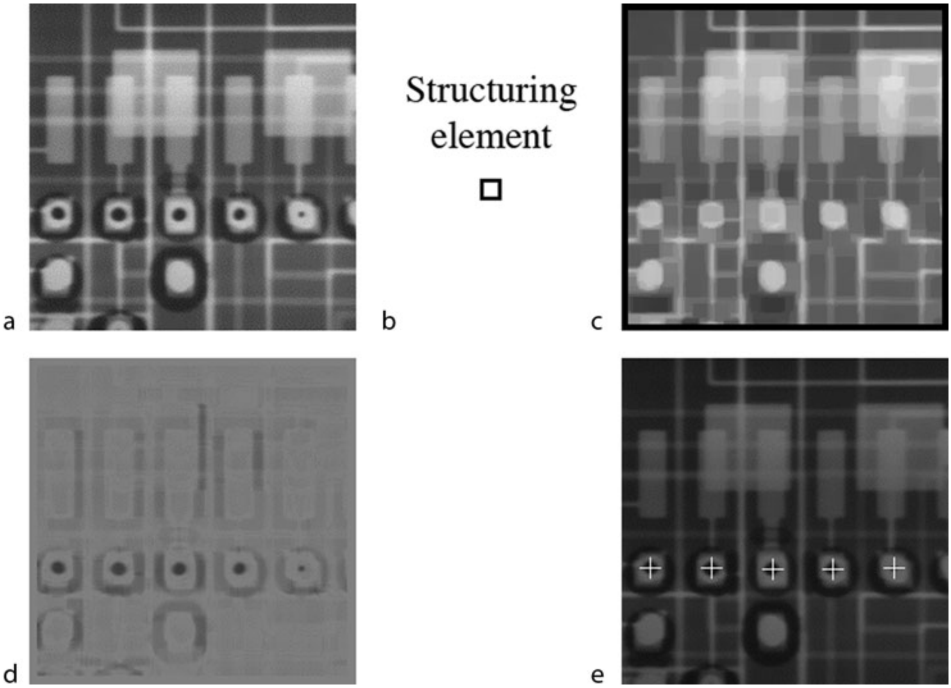

Fig. 19.52
Grey-scale closing (a) Original image, printed circuit board, imaged using x-rays. The grainy appearance is sensor noise in the x-ray system. (b) Structuring element: 11 × 11 pixel 'hollow' square. (c) Closing. (d) Subtracting (a) and (c). (e) Centres of the dark spots. The previous image was thresholded, then the resulting blobs were shrunk to single points and a cross was centred on each white pixel. [QT: *x = ones(11,11); gsc(x), sub, edg(6,128), thr(0,67), dil, shk, crs(8)*]

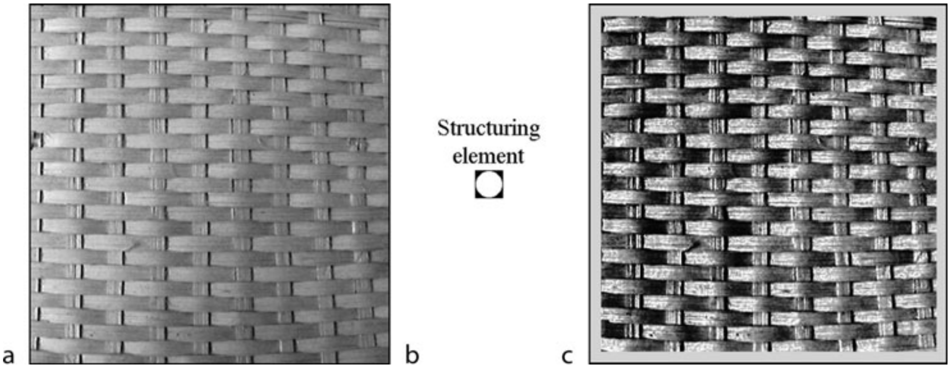

Fig. 19.53
Grey-scale morphology used to enhance contrast. (a) Original image. Rattan cane webbing for furniture. (b) Structuring element. (c) Median filtering within a 5 × 5 neighborhood was applied first, to reduce the noise level. Then, grey-scale closing was applied and the result subtracted from the original. Edge effects were eliminated by masking

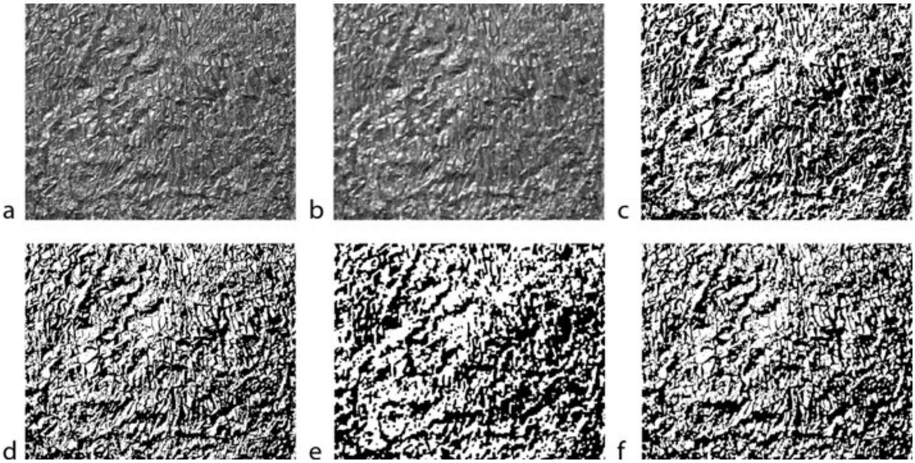

Fig. 19.54
Analysing grey-scale texture using morphology. (a) Original image. (b) Closing using a 5 × 5 flat rectangular structuring element, followed by erosion using the same SE. (c) Thresholding previous image so that 50% is black. (d) Opening using a 5 × 5 pixel flat rectangular structuring element, followed by thresholding. (e) Closing using a 7 × 7 pixel flat rectangular structuring element, followed by opening with the same SE, then thresholding. (f) Opening using a 7 × 7 pixel flat rectangular structuring element, followed by thresholding

wavelength is proportional to the reciprocal of frequency. We have seen that to eliminate a dark gap spanning N pixels, the SE used for dilation must be at least N/2 pixels wide. Hence, if the 'wavelength' of a periodic structure, along a line inclined at θ° to one of the image axes, is N pixels, dilation with an SE of width greater than N/2 pixels will eliminate it. (We measure the width of the SE along the line at θ°.) There may be another periodic structure within the image, at a different orientation. Often this is $(\theta^\circ + 90^\circ)$, in which case the task of designing a filter is simplified.

This discussion relating frequency and wavelength to morphological filters behaviour is approximate and breaks down completely for SEs with complicated shapes. We should not, for example, try to pursue this analogy for SEs with shapes such as V, T or X.

19.12 Concluding Remarks

Morphology provides a valuable class of image processing functions and can be used in a variety of ways. The following is an abbreviated list:

- Feature detection, as a prelude to
  - Location of features or objects
  - Image registration
  - Dimensional measurement
  - Existential inspection
  - Object identification
  - Robotic object handling

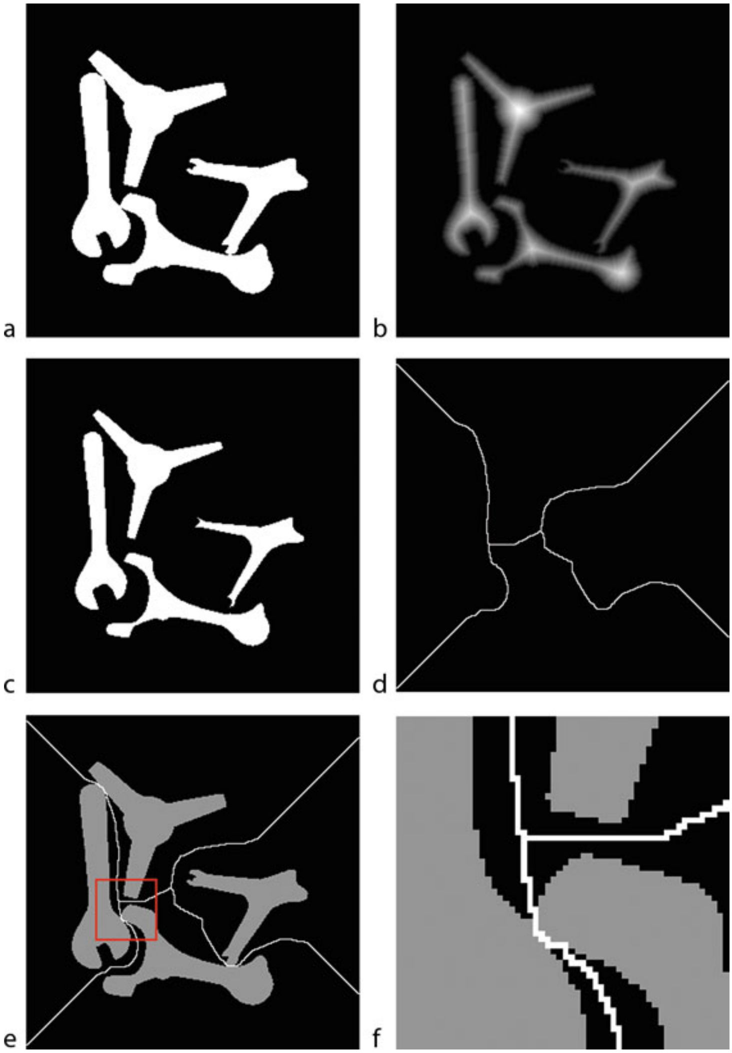

Fig. 19.55

Using the grass-fire and watershed functions to isolate objects that are just touching. (a) Original image. Notice that there are three points of minimal contact among the four objects. (The isolated objects are shown in *Fig. 19.25a*) (b) Grass-fire transform, after contrast enhancement. (c) Thresholded. (d) Watershed. (e) Watershed superimposed on the original. (f) Detail within the red square in (e)

  - Counting objects
  - Automated machining
- Detection of objects whose orientation falls within a limited range of angles
- Image filtering to perform
  - Contrast enhancement
  - Detection or measurement of periodic patterns

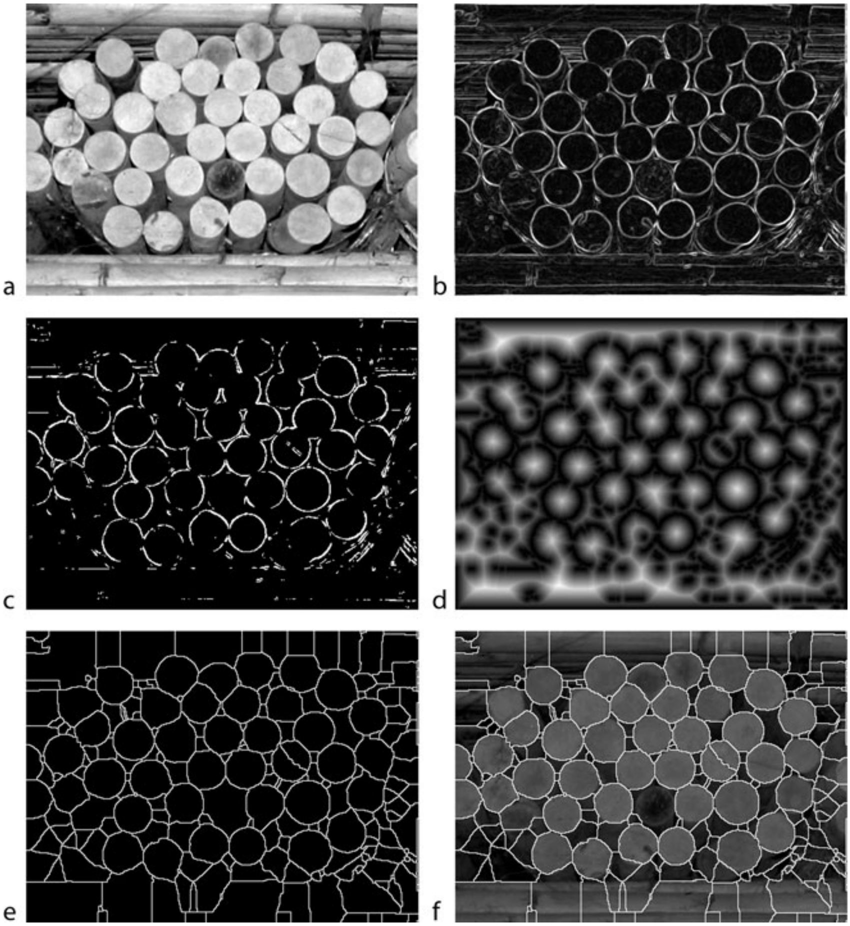

Fig. 19.56

Segmenting an image using the grass-fire and watershed functions. (a) Original image, a bundle of rattan canes viewed end-on. (b) Edge detector. (c) Thesholding. (d) Grass-fire transform. (e) Thresholding and watershed function. (f) Segmentation boundaries superimposed on the original. [QT: *rni(153), sed, thr(32), gft, enc, wsh, rni(original),swi,adi, mxi*]

  - Noise reduction
  - Texture analysis
  - Crack detection
  - Segmentation
  - Low-pass and high-pass filtering (approximate)
- Colour recognition
- Optical character recognition

Table 19.3 summarises the action of the more significant morphological functions and describes how they can be executed in MATLAB and QT.

The implementation of morphological functions to maximise their execution speed has been studied extensively over many years. Many important classes of SE lend themselves

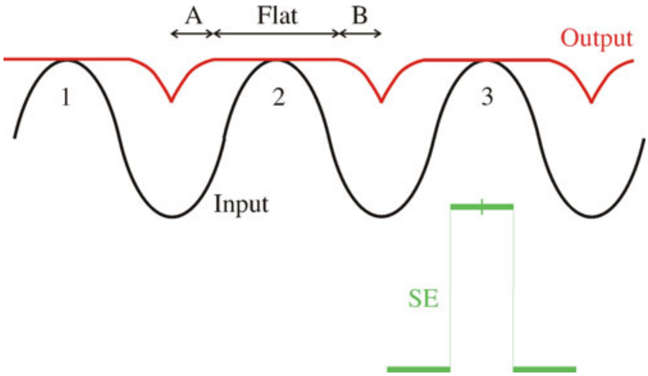

Fig. 19.57

Morphology is not a linear process. The sections of the output labelled ‘Flat, A, and B’ follow peak 2. The SE has a flat top. Grey scale dilation (or erosion) on a sine wave does not generate a sine wave. Since a multitude of high-order harmonics is generated by morphological filtering, the concept of ‘frequency response’ is strictly not valid

to the SKIPSM implementation described in ➲ Chap. 20. This includes shapes such as the following:

T L V O ∪ /— ∠ + X ▲ ▼ ♦ □

(These particular SEs can be implemented in other orientations.) Where direct SKIPSM implementation is not possible, it is usually possible to achieve the desired result easily, by breaking the SE into smaller units. The SKIPSM implementation is important because binary erosion and dilation morphological functions can be performed by accessing each pixel in the input image just once. This means that erosion and dilation can be performed at essentially the same speed as simple operations such as negation and thresholding. In many cases, it is possible to improve upon that, because several erosions and dilations can be performed at the same time.

Morphological structuring elements and convolution kernels are conceptually similar but they differ in the way that the combine the intensity values of the pixels they cover. Dilation uses the maximum (MAX) function; erosion uses minimum (MIN); convolution (local operators and linear N-tuple filters) uses summation. Consider the following equation

$$S_p(W_1, W_2, \ldots, W_N) = \sqrt[p]{\sum_{i=1}^{N} (W_i X_i)^p}$$

S_1 (i.e., $p = 1$) represents a simple summation of the terms $W_i X_i$ for $i = 1, 2, \ldots, N$. That is the type of calculation performed by convolution. As p approaches plus infinity and with all $W_i = 1$, S_p approximates $MAX(W_i X_i)$, which is the heart of the grey-scale dilation operation. To represent grey-scale erosion $MIN(W_i X_i)$, we let p approach minus infinity, again with all $W_i = 1$. The point is that in this one equation we can relate these three functions to one another. (Incidentally, it also suggests a range of other functions in which p is a finite number not equal to unity. Rank and range filters form another closely related family of operations, although they are not encompassed exactly by the above equation. However, we shall leave these ideas for the reader to explore.) The question arises as to why we should use any process other that

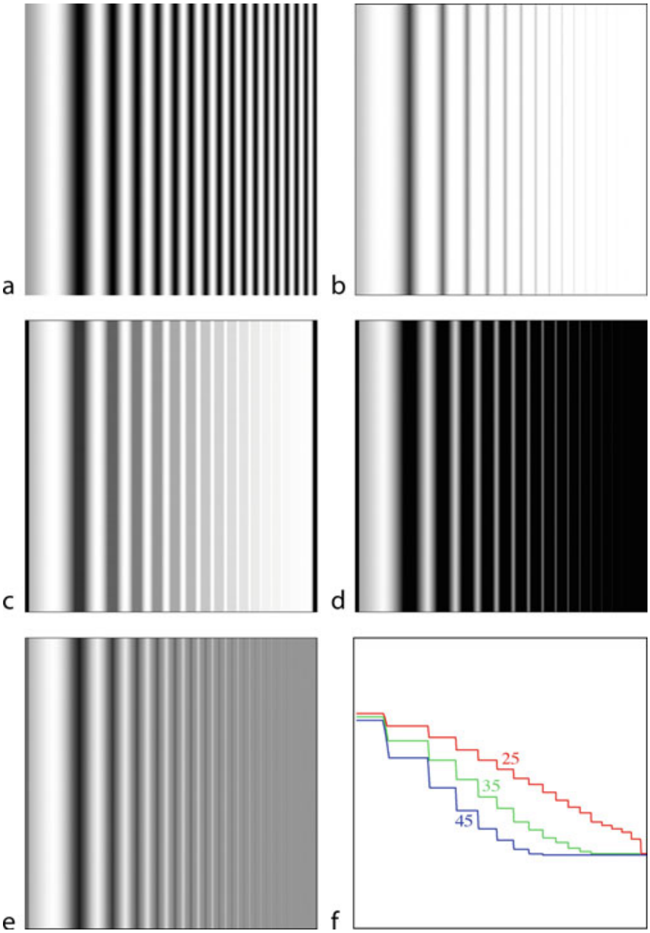

Fig. 19.58

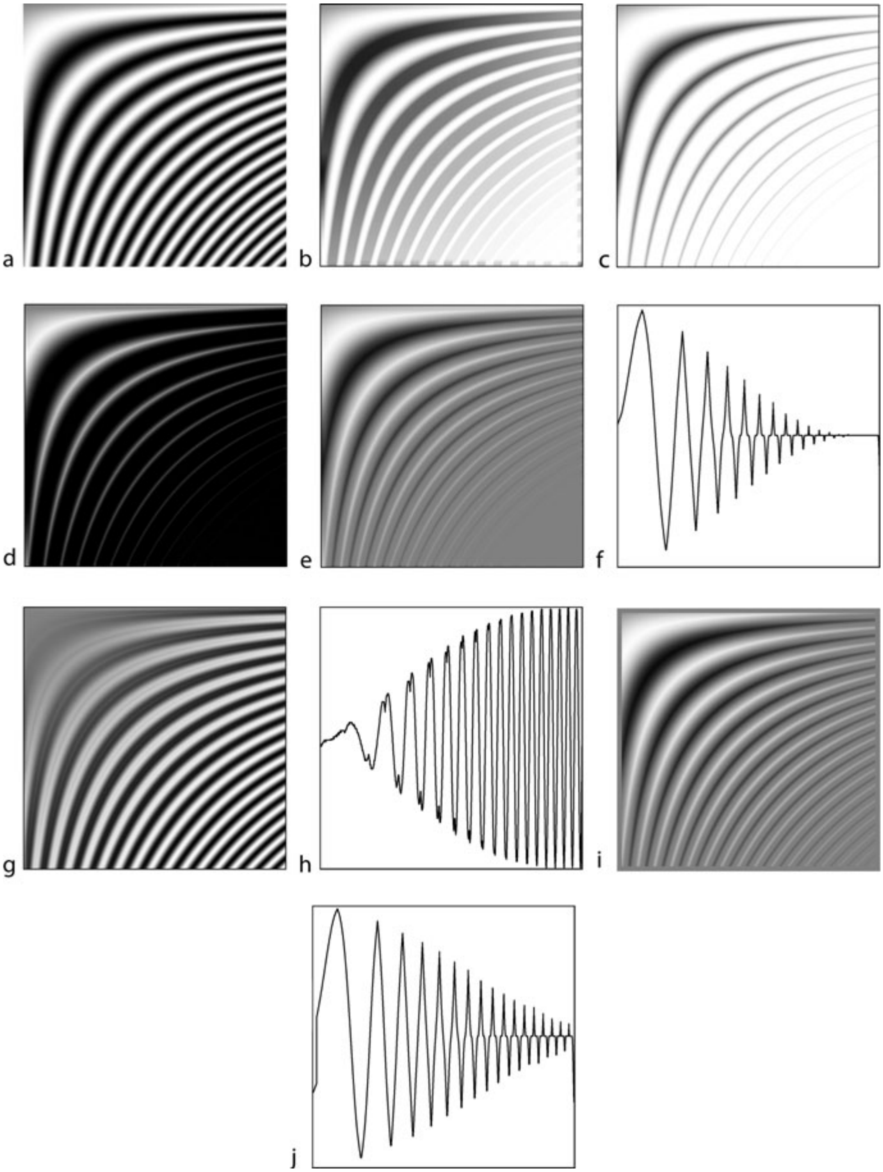
Adjusting the frequency response of a morphological low-pass filter, by varying the size of the structuring element. (a) Variable frequency sinusoidal intensity variation. This image has 1024 × 1024 pixels. (b) Grey-scale dilation using a horizontal line SE of length 30 pixels. (c) Erosion of (b) using the same SE. (d) Erosion of the original image using the same SE. (e) Adding images (b) and (d). Summing the results of dilation and erosion approximates a low-pass filter. (f) The 'low-pass' filter was applied to image (a) and the local contrast measured as a function of horizontal position (i.e., spatial frequency). Three filter sizes were used to measure the strength of the filter output. Numbers indicate the lengths of three horizontal line SEs. As the SE length is increased, the filter attenuates ever lower frequencies. Both axes are linear

convolution, since it and morphology are simply variations of a single theme. Erosion is a *non-integrative* feature-detection process and is therefore highly sensitive to small 'spot' defects, whereas convolution is capable of ignoring them. Dilation is sensitive to isolated black pixels and erosion to isolated white pixels. For this reason, morphology is well suited to detecting small spots, or conversely to eliminating them. Dilation and erosion are capable of discriminating the polarity of 'spot' defects much better than convolution can. Simple unsharp masking



◘ Fig. 19.59

Grey-scale morphological low-pass and high-pass filtering in two dimensions. (a) Variable frequency sine waves. [QT: *vfs*] (b) Closing using a rectangular flat-top structuring element. [QT: *lnb(35), snb(35)*] (c) Dilation [QT: *lnb(35)*]. (d) Erosion. [QT: *snb(35)*] (e) Adding the results of dilation and erosion approximates low-pass filtering [QT: *lnb(35), wri(1), rei(original), snb(35); rei (1), adi*] (f) Intensity profile along the diagonal in (e), showing the reduction in amplitude (local intensity variation) as the frequeny rises. (g) Difference between images (e) and (a), produces an approximation to high-pass filtering. (h) Intensity profile along the diagonal in (g), showing the increase in amplitude as the frequeny rises. (i) Low-pass filter, using a circular disc SE. [QT: *x = gsk(14,18); gsd(x), wri(1), swi, gse(x),rei(1), adi*] (j) Intensity profile along the diagonal in (i)

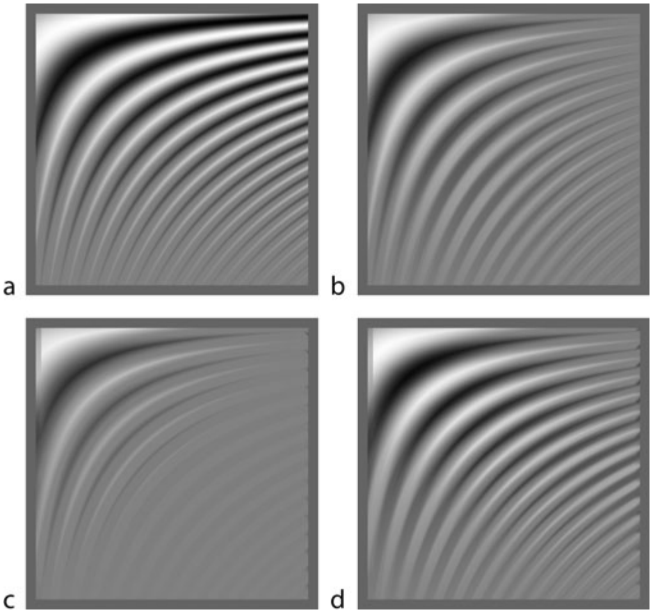


Fig. 19.60

Directional low-pass filtering using grey-scale morphology in two dimensions. In each case, the length of the structuring element is 55 pixels and the image has 1024 × 1024 pixels. Edge effects have been suppressed by masking. (a) SE is a horizontal line (b) SE is a vertical line. (b) SE is a diagonal line, top-left to bottom-right. (d) SE is a diagonal line, bottom-left to top-right

(convolution high-pass filter) produces a bright 'halo' around a dark spot or streak and is difficult to distinguish this from a dark spot. On the other hand, the morphological crack detector (bottom-hat) identifies dark spots and completely ignores well-spaced bright ones. Morphology is well suited to detecting features such as *parts* of printed characters, sharp corners, joints and limb ends of 'skeletons'. Convolution cannot do this with the same ease.

Programs for performing morphological image processing operations are available from many sources. Most commercial software libraries for image processing possess a collection of these functions. QT (➲ Chap. 21) and MATLAB® were used to generate many of the illustrations in this chapter. NeatVision (➲ Chap. 22) provides a comprehensive set of morphological functions, while Photoshop® also has basic erosion and dilation functions.

19.13 Supplement: Definitions of Morphological Operators

We shall use the following notation:

- E, an integer grid
- A, a binary image in E.
- A^C, the complement of A
- B, a structuring element, also in E
- B_Z, the translation of B by the two-element vector Z
- B^S, the rotation of B by 180°

Table 19.3

Common morphological functions, with their implementation in MATLAB and QT (➔ Chap. 21)

Binary edge detection	
Function MATLAB QT Figures	Removes interior pixels. Only object boundary pixels are set to white *new_image = bwperim(old_image,n), n = 4 or 8.* *bed* ➔ *19.20*, ➔ *19.34*
Bottom Hat	
Function MATLAB QT Figures	The output image is the difference between the original image and the result of closing it. *new_image = bwmorph(old_image,'bothat',n), n* is the iteration limit. *btt(n)* ➔ *19.20*, ➔ *19.32*, ➔ *19.49*, ➔ *19.50*, ➔ *19.51*
Bridge	
Function MATLAB *QT* Figure	Black pixels are set to white if they have exactly two white neighbours that are not connected. White pixels remain white. Example: 1 0 0 1 1 0 1 0 1 becomes 1 1 1 0 0 1 0 1 1 *new_image = bwmorph(old_image, 'bridge')* *mbo* ➔ *19.22*
Cleaning	
Function MATLAB QT Figure	Remove white isolated pixels *new_image = bwmorp(old_image, 'clean')* *cln* ➔ *19.19*
Closing	
Function MATLAB QT Figures	Performs morphological closing. That is *dilation* followed by *erosion*, using the same structuring element *new_image = imclose(old_image,se)* *cls(n)* Closing, n selects one of the pre-defined structuring elements *gsc(se)* Grey-scale closing, with structuring element *se*. ➔ *19.11*, ➔ *19.19*, ➔ *19.33*, ➔ *19.49*, ➔ *19.51*, ➔ *19.53*
Count white neighbours	
Function QT Figure	Count the number of white pixels within each 3 × 3 neighbourhood white. *cnw* ➔ *19.21*
Detect pattern	
Function MATLAB *QT* Figures	Retain each pixel at the centre of a given pattern of white eight-neighbours. This pattern is detected in whatever rotations/reflections are defined when constructing a look-up table, *lut*. *new_image = applylut(old_image,lut),* where *lu*t is a look-up table created by *makelut.* sbc, counts the number of white pixels in each 3 × 3 window, including the centre pixel. ➔ *19.27*, ➔ *19.28*

Table 19.3 (Continued)

Diagonal fill		
Function	Uses diagonal fill to eliminate 8-connectivity of the background. Example: $\begin{matrix}0 & 1 & 0\\ 1 & 0 & 0\\ 0 & 0 & 0\end{matrix}$ becomes $\begin{matrix}0 & 1 & 0\\ 1 & 1 & 0\\ 0 & 0 & 0\end{matrix}$	
MATLAB	new_image = bwmorph(old_image, *bwmorp, ‘diag’)*	
Dilation		
Function	Expand white/bright regions	
MATLAB	*dilate*	Perform dilation on binary image.
	imdilate	Dilate image.
QT	*dil*	Dilate with one of four pre-defined structuring elements
	gbd	General binary dilation (Use *cse* or *use* to define the SE.)
	gsd	Grey scale dilation (Use with *gsk*, or *ones* to define the SE.)
	crs	Dilate so that an isolated white point becomes a vertical cross.
	dcr	Dilate so that an isolated white point becomes a diagonal cross.
	dil	Dilate with one of four pre-defined structuring elements.
	dri	Dilate with a*b rectangular structuring element.
	dsq	Dilate so that an isolated white point becomes a square.
Figures	➔ *19.3*, ➔ *19.4*, ➔ *19.7–19.12*, ➔ *19.16*, ➔ *19.29*, ➔ *19.31*, ➔ *19.32*, ➔ *19.34*, ➔ *19.35*, ➔ *19.37*, ➔ *19.45*, ➔ *19.48*, ➔ *19.57*, ➔ *19.58*	
Erosion		
Function	Erosion; shrink white/bright regions	
QT	ero	Erode with one of four pre-defined structuring elements.
	gbe	General binary erosion
Figures	➔ *19.3*, ➔ *19.4*, ➔ *19.6*, ➔ *19.8–19.18*, ➔ *19.27–19.30*, ➔ *19.32–19.35*, ➔ *19.37*, ➔ *19.40*, ➔ *19.41*, ➔ *19.45–19.48*, ➔ *19.58–19.60*	
Eliminate small objects		
Function	Remove small binary objects	
MATLAB	*new_image = bwmorph (old_image, ‘fill’)*, removes isolated black pixels *new_image = bwareaopen (old_image,n,c)*, remove c-connected (c = 4 or 8) objects with fewer that n pixels.	
QT	*cln*, remove isolated white pixels *kgr(n,c)*, remove objects with fewer than *n* white pixels	
Figure	➔ *19.19*	
Euler number		
Function	Returns a number equal to the difference between the number of binary objects (blobs) and the number of lakes (holes). Although this is not a true morphological operation, it is computed in a similar manner, requiring the use of four or eight binary masks.	
MATLAB	*euler_number = bweuler(old_image,n), n =* 4 or 8	
QT	*euler_number = eul(n), n = 4 or 8*	

Table 19.3 (Continued)

Grass-fire transform	
Function	Intensity at each point within a binary object indicates the distance from that point to the nearest edge pixel. Background pixels remain black. Although this is not a true morphological operation, it is computed in a similar manner.
MATLAB	*new_image = bwdist(old_image,'euclidean')*
QT	*gft(n), n = 4 or 8*
Figures	➔ *19.18*, ➔ *19.23*, ➔ *19.55*, ➔ *19.56*
Grey-scale edge detection	
Function	Highlight regions where the intensity gradient is high
QT	*gse(x), sub* *gsd(x), sub*
Figure	➔ *19.48*
Majority	
Function	Sets a pixel to 1 if five or more pixels in its 3-by-3 neighbourhood are 1s; otherwise, it sets the pixel to 0.
MATLAB	*bwmorph, option = 'majority'*
QT	*maj*
Figures	➔ *19.19*, ➔ *19.38*, ➔ *19.51*
Opening	
Function	Performs morphological opening (erosion followed by dilation).
MATLAB	*bwmorph, option =* 'open'
QT	*opn* Binary opening. (Use *cse* or *use* to define the SE.) *gso* Grey-scale opening. (Use with *gsk*, or *ones* to define the SE)
Figures	➔ *19.10*, ➔ *19.12*, ➔ *19.19*, ➔ *19.33*, ➔ *19.50*, ➔ *19.53*
Shrink	
Function	With n = inf, shrinks objects to points. It removes pixels so that objects without holes shrink to a point, and objects with holes shrink to a connected ring halfway between each hole and the outer boundary. This option preserves the Euler number.
MATLAB	*new_image = bwmorph(old_image, 'shrink',n)*
QT	*shk*
Figures	➔ *19.23*, ➔ *19.33*, ➔ *19.36*, ➔ *19.47*, ➔ *19.50*
Skeleton joints/Branch points	
Function	Detect the joints of a skeleton; retain only those white pixels that have three or more white 8-neighbours.
MATLAB	See *Detect Pattern*
QT	*jnt*
Figure	➔ *19.23*
Skeleton limb ends	
Function	Detect the ends of the limbs of a skeleton; retain only those white pixels that have just one white eight-neighbour.
MATLAB	*new_image = bwmorph(old_image, 'endpoints')*
QT	*lmb*
Figure	➔ *19.23*

Table 19.3 (Continued)

Spurs	
Function	Remove spur pixels, which are white pixels at the ends of skeleton limbs, applied recursively.
MATLAB	*new_image = bwmorph(old_image, 'spur',n), n* is the recursion limit
QT	*spr(n)*
Figures	➔ *19.23*, ➔ *19.24*, ➔ *19.26*, ➔ *19.31*, ➔ *19.33*
Structuring elements	
Function	Create/select a structuring element.
MATLAB	strel
	Example *se = strel('disk',size), new_image = imdilate(old_image,se)*
QT	*use* User selects binary structuring element with cursor
	cse Select binary structuring element from set of options
	Example *x = cse(3,7), gbd(x)*
	gsk Select grey-scale structuring element from set of options.
	Example *x = gsk(3,7), gsd(x)*
Thicken	
Function	Thickens binary objects by adding pixels to the exterior of each one until doing so would result in previously unconnected objects becoming 8-connected. The Euler number remains unchanged.
MATLAB	*new_image = bwmorph(old_image, 'thicken',n), n* is a finite iteration limit.
QT	*thicken(n)*
Figures	➔ *19.25*, ➔ *19.26*
Thin	
Function	A binary object without lakes shrinks to a single point. An object with lakes shrinks to a figure consisting of a series of connected rings, surrounding each lake and the outer object boundary nearby. The Euler number remains unchanged.
MATLAB	*new_image = bwmorph(old_image,'thin',n), n* is a finite iteration limit.
QT	*thin(n)*
Figures	➔ *19.16*, ➔ *19.17*, ➔ *19.23*, ➔ *19.31*, ➔ *19.40*
Top Hat	
Function	The output image is the difference between the original image and the result of opening it.
MATLAB	*new_image = bwmorph(current,'tophat',se)*
QT	*tpt(a), a = 0 or 1*
Figures	➔ *19.19*, ➔ *19.20*, ➔ *19.32*, ➔ *19.33*, ➔ *19.41*, ➔ *19.52*
Ultimate thin	
Function	A binary object without lakes shrinks to a single point. An object with lakes shrinks to a figure consisting of a series of connected rings, surrounding each lake and the outer object boundary nearby. The Euler number remains unchanged.
MATLAB	*new_image = bwmorph(old_image,'thin',inf)*
QT	*thn*
Figures	➔ *19.23*, ➔ *19.30*, ➔ *19.56*

Table 19.3 (Continued)

Watershed	
Function	The image resembles a honey-comb; each 'cell' consists of a 4- or 8-connected set of points. Within each cell every point perceives the same blob in the input image as its nearest neighbour.
MATLAB	*new_image* = watershed*(old_image,n), n* = 4 or 8
QT	*wsh(n), n = 4 or 8*
Figures	❯ *19.26*, ❯ *19.38*

19.13.1 Erosion

$$A \,\Theta\, B = \{ z \in E | B_{\approx} \subseteq A \}$$

or

$$A \,\Theta\, B = \bigcap_{b \in B} A_{-b}$$

19.13.2 Dilation

$$A \oplus B = \left\{ z \in E | (B^s)_{\approx} \cap A \neq \emptyset \right\}$$

where *Bs* is given by

$$B^s = \{ x \in E | -x \in B \}.$$

Alternatively

$$A \oplus B = \bigcup_{b \in B} A_b$$

19.13.3 Opening

$$(A \circ B) = (A \Theta B) \oplus B$$

19.13.4 Closing

$$A \bullet B = (A \oplus B) \,\Theta\, B$$

19.13.5 Properties

- Dilation, erosion, opening and closing are all position invariant. The result on each blob is the same irrespective of where it is in the image.
- Dilation and erosion are increasing. So, if

$$A \subseteq C$$

then

$$A \oplus B \subseteq C \oplus B$$

$$A \Theta B_b \subseteq C \,\Theta\, B$$

- Opening and closing are also increasing.
- Dilation is commutative.
- Dilation is associative, so

$$(A \oplus B) \oplus C = A \oplus (B \oplus C).$$

Erosion satisfies

$$(A \Theta B) \Theta C = A \Theta (B \oplus C).$$

- Erosion and dilation satisfy the duality relationship

$$A \oplus B = (A^c \Theta B^s)^c.$$

- Opening and closing satisfy the duality relationship

$$A \bullet B = (A^c \circ B^s)^c.$$

- Dilation is distributive over set union
- Erosion is distributive over set intersection
- Dilation and erosion are pseudo-inverse of one another, in the sense that

$$A \subseteq (C \Theta B)$$

if and only if

$$(A \oplus B) \subseteq C.$$

- Opening and closing are idempotent
- Opening is anti-extensive, so

$$A \circ B \subseteq A$$

- Closing is extensive, so

$$A \subseteq A \bullet B.$$

20 Image Processing Using Finite-State Machines

Frederick M. Waltz
University of Minnesota, Minneapolis, MN, USA

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_20,

Abstract: In a series of papers starting in 1994, Waltz described a powerful and unconventional method of implementing many important neighbourhood image processing operations. These techniques, taken together, have been given the acronym SKIPSM (Separated Kernel Image Processing using finite-State Machines). Note that "Separated" here does NOT imply that the operations must be linearly separable. The resulting implementations are almost always faster, and sometimes much faster, than the same operations implemented in conventional ways *on the same computational platforms.* This chapter presents the basic concepts of image processing using FSMs (finite-state machines), lists many specific image-processing operations which have been implemented with FSMs, gives examples of several typical operations (along with the C-code used to implement them), outlines a completely routine procedure for generating and optimizing SKIPSM C-code for a large class of image operations and neighbourhood sizes, and concludes with some execution-speed comparisons which support the claims of fast execution.

20.1 Introduction

In some applications of image processing, the execution speed of the various operations is not particularly important; e.g., in the development phase of machine-vision inspection algorithms, in which a trial-and-error approach is often used, as discussed elsewhere in this handbook. However, the *on-line applications* of those very algorithms sometimes require extremely fast execution. Years of experience have convinced the authors that, no matter how fast our image processors are, or how much their price/performance ratios decrease, there will always be applications for which they are either too slow or too expensive.

One can attempt to increase execution speed by choosing faster computational hardware. The law of diminishing returns operates with a vengeance here, in that choosing a microprocessor with a faster clock rate has a *minor* effect on execution speed, compared to the *architecture* of the chip; e.g., RISC versus CISC, bus speed, memory access speed, instruction and data pipelining, and internal data-path bit widths. Another way of saying this is that architectures optimized for general-purpose computation are often not well-adapted to image processing. At any given time, there will be a maximum speed achievable with standard hardware. This speed may not be fast enough for the application being considered. Therefore, any implementation scheme which allows image processing operations to execute faster *on a given platform* will be useful.

Once a computational platform has been chosen, the conventional way to improve execution speed is to expend the extra effort to write highly efficient software code; e.g., write the algorithm in assembly language, or write "fall-through" non-branching code to eliminate branches and loops. An expert programmer using this approach might cut execution time in half (or even less) compared to the same operation written by the *same* expert programmer in an intermediate-level language such as C. Beyond a certain point, however, great additional effort often achieves only minor improvements. And once again, the resulting implementation may not be fast enough for the application being considered.

Finally, there is the "special tricks" approach – formulating the problem in an unconventional way in order to take advantage of some *special property* of that *particular operation.* The literature is full of these, and one often marvels at the ingenuity of the people who first thought of them. Of course, things that were "special tricks" when first presented, if they are in fact better, soon become the standard way of doing those operations, and we may forget our initial admiration for their inventors. A good (if ancient) example is the two-dimensional Fast

Fourier Transform: There are some ingenious "tricks" involving the shuffling of data and coefficients which contribute to the speed improvements, but the *important* speed improvement results from the fact that Fourier operations are *linearly separable* – i.e., can be implemented using a row operation followed by a column operation.

The implementations described here use finite-state machines (FSMs), recursion, and row-column separation (of a type *much* more general than linear separability) to carry out image-processing operations. At first glance, one might suppose that these belong in the "special tricks" category. They are certainly extremely unconventional, but they don't fit the "special tricks" definition because *the same basic FSM techniques can be used for a very wide range of image-processing operations*. In fact, they constitute a radically new image-processing paradigm.

This new paradigm was originally developed in about 1990 as a technique for increasing the speed and more importantly the *versatility* of commercially-available pipelined image-processing hardware. As general-purpose computers became faster and began to be used for on-line inspection, it became clear that the widest application of the FSM approach would be for speeding up *software* image-processing programs running on PCs. This chapter therefore concentrates on software implementations written in the C language. Because this paradigm is fundamentally different from conventional image processing algorithms, we begin with a general overview of the method. This is followed by some examples selected from the wide range of operations that can be implemented in this way. Finally, execution-speed comparisons for some of these examples are presented.

Overview of the SKIPSM paradigm: In a series of papers starting in 1994, Waltz (1 through 6) described a powerful and radically new method of implementing many important neighbourhood image processing operations. These techniques, taken together, have been given the acronym SKIPSM (Separated Kernel Image Processing using finite-State Machines). The resulting implementations are almost always faster, and sometimes much faster, than the same operations implemented in conventional ways *on the same computational platforms*. In some cases the improvements in performance (speed or neighbourhood size) are so great, compared to conventional implementations, as to demand a radical rethinking of what is or is not practical. For example, operations such as binary erosion with very large structuring elements (e.g., 51 × 51 = 2,601 pixels), have been implemented *faster* on ordinary desktop computers than these same computers can do a simple 3 × 3 binary erosion (9 pixels) using conventional programming – a speed-improvement ratio of 289:1. Speed improvements or neighbourhood-size increases of 100:1 or more have also been achieved for some other image processing operations.

The image processing categories to which SKIPSM can be applied in software and/or special-purpose image-processing hardware implementations include but are not limited to the following:

- Binary erosion and dilation with large, arbitrary SEs (structuring elements). SEs up to 25 × 25 and larger and with "holes" and other non-convex shapes can be applied in a single image pass, in software or hardware. Multiple SEs can be applied simultaneously in a single pass [1–7]. For example, six erosion stages of the "Grassfire Transform" have been carried out in *one pass* [3].
- Binary opening and closing in a single pass [2, 23].
- Binary template matching with large, arbitrary templates [8].
- "Fuzzy" binary template matching [8].
- Binary correlation [9].

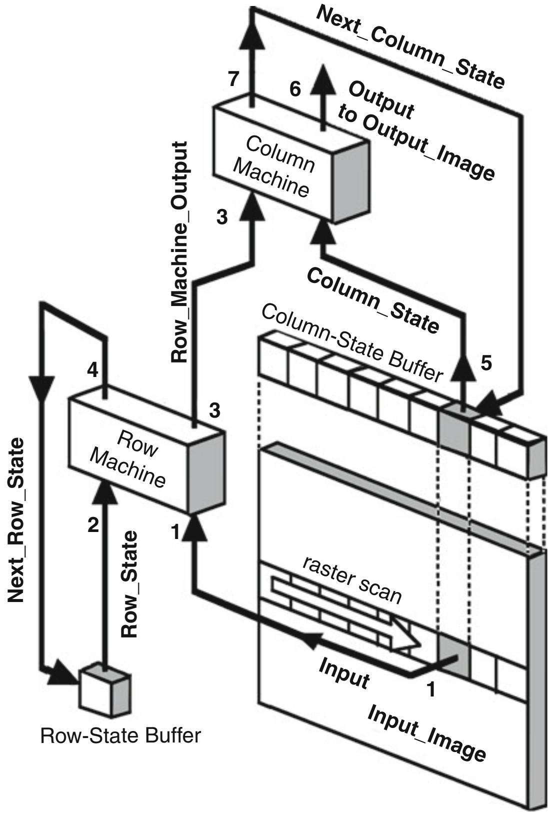
- Binary connected-component analysis, with assistance from a random-access processor for part of the problem [10].
- Grey-scale morphology [11, 12].
- Grey-scale template matching [11].
- Large-kernel Gaussian blurs, difference-of-Gaussian filters, etc. [13].
- Many standard linear neighbourhood operations: edge enhancement, area averaging, horizontal, vertical, and diagonal gradients [14].
- Many standard nonlinear neighbourhood operations: maximum, minimum, maximum of row minimums, minimum of row maximums, Robert's cross, median and other ranked filters, largest gradient, direction of largest gradient, direction of brightest or darkest neighbour, pixels critical for connectivity, all possible functions defined on 3 × 3 binary neighbourhoods, etc. [14–16].
- One-pass binary skeletonisation [17, 18].
- Binary run-length encoding on rows, columns, or diagonals [19].
- Grey-scale run-length encoding on rows, columns, or diagonals [19].
- Certain operations previously thought to be impossible in pipelined systems, such as "blob fill" and "patterned blob fill." [19].
- Various "smearing" operations, including row, column, and diagonal summations and Hough transforms [19].
- One-pass generation of certain standard images (e.g., grey-level wedges) and arbitrary image textures, either whole-image or masked arbitrarily [19].
- Grey-scale morphology and other operations on colour images [20].
- Operations in colour space [20].
- Three-dimensional and higher-dimensional binary morphology [24].

20.2 The SKIPSM Paradigm: Sequence of Operations

All SKIPSM applications for two-dimensional data arrays take the same general form (see ➲ *Fig. 20.1*) and have these characteristics:

- The overall operation is separated into a row operation followed by a column operation (or column operation, then row operation). *Note that the separability requirement is not particularly restrictive*, because most operations are separable by this technique, which is much more general than separability as defined for linear convolutions, Fourier Transforms, etc.
- These row and column operations are put in recursive form – that is, in the form needed for a single-pass software implementation or a pipelined hardware implementation.
- The resulting operations are realized as finite-state machines (FSMs).
- These FSMs can be implemented either in software or in pipelined hardware.

Overall scheme: The pixels of the input image are processed in raster-scan order. It makes no difference if the scan is row-by-row or column-by-column, top-to-bottom or bottom-to-top, left-to-right or right to left. (*Interlaced* scans are not allowed, because the concept of a pixel's *neighbours* is destroyed in interlaced scans.) The usual case, in which the scanning is along the rows, is shown in ➲ *Fig. 20.1*. In whatever order the pixels are scanned, each input-image pixel is accessed *once and only once*. All needed neighbourhood information is encoded (often in extremely compact form) in the state buffers of the two FSMs.



■ **Fig. 20.1**
SKIPSM sequence diagram

The inner-loop steps, applicable to all implementations, are executed *once* for each pixel in the input image. The steps are shown in ➲ *Fig. 20.1*, and are as follows:

1. Fetch **Input**, the next input pixel value (in raster-scan order) from **Input_Image**.
2. Fetch **Row_State** (the contents of the **Row-State Buffer**).
3. *Row machine computation*: Using the **Input** value and the **Row_State** value, carry out the row-machine computations required for the particular image-processing operation being implemented. These computations can be carried out either with a lookup table or with a sequence of computational steps in C code. *By definition*, this computation produces two values:
   (a) The value of the **Next_Row_State**. This is written to the **Row-State Buffer**, overwriting the previous value, which will never be needed again. This is called *updating the row state.*
   (b) The **Row_Machine_Output**, which is used immediately by the column machine. See Step 5 below.
4. Fetch the **Column_State** value from the register in the **Column-State Buffer** corresponding to the current image column.

5. *Column machine computation*: Using the **Row_Machine_Output** (step 3b) and the **Column_State** value (step 4), carry out the column-machine computations required for the particular image-processing operation being implemented. (As in step 3, these computations can be carried out either with a lookup table or with a sequence of computational steps in C code.) *By definition*, this produces two values:
   (a) The value of the **Next_Column_State**. This is written to the same place in the **Column-State Buffer** from which the column state was obtained in step 4, thus overwriting the old value, which will never be needed again. This is called *updating the column state.*
   (b) The overall **Output** (i.e., column-machine output). This is written immediately to the appropriate location in **Output_Image**, corresponding to the *centre* of the neighbourhood. For any neighbourhood larger than 1 × 1, this location is *always* "behind" the input pixel in the raster-scan sequence. *Therefore, the input image buffer may also be used for the output image*, if desired. No information will ever be lost if this is done, because *all the needed neighbourhood information is encoded in the states of the two FSMs.*

Now, repeat these steps for the next pixel in the raster scan. And so on.

Steps 3 and 5 can be done with special-purpose hardware, or with pre-computed lookup tables, or with compiled step-by-step run-time code. For some operations, the lookup-table approach can be much faster that conventional implementations of the same operations on the same computer. For software implementations, only the code in steps 3 and 5 (or the values in the lookup tables) change when a different operation is implemented.

In the lookup-table implementation, the lookup tables are created in advance using the same inner-loop code (steps 3 and 5), applied to all possible inputs and all resulting FSM states. At inspection-system boot-up, *all* the lookup tables needed for *all* the operations involved in an application are usually preloaded from disk or ROM or RAM. Stepping through a sequence of operations then consists of selecting a sequence of pointers, pointing to appropriate locations for each lookup-table in turn. This kind of implementation is most advantageous in production situations, when the same inspection algorithm is used over and over. The lookup tables themselves are usually small (a few KB) but can be large for some operations, such as applying gigantic (e.g., 25 × 25) morphology structuring elements in one pass. Large lookup tables, when required, would appear to be a factor working against the lookup-table implementation, but this is also precisely the situation in which enormous speedups are achieved. In such cases, large lookup tables are often justified. (Using lookup tables, it takes approximately the same time to execute a 25 × 25 operation as to execute a 3 × 3 operation. Execution speed is essentially independent of neighbourhood size.)

20.3 Edge Effects

Whenever a neighbourhood image-processing operation is used, the values of the output image are, strictly speaking, not defined unless the computational neighbourhood is completely *inside* the boundaries of the input image. Therefore, pixel values for some rows and columns next to the four edges of the output image can not be computed according to the same rule used for interior pixels. A decision must be made about these pixels. One approach to this shrinkage is to specify an output image which is *smaller* than the input image, and ignore the "undefined" pixels. For example, suppose that the processing

Fig. 20.2
Image definitions and edge effects

neighbourhood has M columns and N rows, and that the computed output is to be placed at the pixel corresponding to the centre of this neighbourhood. (See *Fig. 20.2*.) Then, if M is an odd number, M2 = INTEGER(M/2) columns will be lost at the left edge of the output image, and M2 columns will be lost at the right edge of the output image. Likewise, if N is an odd number, N2 = INTEGER(N/2) rows will be lost at the top edge of the output image, and N2 rows will be lost at the bottom edge of the output image. For example, if M = 19 and N = 15, then nine columns will be lost at the left edge of the output image, and nine columns will be lost at the right edge of the output image. Likewise, seven rows will be lost at the top edge of the output image, and seven rows will be lost at the bottom edge of the output image.

Because many of the algorithms used in machine vision involve the comparison and/or combination (addition, subtraction, OR, XOR, AND, etc.) of images at various stages of the computation, this image shrinkage can cause difficulties. Therefore, it is common practice in machine vision to "pad out" the output image to the same size as the input image by filling in these border rows and columns in some defined way.

A full discussion of edge effects, which are present in *all* neighbourhood operations, regardless of computational method, is beyond the scope of this short article. However, some decision must be made in every case, either to omit the edge pixels or to fill them in according to some rule(s).

One simple approach is to set these output pixels to a fixed value, such as zero. Another approach is to attempt to provide smoother edge transitions and allow the border pixels to contain *some* information, by "phasing in" the computations at the top and left edges as the neighbourhood operator moves onto the input image, and "phasing out" the computations at the right and bottom edges as the operator moves beyond the input image. In effect, one computes the output based on only the part of the processing neighbourhood that corresponds to input image pixels. This makes eminent sense for certain operations, such as MAX or MIN or MAX-MIN. For others, special provisions should be made: e.g., for averaging, one should adjust the normalizing constant to reflect the number of image pixels actually being averaged. These details will not be pursued further here, and the inner-loop C-code given in the examples below does not include steps to compute the values of the output image edge pixels.

20.4 Automated Generation of Lookup Tables

The lookup-table approach would be of little practical interest unless the LUTs could be created easily and routinely. Fortunately, while the *results* of these operations can be very complex, the principles behind the automated creation of SKIPSM lookup tables are very straightforward: Calculate the results of applying the specified neighbourhood image processing operation to all possible *combinations* of input values (i.e., input image pixel values) in the defined neighbourhood, sort them into numerical order, and make a table of the results. This might seem impossibly difficult, but for some simple operations it can be done "in your head" and for others the procedure can easily be automated. The earliest automated procedure was implemented for binary morphology on a 1995-era Macintosh desktop computer using a Microsoft Excel® spreadsheet. Cell formulas were used to define the desired neighbourhood image processing operation. A macro took the result of the image processing for each sequentially-applied input image value and the current state value and determined the resulting new state and the output. It then appended these newly-calculated states to the list of states, sorted the states into numerical order, and deleted duplicate states. This continued until no new states were generated. (This process ALWAYS terminates because these are finite-state machines. In practice, even "analog" values are represented by a finite number of discrete levels, typically 256, so that finite-state machines can be used for grey-scale operations also.) Finally, the macros sorted all of these results, renamed the states with consecutive integer values, and created the final lookup table. Small tables (100 or fewer states) were created in a second or two. For the most complex binary-morphology situation we attempted, it took a few minutes to grind out a pair of state tables with more than 10,000 states. This approach is shown in some detail in [2, 3, 8].

Later, the same procedures for binary morphology were implemented in C-code as four programs, which were faster than the spreadsheet implementation but otherwise gave identical results:

CREATE_ROW_FSM The user specifies a binary row pattern, e.g., [0 0 1 1 1 0 0]. The output of this program is the corresponding row LUT. This process is repeated for all of the SE row patterns.

COMBINE_ROW_FSMs The user specifies the file names of a *pair* of row LUTs, and the program produces a combined row LUT. Using the same program, this LUT is combined in turn with *another* of the row LUTs, until all have been combined into a single combined row LUT.

CREATE_COLUMN_FSM The user specifies the row-pattern identifiers for the SE. For example, in ➲ *Fig. 20.4*, the nine distinct row-pattern identifiers are, from top to bottom [1 2 3 3 3 3 3 2 1]. The output of this program is a column LUT. If only one SE is being applied, this is the last step.

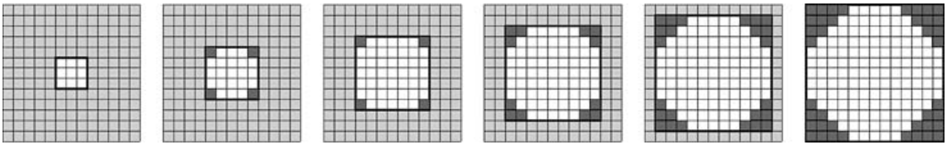

Fig. 20.3
SEs for six simultaneous erosions, performed very rapidly in one pass using SKIPSM LUTs

There is one additional program, **COL_COMBINER**, which is used to create combined column LUTs. A combined column LUT, along with the combined row LUT used to generate it, carries out more than one neighbourhood image-processing operation simultaneously. This allows the execution of *multiple SEs* in one pass. For example, six different concentric (nested) circular SEs have been combined into a single operator to provide *six stages* of Grassfire transform erosion in a single pass. (See *Fig. 20.3*)

There is, in principle, no limit to how many different SEs can be applied simultaneously in a single pass, although attempts to combine very large and/or very complex SEs may result in unmanageably-large LUTs. There is also the restriction that all the SEs being combined into a single operation must share the same combined row LUT, which means that they must have the same neighbourhood size. This is easily overcome by "padding" the smaller SEs with "don't care" pixels to fill them out to the size of the largest one, as was done in *Fig. 20.3*. The added pixels are shown in a lighter grey. Needless to say, when a small SE is "padded," it loses the same number of edge rows and columns as the largest SE in the set, and therefore can not "reach as far into the corners" of the image as if it had been applied by itself.

20.5 Binary Erosion with Very Large Rectangular Structuring Elements (SEs)

Binary morphology has been used widely in inspection algorithms, optimal-packing problems, etc. When large SEs (e.g., 25 × 25, 51 × 51) are required, the usual approach is to carry out many erosion operations in sequence using small (typically 3 × 3) SEs, a time-consuming process. Using SKIPSM, such large-SE erosions can be done very rapidly in one image pass. Binary dilations can be implemented just as easily.

As a first example, consider large square or rectangular binary-erosion SEs with N rows and M columns. These simple SEs are not very interesting in themselves. Furthermore, they are very easy to implement using other techniques. However, they will serve to illustrate the concept of finite-state machines, separation, and recursion.

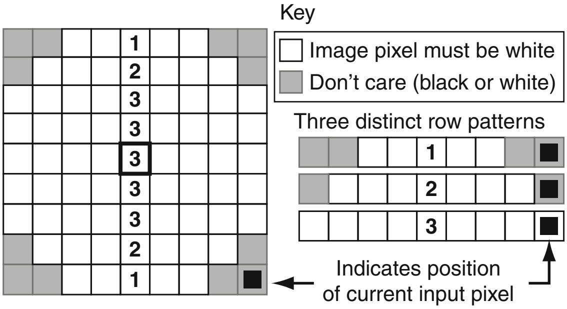
Here is the complete inner-loop code for a direct implementation (i.e., using compiled C-code) for this example. As always, each input-image pixel is fetched *once*. There are *no other inner-loop steps*, no matter how large the SE happens to be. Thus, the speed is essentially independent of N and M. Note that a *threshold* step is included to allow this code to operate on either binary images (values 0 and 1) or grey-scale images. That is, the thresholding operation is built into the code so that a separate thresholding operation is not needed. Edge effects are ignored here.

```
// The SKIPSM row machine for a rectangular binary-erosion SE with M columns
   if (Input_Image[j][i] < Threshold) Row_State = 0;
       // Input pixel is black. Set Row_State to 0.
   else Row_State = Minimum(Row_State + 1, M);
       // Input pixel is white. Increment the Row_State, clamping its value at M.
   if (Row_State < M) Row_Machine_Output = 0;
       // There is at least one black pixel in the 1xM neighborhood. Set
       Row_Machine_Output to 0.
   else Row_Machine_Output = 1;
       // The current 1xM row neighborhood has M white pixels. Set
       Row_Machine_Output to 1.
// The SKIPSM column machine for a rectangular binary-erosion SE with N rows
   Column_State[i] = Minimum(Column_State[i] + Row_Machine_Output, N);
       // Increment the column state, clamping its value at N.
   if (Column_State[i] < N) Output = BlackValue;
       // The SE does not ``fit'' here. Set Column_State to zero.
   else Output = WhiteValue;
       // The SE ``fits'' at the current location and the final output is white.
```

There are much more efficient ways to implement these steps, including a very fast method using only left-shifts and masking. However, the goal here is to illustrate the SKIPSM concepts, so a straightforward C-code implementation is shown because it is easier to understand.

20.6 Lookup-Table Implementation of Binary Erosion with a 9 × 9 Circular SE

Next, consider the more difficult and much more interesting task of binary erosion with large and complex SEs. As an example, we will use the 9 × 9 circular SE shown in Fig. 20.4, although much larger SEs can be implemented with almost equal ease. The conventional approach to this particular operation is to make four successive passes through the image



Key

with 3 × 3 SEs. (Note that SEs larger than 9 × 9 would require even more 3 × 3 passes, and that SEs with holes or concavities, which are difficult or impossible to achieve using successive small SEs, can also be done easily in one pass using SKIPSM.) Instead, we will use a lookup-table implementation to execute this operation in one pass.

Because the column machine is required to keep track of all the partially-completed patterns as it moves down the columns of the image, it always needs to know which (if any) of the distinct row patterns the *current* image row satisfies. (The column machine incorporates all needed information about *previous* rows into its own column state.) Thus, the overall row-and-column operator must somehow make *simultaneous* comparisons of the current image row with *all three* of the different row patterns, shown in the figure as distinct row patterns 1, 2, and 3. Since the column machine's *only* source of this information is the row machine output, this implies that the row machine must detect and "encode" all three row patterns simultaneously into a single number.

It turns out that only 25 states are sufficient to encode all the necessary row information for the *simultaneous* testing of all three distinct row patterns. The combined row machine output is (and must be) in the form of a *single number.* In this case, it takes on the values **0**, **1**, **2**, or **3**. An output of **3** implies that all three row patterns are "satisfied." **2** implies that only row patterns **1** and **2** are "satisfied." **1** implies that only row pattern **1** is "satisfied." **0** implies that none of the row patterns is "satisfied." (These particular row patterns can be said to be "well ordered," in that they can easily be placed in increasing order: all of the white pixels in **1** are present in **2** and all of the white pixels in **2** are present in **3**. Cases where the rows are not well-ordered, such as 0 1 1 0 1 1 0 and 1 1 0 0 0 1 1, require additional row-machine output values to encode the various combinations, but are easily handled. The details are omitted here.)

For the binary structuring element shown in ➤ *Fig. 20.4*, ➤ *Fig. 20.5* gives the *updated* **Row_State** and the **Row_Machine_Output** as functions of the input pixel **Input** (value 0 or 1) and the current row state **Row_State**, fetched from the row-state register.

Fig. 20.6
Column_State_Table and Column_Out_Table, the column-machine lookup tables for 9 × 9 circular SE

For the binary structuring element shown in Fig. 20.4, Fig. 20.6 give lookup tables for the *updated* **Column_State** and the **Output** as functions of **Row_Machine_Output** and the current **Column_State**, fetched from the column-state buffer.

The inner-loop code for this implementation is shown below. As always, the two outer loops (not shown) step through the image, one pixel at a time, in raster-scan order. *Each input-image pixel is fetched once. There are no other inner-loop steps.* Note that all lookup-table implementations of SKIPSM operators will have this general form, with the exception of the first two steps, which depend on the operator and the type of image being processed. Although there are more efficient ways to implement these steps using single-index lookup tables, an approach using dual-index tables is presented here because it is the easiest to understand. Again, edge effects are ignored here.

```
// Row machine.
  if (Input_Image[j][i] < Threshold) In = 0;
      // If the input is a grey-scale image, this step converts it to binary so
      that binary erosion
      // can be performed. Thus, this code works with either kind of image.
  else In = 1;
      // Input pixel is ``white.'' Set In to 1.
  Row_Machine_Output = Row_Out_Table[In][Row_State];
      // Fetch the row machine output from the row-machine LUT.
  Row_State = Row_State_Table[In][Row_State];
      // Fetch the next row state from the LUT and update the row-state register.
// Column machine Uses Row_Machine_Output as the column-machine input.
   Output_Image[j-M2] [i-N2] = Column_Out_Table[Row_Machine_Output]
   [Column_State[i]];
       // Fetch result from LUT, write output.
   Column_State[i] = Column_State_Table[Row_Machine_Output]
   [Column_State[i]];
       // Fetch next column state and update column-state buffer.
```

20.7 Gaussian Blurs

Many different low-pass filtering operations are used in image processing – low pass in the sense of passing low spatial frequencies and rejecting high spatial frequencies. These are usually given names suggesting smoothing, averaging, or blurring. One of the most widely-used operations of this type is the so-called Gaussian blur, which has the advantages of being very "smooth" and also circularly symmetric, so that edges and lines in various directions are treated similarly. For machine vision applications, blurring operators are often defined on small neighbourhoods (e.g., 3 × 3, 11 × 11), and for a small finite number of grey levels (e.g., 256). In such cases, the ideal Gaussian "bell curve" must be approximated by a rather small number of integer values. The values are usually based on Pascal's triangle (the binomial coefficients). These approach the true Gaussian curve more and more closely as the number of points increases. However, the execution times of these operations can be rather long, especially where large kernels are involved.

Proper use of two properties of Gaussian blurs can help to reduce these long execution times:

1. Large kernels can be decomposed into the sequential application of small kernels. However, this can result in the accumulation of unacceptable rounding errors.
2. Gaussian blurs are separable into independent row and column operations. The row and column operators can be interchanged, with identical results, except for differences in rounding errors.

   The SKIPSM implementation makes use of both of these characteristics and adds a third one:
3. The row and column operations can be formulated as finite-state machines (FSMs) to produce highly efficient code. Furthermore, for multi-step sequential decompositions, *the necessity of writing results to intermediate buffers and then fetching these results for the next operation is eliminated.* This not only saves time, but eliminates the accumulation of rounding errors and often provides a significantly better approximation to the desired Gaussian "bell" curve.

The 3 × 3 *Gaussian blur*: The SKIPSM 3 × 3 implementation requires two temporary variables, two memory locations for the state of the row machine, and two column state buffers. The column state buffers are set to zero at the start of the overall operation, and the row state registers are set to zero at the start of each row. The inner loop code is given below. The output is written to address [j−1][i−1] because this is the centre of the current 3 × 3 neighbourhood.

Inner loop code for 3 × 3 Gaussian blur with SE rows [1 2 1] [2 4 2] [1 2 1]

```
    Temp1 = Input_Image[j][i]                      // Step 1: input
    Temp2 = Row_State0 + Temp1                     // Step 2: add
    Row_State0 = Temp1                             // Step 3: update
    Temp1 = Row_State1 + Temp2                     // Step 4: add
    Row_State1 = Temp2                             // Step 5: update
    Temp2 = Column_State0[j] + Temp1               // Step 6: add
    Column_State0[j] = Temp1                       // Step 7: update
    Temp1 = Column_State1[j] + Temp2               // Step 8: add
    Output_Image[j-1][i-1] = (Temp1 + 8)/16       // Step 9: output
    Column_State1[j] = Temp1                      // Step 10: update
```

This 3 × 3 SKIPSM implementation requires ten steps. The brute-force approach for this case requires 24 steps (9 dual-index pixel fetches, 5 multiplies, 8 additions, 1 scaling step, and a dual-index "write" to the output image).

The 5 × 5 *Gaussian blur*: [1 4 6 4 1] [4 16 24 16 4] [6 24 36 24 6] [4 16 24 16 4] [1 4 6 4 1]

The SKIPSM 5 × 5 implementation requires two temporary variables, four memory locations or registers for the state of the row machine, Row_State0 through Row_State3, and four column state buffers. The column state buffers are set to zero at the start of the overall operation, and the row state buffers are set to zero at the start of each row. The inner loop code is given below. The output is written to address [j−2][i−2] because this is the centre of the current 5 × 5 neighbourhood.

Inner-loop code for 5 × 5 Gaussian blur

```
// Row machine
    Temp1 = Input_Image[j][i]                      // Step 1: input
    Temp2 = Row_State0 + Temp1                     // Step 2: add
    Row_State0 = Temp1                             // Step 3: update
    Temp1 = Row_State1 + Temp2                     // Step 4: add
    Row_State1 = Temp2                             // Step 5: update
    Temp2 = Row_State2 + Temp1                     // Step 6: add
    Row_State2 = Temp1                             // Step 7: update
    Temp1 = Row_State3 + Temp2                     // Step 8: add
    Row_State3 = Temp2                             // Step 9: update

// Column machine
    Temp2 = Column_State0[i] + Temp1               // Step 10: add
    Column_State0[i] = Temp1                       // Step 11: update
    Temp1 = Column_State1[i] + Temp2               // Step 12: add
    Column_State1[i] = Temp2                       // Step 13: update
    Temp2 = Column_State2[i] + Temp1               // Step 14: add
    Column_State2[i] = Temp1                       // Step 15: update
    Temp1 = (Column_State3[i] + Temp2 + 128)/256 // Step 16: add and normalize
    Column_State3[i] = Temp2                       // Step 17: update
    Output_Image[j-2][i-2] = Temp1                 // Step 18: output
```

This 5 × 5 SKIPSM Gaussian blur implementation requires 18 steps. In comparison, the brute-force approach for this case requires 72 steps (25 dual-index pixel fetches, 21 multiplications, 24 additions, 1 scaling step, and 1 "write" to the output image). The numbers in the block diagram (➲ *Fig. 20.7*) correspond to step numbers in the above code.

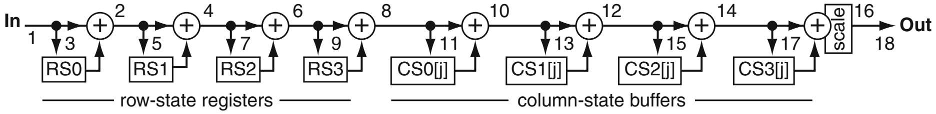

Fig. 20.7
Block diagram for 5 × 5 Gaussian blur in one pass

Difference-of-Gaussian (DoG) filters: The SKIPSM paradigm can be used to apply Difference-of-Gaussian (DoG) band-pass filters in one pass. This involves carrying out two simultaneous concentric Gaussian blurs of different sizes, and subtracting one result from the other. DoG filters can be used to enhance objects or features selectively, according to their size. Thus, they operates in the spatial domain to produce results similar to the effect of a Fourier filter operating in the spatial-frequency domain, but without the excessive time penalty incurred when *two* so-called Fast Fourier Transforms must be applied. However, even though DoG filters are faster than Fourier transforms when only a few spatial-frequency bands need to be detected or enhanced, they are still fairly slow for large diameters. SKIPSM provides a meaningful decrease in DoG filter execution time, compared to conventional implementations of DoG filters. See [13].

20.8 The 4M Filter, a Pseudo-Median 3 × 3 Filter

This example involves a useful filtering operation which has not been widely discussed in the literature. The operation is similar to a median filter, but is faster because the sorting steps required by ranked filters, which are generally very slow, are replaced by a few comparisons.

Definition of the 4M filter: See ➋ *Fig. 20.8*. Two operations are performed simultaneously on the current 3 × 3 neighbourhood, and the results are averaged. The two operations are

1. **min-max** (minimum of the row maximums): Select the *maximum* of each of the three rows in the current 3 × 3 neighbourhood. From these three row values, select the *minimum* value. This is the output of the **min-max** operation.
2. **max-min** (maximum of the row minimums): Select the *minimum* of each of the three rows in the same 3 × 3 neighbourhood. From these three row values, select the *maximum* value. This is the output of the **max-min** operation.

Requirements for storage of state information:

Three registers for row state: Row_State1, Row_State2, Row_State3
Five temporary registers: Temp, Row_Machine_Output1, Row_Machine_Output2, COut1, COut2
Four column state buffers: Column_State1[j], Column_State2[j], Column_State3[j], Column_State4[j], j = 1,. . .,N

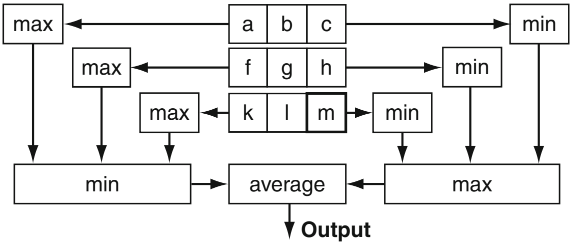

Fig. 20.8
Functional diagram of the 4M filter

Inner loop code for the 4M filter

This code is executed *once* for each input image pixel. There are no other main-loop steps.

```
    Temp = Input_Image[j][i];
    Row_Machine_Output1 = Maximum(Temp,Row_State2);
    Row_Machine_Output2 = Minimum(Temp,Row_State3);
    Row_State2 = Maximum(Temp,Row_State1);
    Row_State3 = Minimum(Temp,Row_State1);
    Row_State1 = Temp;
    COut1 = Minimum(Row_Machine_Output1,Column_State2[j]);
    COut2 = Maximum(Row_Machine_Output2,Column_State4[j]);
    Output[j-1][i-1] = (COut1+COut2)/2;
    Column_State2[j] = Minimum(Row_Machine_Output1,Column_State1[j]);
    Column_State4[j] = Maximum(Row_Machine_Output2,Column_State3[j]);
    Column_State1[j] = Row_Machine_Output1;
    Column_State3[j] = Row_Machine_Output2;
```

The *Minimum* and *Maximum* operators used here involve the comparison of two grey-scale values, and can be implemented in various ways. The individual **min-max** and **max-min** operators, when implemented separately in SKIPSM, are relatively fast. There is a further saving of execution time when they are implemented simultaneously because certain steps can be shared. If the processor being used has an adequate cache, most of the intermediate results will remain in cache, further speeding up the operation.

20.9 "Separable Median Filter"

The so-called "separable median filter" [16, 21, 22] does not produce the true median (rank 5) of the 9 pixels in its 3 × 3 neighbourhood. In spite of this, it can be very useful because it *approximates* the median and is relatively fast compared to a true median filter.

From a philosophical or theoretical standpoint, there is seldom solid justification for insisting on one particular image-processing operation in preference to other similar operations. A typical use of median or other ranked filters is for "cleaning up" images subject to "dropouts," "snow," "salt and pepper" noise, etc. For these applications, it is difficult in most cases to find a convincing argument that the separable median filter (rank 4, 5, or 6) described here is significantly inferior in any meaningful way to the true median filter (rank 5) in most cases. A flexible prototyping system for the development of machine vision algorithms, as advocated and described elsewhere in this handbook, can be used to verify *experimentally* whether a true median filter (rank 5) is required in any particular application, in preference to this "rank 4-5-6" filter. When speed of operation is important, the separable median filter, (which calculates the median of the row medians) is a useful option in the prototyping system, because it has only 11 program steps in the inner loop, making it faster than the rank-5 filter, which has more steps.

➔ *Figure 20.9* shows a functional diagram for this filter. The rectangular boxes in this diagram are three-input sorters, the middle outputs of which are the medians of the three inputs. In practice, three-input sorters are implemented using three two-input sorters. Each two-input sorter uses one if-then-else statement, followed by either the interchanging of

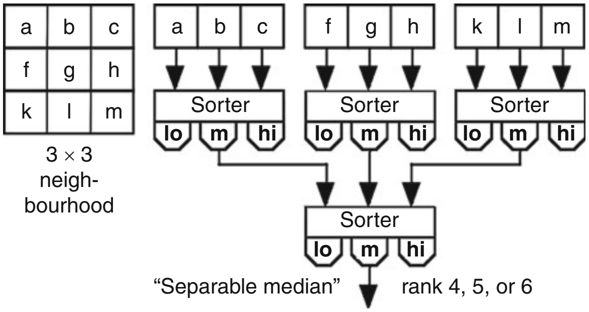

Fig. 20.9
Separable median functional diagram

the two input variables, or leaving them unchanged. This is the operation used in a "bubble" sorter. The three-input sorters used here can be thought of as three-stage bubble sorters in which only the middle output is used, and the other two outputs are ignored.

Figure 20.10 shows the same algorithm in pipelined form: Each pixel is fetched only once, and all information necessary to compute the output is incorporated into the "states" of two finite-state machines (FSMs). Two registers, Row_State0 and Row_State1, are needed to store the state of the row machine. Two column state buffers, Column_State0[i] and Column_State1 [i], each with a number of addresses equal to the number of pixels in an image row, are needed to "remember" the relevant information from the two previous rows. It is sufficient that these registers and buffers have the same word length as the input image, although longer word lengths may be used if more convenient for programming. In the figure, **B** = median (**a**, **b**, **c**), **G** = median (**f**, **g**, **h**), and **L** = median(**k**, **l**, **m**).

The corresponding inner loop code is given below. The numbers in the small grey boxes in the figure refer to the step numbers in the code comments. Because of the 1-pixel offset, the output may be written back into the input image buffer, if desired.

```
// Row machine for ``separable median'' filter
  if (Row_State1 > Row_State0) { Min = Row_State0; Med = Row_State1; }
      // Step 1a: Compare k with l
  else { Min = Row_State1; Med = Row_State0; }
      // Step 1b: Med=max(k,l). Save Min=min(k,l) for step 5
  Row_State1 = Row_State0;
      // Step 2: Update row state register Row_State1; it now contains l
  Row_State0 = Input_Image[j][i];
      // Step 3: Load next pixel into Row_State0; it now contains m
  if (Row_State0 < Med) Med = Row_State0;
      // Step 4: Med = min(m, max(k, l))
  if (Min > Med) Med = Min;
      // Step 5: Med = med(k, l, m). Save for step 8
// Column machine for ``separable median'' filter
   if (Column_State1[i] > Column_State0[i]) { Min = Column_State0[i]; Out =
   Column_State1[i]; }
      // Step 6a: Compare previous medians B and G
```

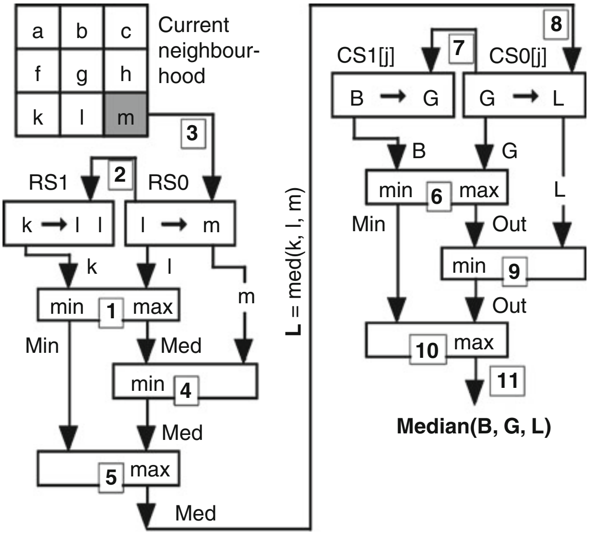

Fig. 20.10
Separable median sequence diagram

```
else { Min = Column_State1[i]; Out = Column_State0[i]; }
    // Step 6b: Result: Out = max(B, G); Min = min(B, G)
Column_State1[i] = Column_State0[i];
    // Step 7: Column state register Column_State1[i] now contains G
Column_State0[i] = Med;
    // Step 8: Column state register Column_State0[i] now contains L
if (Column_State0[i] < Out) Out = Column_State0[i];
    // Step 9: Out = min(L, max(B, G))
if (Min > Out) Out = Min;
    // Step 10: Final output Out = med(B, G, L)
Output_Image[j-1][i-1] = Out
    // Step 11: Write output, with offset to compensate for latency
```

Notations such as **B** → **G** in the register boxes in Fig. 20.10 indicate the register contents *before* inner-loop processing starts (e.g., **B**) and *after* it is completed (e.g., **G**). Note that, as always, once state buffer initializations and edge-effect computations have been completed, these 11 steps are executed once for each pixel in the image. No other steps are required. Note also that the temporary variables **Min**, **Med**, and **Out** are used and reused in such a way as to eliminate the "else" clause from four of the six "if" statements (steps 4, 5, 9, and 10).

Comparison of the SKIPSM "separable median" algorithm with algorithms intended for similar uses but implemented in other ways (See [16] for an extended discussion of this topic): The well-known "bubble-sort" algorithm for a *full ranked filter* (nine ranked outputs) requires 36 conditional-interchange operations, plus all the usual image reads, image writes, etc. A "bubble-sort" algorithm for the *true median* based on the ranked filter but omitting calculation of the other eight ranks requires 30 conditional-interchange operations. Mahmoodi's improved version for the *true median* (private correspondence) reduces this to 19 conditional-interchange operations. A rank 4-5-6 filter based on Mahmoodi's algorithm, which is the starting point for the SKIPSM "separable median" filter (see ➲ *Fig. 20.9*), has 12 conditional-interchange operations, three for each three-input sorter. By saving the previously-computed row medians as part of the column state, the SKIPSM implementation reduces this to only *six* conditional-interchange operations. Furthermore, it eliminates most of the input-image pixel fetches and many of the other intermediate steps used in "brute-force" and "bubble-sort" implementations, resulting in considerably faster execution times.

20.10 Grey-Scale Erosion with a 7 × 7 Diamond

➲ *Figure 20.11* shows the structuring element and sequence diagram for dilation of a grey-scale image with a 7 × 7 diamond-shaped structuring element. The corresponding inner-loop code is given below. The boxes labelled "MN" calculate the minimum of the two inputs.

```
// Row machine for grey-scale erosion with a 7 × 7 diamond:
    P = Input_Image[j][i];                              // Step 1
    R1 = Row_State6;                                    // Step 2
    R2 = Row_State3;                                    // Step 3
    R3 = Row_State1;                                    // Step 4
    R4 = Min(Row_State0,P);                             // Step 5
    Row_State0 = Min(Row_State1,P);                     // Step 6
    Row_State1 = Min(Row_State2,P);                     // Step 7
    Row_State2 = Min[Row_State4,P);                     // Step 8
    Row_State3 = Row_State4;                            // Step 9
    Row_State4 = Min(Row_State5,P);                     // Step 10
    Row_State5 = Min(Row_State8,P);                     // Step 11
    Row_State6 = Row_State7;                            // Step 12
    Row_State7 = Row_State8;                            // Step 13
    Row_State8 = P;                                     // Step 14

// Column machine for grey-scale erosion with a 7 × 7 diamond:
    Output_Image[j-3][i-3] = Min(Column_State0[j],R1); // Step 15
    Column_State0[j] = Min(Column_State1[j],R2);        // Step 16
    Column_State1[j] = Min(Column_State2[j],R3);        // Step 17
    Column_State2[j] = Min(Column_State3[j],R4);        // Step 18
    Column_State3[j] = Min(Column_State4[j],R3);        // Step 19
    Column_State4[j] = Min(Column_State5[j],R2);        // Step 20
    Column_State5[j] = R1;                              // Step 21
```

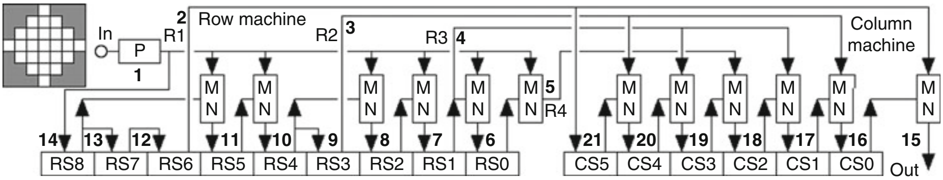

Fig. 20.11
Grey-scale erosion with 7 × 7 diamond

20.11 Grey-Scale Dilation with a 7 × 7 Circle

Figure 20.12 shows the structuring element and sequence diagram for dilation of a grey-scale image with a 7 × 7 circular structuring element. The corresponding inner-loop code is given below. The boxes labelled "MX" in the figure calculate the maximum of the 2 inputs, and 11 such operations are required. These are indicated by "Max" in the code below.

```
// Row machine for grey-scale dilation with a 7 × 7 circle:
    P = Input_Image[j][i];                                    // Step 1
    R1 = Row_State3;                                          // Step 2
    R2 = Row_State2;                                          // Step 3
    R3 = Max(Row_State0,P);                                   // Step 4
    Row_State0 = Max(Row_State1,P);                           // Step 5
    Row_State1 = Max(Row_State2,P);                           // Step 6
    Row_State2 = Max(Row_State4,P);                           // Step 7
    Row_State3 = Row_State4;                                  // Step 8
    Row_State4 = Max(Row_State5,P);                           // Step 9
    Row_State5 = Max(Row_State6,P);                           // Step 10
    Row_State6 = P;                                           // Step 11
// Column machine for grey-scale dilation with a 7 × 7 circle:
    Output_Image[j-3][i-3] = Max(Column_State[j],R1); // Step 12
    Column_State0[i] = Max(Column_State1[j],R2);           // Step 13
    Column_State1[i] = Max(Column_State2[j],R3);           // Step 14
    Column_State2[i] = Max(Column_State3[j],R3);           // Step 15
    Column_State3[i] = Max(Column_State4[j],R3);           // Step 16
    Column_State4[i] = Max(Column_State5[j],R2);           // Step 17
    Column_State5[i] = R1;                                    // Step 18
```

20.12 Automated Generation of Efficient Code for SKIPSM Grey-Scale Image Processing

When the SKIPSM paradigm is applied to grey-scale image-processing operators, either direct code or lookup tables must be created for two finite-state machines (row and column). The computer programs for the creation of lookup tables (**CREATE_ROW_FSM**, etc.) mentioned in Sect. 20.4 are for *binary image processing* only, and therefore are of no use here. In fact, with grey-scale images having more than a few grey levels (16 or so), the lookup-table implementation becomes impractical. Therefore, all of the grey-scale examples presented

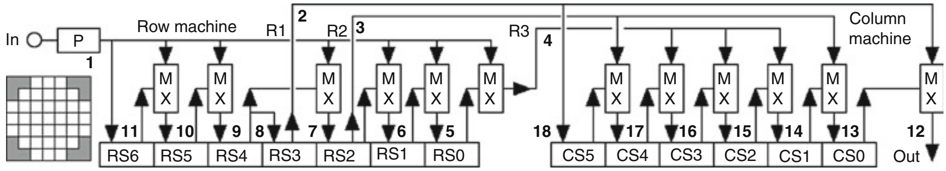

Fig. 20.12
Grey-scale dilation with a 7 × 7 circle

here use *direct* rather than LUT implementations. The essential question then becomes "How does one generate the direct software code for grey-scale applications?" Careful inspection of the examples above shows certain patterns in the column-machine code, but neither guesswork nor intuition could ever lead to the code for the *combined* row machines.

In response to this difficulty, this section presents a *completely routine procedure* for generating efficient compilable C code for *arbitrary operations* (within rather broad limits) on *arbitrary neighbourhoods* specified by the user [25]. No user decisions are required beyond the initial choice of the neighbourhood and of the function to be performed (e.g., grey-scale dilation, grey-scale erosion, area sum, geometric mean, blur, etc.) The specified neighbourhoods may be square or round, "solid" or with holes, connected or disjoint, convex or not convex, and of any size. As a general rule, complex shapes cause more code steps to be generated. There is not enough space here to give the complete routine procedure in detail. Instead, one step-by-step example will be presented.

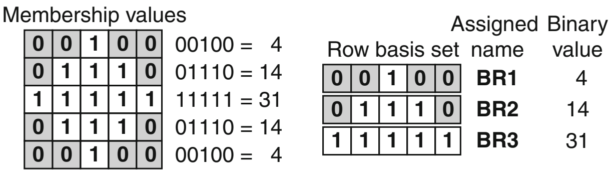
20.12.1 Step 1: Define the Processing Neighbourhood

Start with a user-defined rectangle which is just large enough to encompass all the pixels of interest. ➋ *Figure 20.13* shows the 5 × 5 diamond-shaped processing neighbourhood chosen for this example. Let shaded squares represent pixels within the rectangle which are *not* part of the computation neighbourhood, and assign to them the *membership value* 0 (i.e., MV = 0). Let white squares represent pixels which *are* part of the neighbourhood, and assign to them the *membership value* 1 (i.e., MV = 1). Note that this *does not* imply that binary processing is being done. Ones and zeros are used *only* to indicate that the given pixel belongs to or does not belong to the processing neighbourhood.

Let the membership values for each row (in left-to-right order) be considered as a binary number. Use these numbers to identify and delete all repeated rows. Arrange the non-deleted rows in increasing numerical order. Call this the *row basis set*. In this example there are three rows in the row basis set. Arbitrarily assign names to the three basis rows. Here, the names **BR1**, **BR2**, and **BR3** are used.

20.12.2 Step 2: Create the Preliminary Code

For each of the basis rows, create a sequence of code statements of the form shown below, with as many *code lines* as there are *pixels in the basis row* (including *don't care* pixels), starting with the row having the highest binary value and continuing in descending order of binary value. For each row machine, the right-hand side of the bottom row is always either **G**{P, **null** | 0} or **G** {P, **null** | 1}, where **G** is the special *SKIPSM Generator Function* defined below. The rows above



Membership values

0	0	1	0	0	00100 = 4
0	1	1	1	0	01110 = 14
1	1	1	1	1	11111 = 31
0	1	1	1	0	01110 = 14
0	0	1	0	0	00100 = 4

Row basis set					Assigned name	Binary value
0	0	1	0	0	**BR1**	4
0	1	1	1	0	**BR2**	14
1	1	1	1	1	**BR3**	31

Fig. 20.13
Membership function and row basis set

the bottom rows are “chained” in the sense that the left-hand side of each code line is the second arguments of **G** for the code line above it, with the first argument always being the current input pixel grey value **P**. The actual neighbourhood being implemented is then determined by the 0s or 1s which are inserted as the parameter after the “|” in the function **G** in accordance with the corresponding membership value MV (0 or 1). These membership values are *the only user input* to the code-generation process, other than the original user choice of the 5 × 5 neighbourhood and the choice of the functions **F**r and **F**c, defined below. All the remaining steps are automatic. Here is the resulting preliminary code:

```
R3 = G{ P, Row_State3_0 | 1 };          // Output of row machine 3, to column
                                        machine
Row_State3_0 = G{ P, Row_State3_1 | 1 };
Row_State3_1 = G{ P, Row_State3_2 | 1 };
Row_State3_2 = G{ P, Row_State3_3 | 1 };
Row_State3_3 = G{ P, null | 1 };        // Input to row machine 3, from input
                                        image

R2 = G{ P, Row_State2_0 | 0 };          // Output of row machine 2, to column
                                        machine
Row_State2_0 = G{ P, Row_State2_1 | 1 };
Row_State2_1 = G{ P, Row_State2_2 | 1 };
Row_State2_2 = G{ P, Row_State2_3 | 1 };
Row_State2_3 = G{ P, null | 0 };        // Input to row machine 2, from input
                                        image

R1 = G{ P, Row_State1_0 | 0 };          // Output of row machine 1, to column
                                        machine
Row_State1_0 = G{ P, Row_State1_1 | 0 };
Row_State1_1 = G{ P, Row_State1_2 | 1 };
Row_State1_2 = G{ P, Row_State1_3 | 0 };
Row_State1_3 = G{ P, null | 0 };        // Input to row machine 1, from input
                                        image
```

Notation: Row_State3_0 denotes the first row-state register for row machine 3, Row_State3_1 denotes the second row-state register for row machine 3, etc. R3, R2, and R1 are the row-machine outputs. Note that there are 12 state variables and three outputs.

➲ *Figure 20.14* shows the functional diagram corresponding to this code, which applies to all 5 × 5 SEs with three basis rows. Initially, there is one memory location or register for each row state variable. This is the only memory required for the combined row machine, and (as will be seen below) some of these registers will be eliminated.

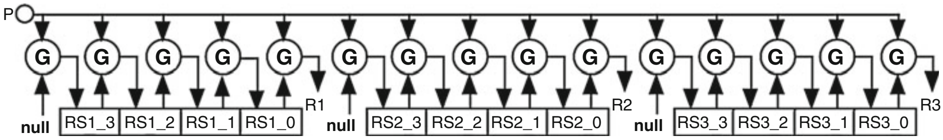


Fig. 20.14
Preliminary diagram for the three generic row machines

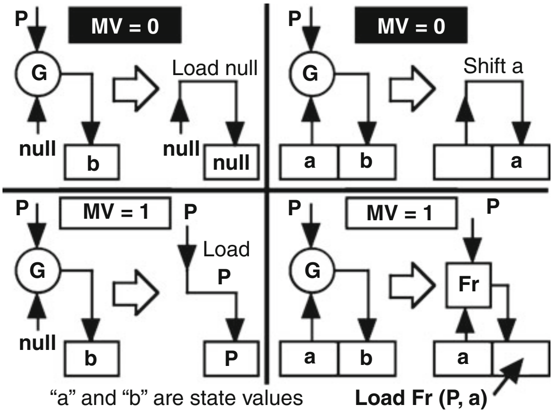

Fig. 20.15
Rules for evaluating G-functions

This code is NOT the final code. It is only the first routine step in the generation of the code. After a series of transformations and simplifications following the deterministic rules given below, these steps will be transformed into executable C-code for the combined row machine, which implements all three row machines.

20.12.3 Step 3: Evaluate G and Propagate the Null

To complete the C-code for these row machines, the generator function **G** must be evaluated according to these rules, also shown graphically in *Fig. 20.15*:

$$\begin{array}{l|l} \mathbf{G}\{\text{P}, \mathbf{null}|0\} = \mathbf{null} & \mathbf{G}\{\text{P}, \text{Row\_StateX}|0\} = \text{Row\_StateX} \\ \hline \mathbf{G}\{\text{P}, \mathbf{null}|1\} = \text{P} & \mathbf{G}\{\text{P}, \text{Row\_StateX}|1\} = \mathbf{Fr}(\text{P}, \text{Row\_StateX}) \end{array}$$

The row-machine function **Fr** specifies the image-processing operation being performed on the rows; e.g., addition, maximum, minimum, etc. **Fr** and the corresponding column-machine function **Fc** will be discussed later. In practice, **Fr** and **Fc** are often the same function, but this is not *necessary*. For example, a minimum-maximum function would use **Fr** = minimum(A,B) and **Fc** = maximum(P,Q).

The **null** variable plays an essential role here: When the input to a register is **null** for whatever reason, *that register itself is eliminated*, and the **null** is passed on to the next-stage **G** function. This is called *propagating the* **null**, and leads to a reduction in the number of registers and hence computing steps. To propagate the **null**, start at the **bottom** of the list for each row machine, and apply the rules for **G**. Then move **up** the list, propagating the **null** as far as it will go.

The resulting code is fully functional at this point. However, when there is more than one row machine, a new possibility arises: Instead of simply computing all the row machines separately, in parallel or sequentially, it is usually possible to reduce the number of state registers (and thus computational steps) by combining expressions with identical right-hand sides. This will now be done for this example.

20.12.4 Step 4: Simplify Recursively

Propagating the **nulls** and evaluating the **G** functions for this example (and using a strikethrough to mark the **null** lines for deletion) gives the code shown in Stage 1 below. Notice that lines 5, 9, and 13 all have the same right-hand side, and hence define states which are always identical. We choose to retain the first state name (Row_State3_3) and discard the other two, after first replacing Row_State2_2 and Row_State1_1 by Row_State3_3 everywhere.

// Stage 1 of simplification

```
// Row machine 1
R3 = Fr ( P, Row_State3_0 ) ;
Row_State3_0 = Fr ( P, Row_State3_1 ) ;
Row_State3_1 = Fr ( P, Row_State3_2 ) ;
Row_State3_2 = Fr ( P, Row_State3_3 ) ;
Row_State3_3 = P ;
// Row machine 2
R2 = Row_State2_0 ;
Row_State2_0 = Fr ( P, Row_State2_1 ) ;
Row_State2_1 = Fr ( P, Row_State2_2 ) ;
Row_State2_2 = P ;
~~Row_State2_3 = null;~~
// Row machine 3
R1 = Row_State1_0 ;
Row_State1_0 = Row_State1_1 ;
Row_State1_1 = P ;
~~Row_State1_2 = null;~~
~~Row_State1_3 = null;~~
```

Stage 2 shows the result of substituting Row_State3_3 for Row_State2_2 and Row_State1_1 and deleting the null steps (lines 10, 14, and 15). We note that lines 9 and 13 are now duplicates of line 5, and mark them for deletion with strikethroughs. We note further that, because of the substitutions, lines 4 and 8 have the same right-hand side. Therefore, states Row_State3_2 and Row_State2_1 can be merged into one state.

// Stage 2 of simplification

```
// Row machine 1
R3 = Fr ( P, Row_State3_0 ) ;
Row_State3_0 = Fr ( P, Row_State3_1 ) ;
Row_State3_1 = Fr ( P, Row_State3_2 ) ;
Row_State3_2 = Fr ( P, Row_State3_3 ) ;
Row_State3_3 = P ;
// Reduced row machine 2
R2 = Row_State2_0 ;
Row_State2_0 = Fr ( P, Row_State2_1 ) ;
Row_State2_1 = Fr ( P, Row_State3_3 ) ;
~~Row_State3_3 = P ;~~
// Row_State3_3 replaces Row_State2_2
// Reduced row machine 3
R1 = Row_State1_0 ;
Row_State1_0 = Row_State3_3 ;
~~Row_State3_3 = P ;~~
// Row_State3_3 replaces Row_State1_1
```

Stage 3 shows the result of deleting lines 9 and 13, replacing Row_State2_1 everywhere by its equivalent state Row_State3_2, and marking line 8 (which is now identical to line 4) for deletion. We *now* notice that lines 3 and 7 have the same right-hand side. Therefore, states Row_State3_1 and Row_State2_0 can be merged into one state.

// Stage 3 of simplification

```
// Row machine 1
R3 = Fr( P, Row_State3_0 );
Row_State3_0 = Fr( P, Row_State3_1 );
Row_State3_1 = Fr( P, Row_State3_2 );
Row_State3_2 = Fr( P, Row_State3_3 );
Row_State3_3 = P ;
// Reduced row machine 2
R2 = Row_State2_0 ;
Row_State2_0 = Fr( P, Row_State3_2 );
~~Row_State3_2 = Fr( P, Row_State3_3 );~~
// Row_State3_2 replaces Row_State2_1
// Reduced row machine 3
R1 = Row_State1_0 ;
Row_State1_0 = Row_State3_3 ;
```

Stage 4 shows the result of deleting line 8, replacing Row_State2_0 by Row_State3_1, and marking line 7 for deletion.

// Stage 4 of simplification

```
// Row machine 1
R3 = Fr( P, Row_State3_0 );
Row_State3_0 = Fr( P, Row_State3_1 );
Row_State3_1 = Fr( P, Row_State3_2 );
Row_State3_2 = Fr( P, Row_State3_3 );
Row_State3_3 = P ;
// Reduced row machine 2
R2 = Row_State3_1 ;
~~Row_State3_1 = Fr( P, Row_State3_2 );~~
// Row_State3_1 replaces Row_State2_0
// Reduced row machine 3
R1 = Row_State1_0 ;
Row_State1_0 = Row_State3_3 ;
```

Stage 5 shows the almost-final code, with line 7 deleted. Since there are no more duplicated right-hand sides, no further reductions are possible. However, the cumbersome state names, needed for the generic formulation, can be replaced, if desired, by something simpler.

// Stage 5 of simplification

```
R3 = Fr( P, Row_State3_0 );
Row_State3_0 = Fr( P, Row_State3_1 );
Row_State3_1 = Fr( P, Row_State3_2 );
Row_State3_2 = Fr( P, Row_State3_3 );
Row_State3_3 = P ;
R2 = Row_State3_1 ;
R1 = Row_State1_0 ;
Row_State1_0 = Row_State3_3 ;
// Optional step: Rename the states:
Row_State3_0 = Row_State0,
Row_State3_1 = Row_State1,
Row_State3_2 = Row_State2,
Row_State1_0 = Row_State3,
Row_State3_3 = Row_State4
```

This is done in the column headed by *Necessary final step*, in which the code lines have been rearranged so that *all* appearances of a state variable on the *right-hand side* of an expression occur in the list *above* its appearance on the left-hand side. This is necessary so that all the occurrences of the *current* values appearing in the code are used for the current computations *before* they are updated due to the arrival of the next pixel value from the raster scan of the input image. The order shown is one of the possible ways to do this.

// Necessary final step:

```
// Rearrange the code so that every use of a variable (right-hand side)
// is executed before the updating of that variable (left-hand side).
R3 = Fr( P, Row_State0 );
R2 = Row_State1 ;
R1 = Row_State3 ;
Row_State0 = Fr( P, Row_State1 );
Row_State1 = Fr( P, Row_State2 );
Row_State2 = Fr( P, Row_State4 );
Row_State3 = Row_State4 ;
Row_State4 = P ; // Next input pixel.
```

After **null** propagation, the original code for the three separate row machines had 12 states, and thus 12 registers and 15 lines of code. This has been reduced to five registers and eight lines

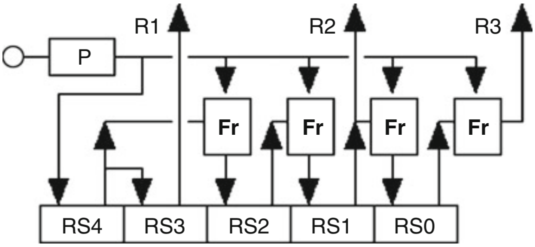

Fig. 20.16
Combined row machine

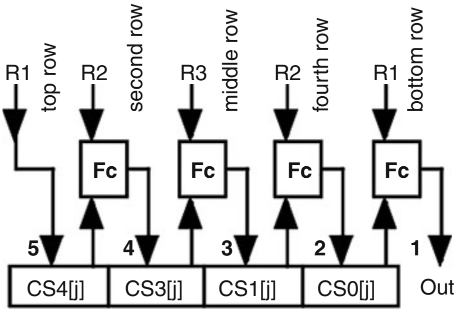

Fig. 20.17
Column machine

of code. More importantly, the number of **Fr** steps, which are often computationally intensive, has been reduced from *six to four*. *Figure 20.16* shows a block diagram corresponding to this code.

20.12.5 Step 5: Create the Column Machine

Compared to combined row machines, column machines are very straightforward. *Figure 20.17* shows the result for this case, as well as the general pattern: The number of column state buffers is always one fewer than the number of rows in the neighbourhood. Each receives its input from the row machine corresponding to its row pattern via the functional block **F**c, which is the function appropriate to the operation being performed. The sequence is right-to-left in the diagram, as indicated by the little numbers. (As always, one must "read before writing.") Here is the corresponding code:

```
Output_Image[j-2][i-2] = Fc( R1, Column_State0[j]);
Column_State0[j]       = Fc( R2, Column_State1[j]);
Column_State1[j]       = Fc( R3, Column_State2[j]);
Column_State2[j]       = Fc( R2, Column_State3[j]);
Column_State3[j]       = R1;
```

Because of the top-to-bottom symmetry of the neighbourhood in this particular example, one can not tell from this diagram which order (left-to-right or right-to-left) the row-machine outputs should be applied, so the diagram includes this information also. This is the pattern, in general, for all five-row column machines.

Comments on functions **F**r *and* **F**c: A wide range of operators may be used for **F**r and **F**c. Examples: maximum, minimum, addition, multiplication, exponential decay. Some other operators *will not work*. Examples: subtraction, division, median (or any rank *except* maximum and minimum). The sole requirement on the functions is that they have what could be called a uni-directional associative property, defined thus: Let a, b, c, d, e, f, g, . . . denote a string of pixels *presented in raster-scan order*. Then, for **F**r to be used with a recursive implementation such as SKIPSM, **F**r must satisfy

$$\mathbf{F}\mathrm{r}(c, \mathbf{F}\mathrm{r}(b, a)) = \mathbf{F}\mathrm{r}(c, b, a), \quad \mathbf{F}\mathrm{r}(d, \mathbf{F}\mathrm{r}(c, \mathbf{F}\mathrm{r}(b, a))) = \mathbf{F}\mathrm{r}(d, c, b, a), \quad \text{etc.}$$

The uni-directional requirement is just another way of saying that the functions need not be commutative. Most operators of interest are both associative and commutative, but this is not necessary.

Examples which meet the uni-directional associative condition:

Fr = Addition	$c + (b + a) = c + b + a$
Fr = Multiplication	$c \bullet (b \bullet a) = c \bullet b \bullet a$
Fr = Maximum	Maximum(c, Maximum(b, a)) = Maximum(c, b, a)
Fr = Minimum	Minimum(c, Minimum(b, a)) = Minimum(c, b, a)

Examples which fail to meet the condition:

Fr = Subtraction	$c - (b - a) \neq c - b - a$
Fr = Median	Median(c, Median(b, a)) may not equal Median(c, b, a)

The column function must meet the same condition. Let A, B, C, D, E, . . . represent row-machine outputs presented to the column machine in raster-scan order: Then **F**c(C, **F**c(B, A)) must equal **F**c(C, B, A), etc. **Fr** and **Fc** are usually the same function, but this is not necessary. For example, **Fr** = Minimum, **Fc** = Maximum is a useful combination. (See the 4M filter example in ➔ Sect. 20.8.)

20.13 Speed Comparisons

In the late 1990s, comparison tests were made for three examples to estimate the relative execution speeds of SKIPSM implementations versus conventional implementations. As the reader will note from the discussion below, familiar measures of computing power (such as processor speed) turned out to be not particularly reliable in estimating the relative speeds of the various implementations. Computer *architecture* seems to play an important role, not just raw computing power. Ideally, similar tests would be performed using currently-available computing platforms and architectures, in order to get a realistic picture of what speeds one could expect today. However, there is neither budget nor equipment available to perform these tests. Therefore, the conclusions about relative speeds should be taken as *indications* of what one might expect, but should not be considered as definitive.

Test 1 – Gaussian Blur: One set of tests was for Gaussian blurs. Because the tests were made some years ago, computing platforms which are now obsolete were used. Nonetheless, the *relative-speed* results are still valid. A comparison was made between SKIPSM and two other approaches for implementing Gaussian filters. The "brute force" technique used the 5 × 5 kernel given below. In order to get a filtered pixel value, 25 multiplications and 24 additions are needed.

1	4	6	4	1	Normalizing constant: 256
4	16	24	16	4	
6	24	36	24	6	
4	16	24	16	4	
1	4	6	4	1	

The second approach used the usual one-dimensional decomposition [1 4 6 4 1] and [1 4 6 4 1]-transposed.

Each program was compiled using the DOS port of GCC (DJGPP) using -O3 for optimization. No attempt was made to use the special Pentium® compiler with -O6 optimization but results would probably be around 10–15% faster with it. The different approaches were all tested on a PC-compatible computer using a 166 MHz AMD K6 CPU with 512 KB of secondary cache and 64 MB of memory under Windows 95®. There were a number of background processes running which may have increased times slightly but would not invalidate the comparisons since all tests were performed under the same conditions. Given that the execution times for a single image were under a second for all of the approaches, processing was repeated on the input image as needed so that the total time was on the order of 1 min. The average times for each iteration were calculated for the three different methods, and are as follows:

Implementation approach	Execution time per iteration
5 × 5 conventional convolution	919 ms
5 × 5 decomposition	450 ms
5 × 5 SKIPSM	108 ms

As expected, implementing the Gaussian blur filter through standard convolution was relatively slow. Decomposition was about twice as fast. But the best results by far were obtained with the SKIPSM approach, which was almost nine times as fast as standard convolution. The speed advantages of the SKIPSM implementation should be even greater for larger values of N.

Test 2 – Binary morphology with large rectangular structuring elements: Speed comparisons were made between the SKIPSM LUT method, the SKIPSM direct-code method, sequential decompositions, and "brute force" code (rectangles only). All tests were on 512 × 512 images. Averages were taken over 500 repeats of each operation. The system used was a Micron Millennia Mme, model Anchorage-233M-T, with 160 MB of RAM and an Intel Pentium MMX with a chip clock speed of 233 MHz and a bus clock speed of 66 MHz. This system has 512 KB of Level 2 SRAM cache and 640 KB of system RAM cache. The operation system was Windows 95 version 4.00.1111, booted in DOS mode. Code was compiled using DJGPP Rhide with no options set.

Comments on "brute-force" code: For each input pixel, this code fetches and examines all the pixels in the M×N neighbourhood, *but stops as soon as it finds a black pixel.* This is a "smart" way to do brute-force processing, possible with binary erosion but not with most other operations. However, it makes the timing very dependent on the number of object (white) pixels in the image. The image used for these timing tests happened to have relatively few white pixels. Therefore, the results (➋ *Fig. 20.18*) should be taken as very optimistic for the "brute force" code. The times for all the other methods are dependent on the *size of* the image but totally independent of the *content* of the image.

These results were surprising. We expected the direct SKIPSM code to be fast, as software implementations go, but we did not expect that in some cases it would be 25% faster than the LUT method, which until then had always been the "speed champion," consistently outperforming both "brute-force" methods and sequential decompositions for morphological operations. Additional comment: In some later tests (with a faster PC, but still ancient by today's standards) speeds exceeding 30 frames/s were achieved on similar operations.

However, note that for sufficiently large non-rectangular SEs the SKIPSM LUT method does *not* slow down measurably, but the direct-code method does. Thus, for large or complex

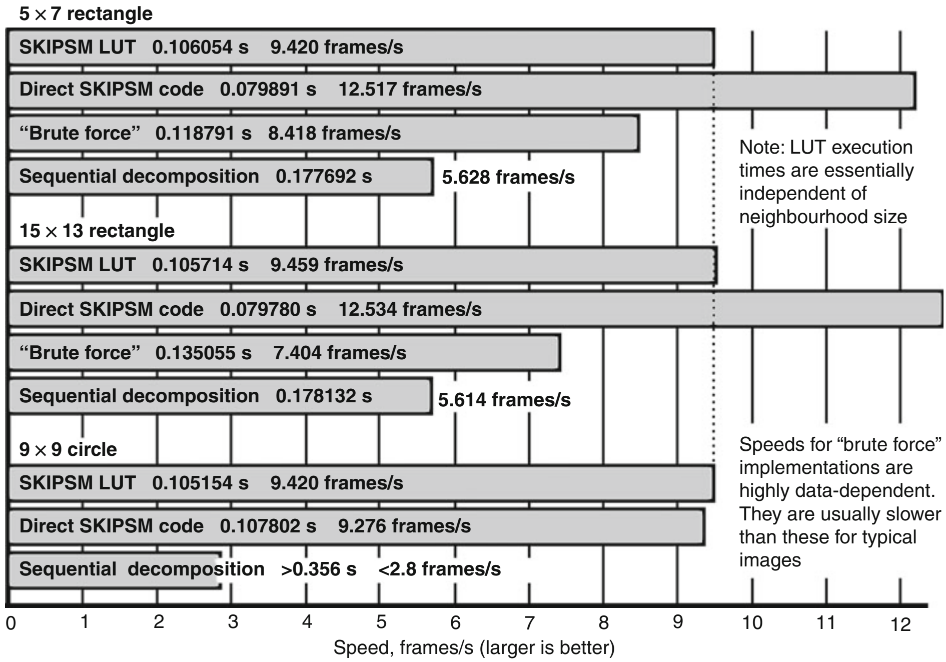

Fig. 20.18

Execution speed comparisons for binary morphology. Longer bars indicate faster execution

SEs, the LUT approach will again win out. This expectation is supported by the results in these tests. The dotted line overlaid on *Fig. 20.18* shows that execution times of the three SKIPSM LUT implementations (neighbourhood sizes 5 × 7 = 35, 15 × 13 = 195, and 9 × 9 = 81) were only trivially different, and hence are approximately independent of neighbourhood size. We suspect that part of the reason for the slower-than-expected times for the LUT method results from the fact that the Intel MMX vector technology used for these comparisons generally does a poor job with lookup tables, so that the speed increases hoped for with MMX increase the speed of direct implementations but do not materialize for the LUT implementations.

It would be ideal for SKIPSM implementations of all types (not just this one), if the chip architecture allowed at least part of the high-level chip cache to be dedicated to functions *specified by the user*. For the class of applications described here, the column state buffer would be left in cache at all times. For other SKIPSM applications, the lookup tables would be placed there. This is not likely to happen, because such partial dedication of the cache space requires additional on-chip cache-management hardware, which vendors are unwilling to provide.

Also, it would be interesting to see how these approaches would compare if a RISC machine were used. These tests have not been made. In earlier tests in which direct comparisons were made, Macintosh computers based on PowerPC RISC chips significantly and consistently outperformed Intel CISC chips of comparable clock speeds.

Conclusions: Speed comparisons for additional image-processing operations would be desirable, but it could be argued that additional tests are really not necessary, because it is easy to count the number of code steps in the inner loop in various implementations to get a *very* good idea of comparative speeds. Conventional implementations typically have more steps that their SKIPSM counterparts.

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_21,

Abstract: QT is the latest in a series of interactive image processing tool-kits for prototype development of Machine Vision systems. Experience gained over more than 35 years has shown that a command-line system with short mnemonic function names is an effective tool for developing vision algorithms. Parameter lists are also required for some functions. When the user types a command, such as *neg* (negate), *thr(89,127)* (threshold) or *lpf* (low-pass filter, blur), the operation is performed immediately and the result is displayed, together with the image before processing. When running on a modern computer, typical response times for processing an image of good resolution are rarely more that one second. Measurements are obtained in an obvious way. For example, to count the number of distinct objects (blobs) in a binary image, the user types $x = cbl$, while the command $y = avg$ computes the average intensity in a grey-scale image. Binary, grey-scale and colour images are all processed by QT, which is built on top of MATLAB™. The advantage of QT over MATLAB lies in its greater ease of use. The command names are short but most importantly, the user does not have to keep track of source and destination images. QT always processes the image displayed on the left of the computer screen. It then replaces this with the result of the operation selected by the user and displays the input image for the last processing step on the right. In addition, to image processing commands, QT provides facilities for a range of other operations, including image capture from local or remote cameras, controlling external devices, speech synthesis, on-line documentation, consulting the Catalogue of Lighting-Viewing methods (➲ Chap. 40). Any MATLAB function can be invoked from QT and programming new functions is straightforward. Many of the illustrations in the book were prepared using QT and several chapters exploit its ability to express image processing algorithms succinctly. Since it is a prototyping tool, QT is not fast enough for any but the least demanding factory applications. However, it is a powerful exploratory tool in the hands of an experienced user. On numerous occasions, QT or one of its predecessors, has been used to discover/invent algorithms very quickly in response to new visual inspection and control applications. QT has been interfaced to Prolog to produce an even more powerful language (PQT) that facilitates intelligent reasoning about images (➲ Chap. 23).

21.1 Introduction

QT is a software package for interactive image processing and was specifically designed to assist in the development of prototype Machine Vision systems. It allows rapid selection and testing of image processing algorithms and provides a large repertoire of easily executable operators: simply type the name of the appropriate function and, if necessary, a short list of control parameters. QT's antecedents were originally used exclusively in laboratory studies of tasks relating to Automated Visual Inspection and were successful in demonstrating feasibility in a very wide range of applications. Later, similar systems were used to control robotic devices, again in the laboratory. There has always been a clear distinction between target systems that are installed in a factory and prototyping systems, like QT, that are used to design them. Interactive image processing systems are also valuable for education, training and convincing potential investors in this technology. However, there is also a need for easily programmable, multi-function vision systems that can be used in factory-floor experiments. These are often required to convince sceptical managers who fear that this technology is unproven, unreliable, or impractical. While QT has the image processing capability for this purpose, the software must be able to control the appropriate hardware: lamps, cameras, solenoids, relays, lathes, machines for drilling, cutting, grinding, moulding, spraying, polishing, parts handling, etc. and even multi-axis robots. Ideally, we would like to provide QT with a "universal" interface module that would allow it to be connected immediately to any type of external device but clearly this is impossible. However, it is possible to provide it with a versatile interface module that allows it to operate a wide range of types of external equipment.

QT is the most recent in a family of similar systems, originating with SUSIE (Southampton University, 1976) [1] and including Autoview (British Robotics Systems Ltd.) VCS (Vision Dynamics Ltd.) [8], System 7 (3M Company), SuperVision (Image Inspection Ltd.), Prolog+ (Cardiff University) and PIP (Cardiff University) [4]. QT has been implemented using the MATLAB Image Processing Toolbox and employs MATLAB's programming syntax [MATLAB, Mathworks, Inc, URL http://www.mathworks.com/, accessed 26th November 2009]. QT employs the same function names as its predecessors, just mentioned. It is possible to extend QT indefinitely, simply by writing additional MATLAB M-files and placing them in the appropriate folder.

A copy of QT is supplied with this Handbook. The latest version of the software and a number of other utilities for Machine Vision system design, can be accessed by visiting http://bruce.cf.cs.ac.uk

21.2 Paradigm for Interactive Image Processing

Unlike many image processing systems, QT uses and displays only two images, called *Current* and *Alternate* (➋ *Fig. 21.1*). The *Current* Image is always displayed on the left and the *Alternate* Image on the right. When a typical command, such as *neg* (negate) is typed, the following happens:

1. The *Current* Image is copied into the *Alternate* Image. The original contents of the *Alternate* Image are discarded.
2. The specified operation is performed on the *Current* Image.
3. The result (negative image) is then stored in the *Current* Image.
4. The revised *Alternate* Image is also displayed alongside the Current Image.

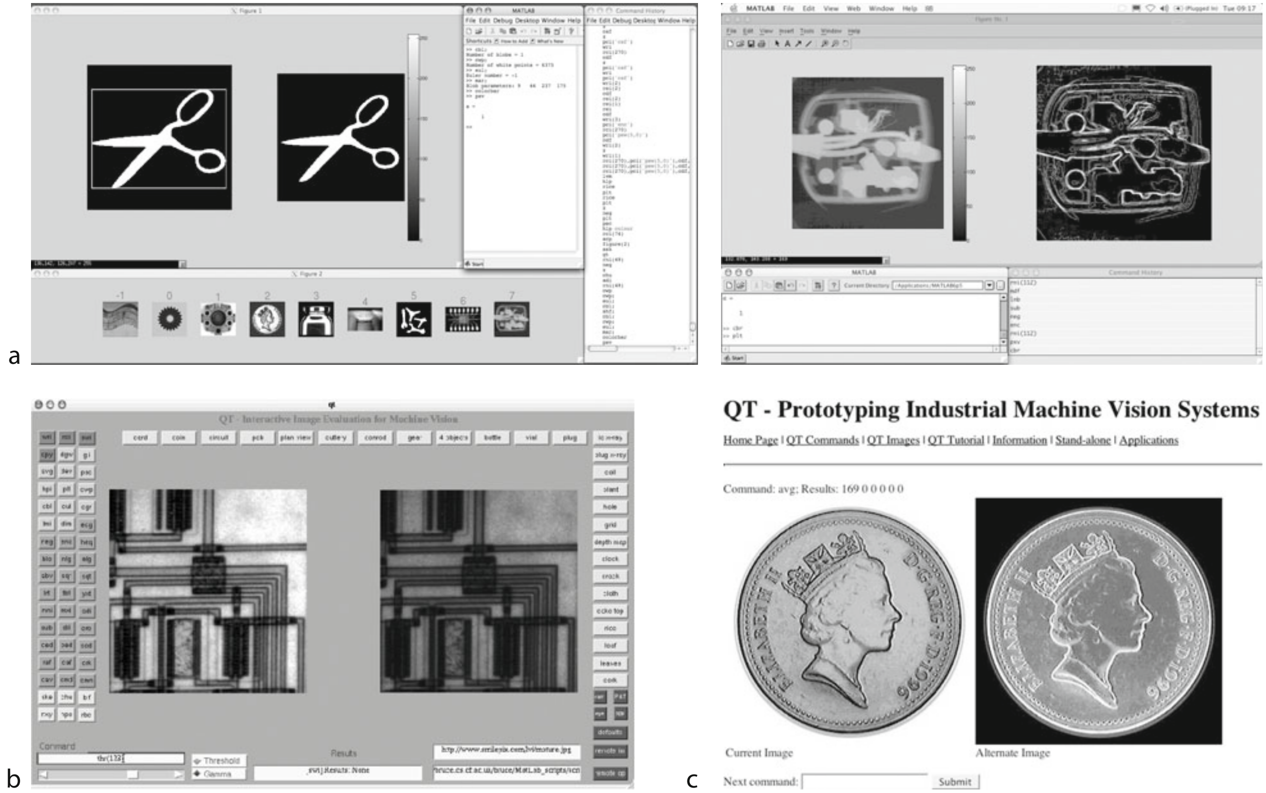
See ➋ *Fig. 21.2* Thesholding (function *thr*) requires zero, one or two parameters; the following are typical commands:

• *thr(123,234)*	Two arguments supplied
• *thr(156)*	Second argument is, by default, assumed to be 255 (white)
• *thr*	First argument default value is 128. Second is 255.

thr, with and without arguments, *neg* and most other QT commands, rely on the *Current-alternate* operating paradigm. However, there are some deviations from this model, reflecting the different types of operators. There are five other situations to consider:

(a) Some commands return values calculated from the Current Image but do not alter it, nor the Alternate Image. For example, *avg* computes the average grey level. Neither image is modified during this calculation.

(b) Some commands generate images. For example, *gsn* generates a random image from a Gaussian noise source. In this case, the *Current* Image is first copied to the *Alternate* Image. The *Current* Image is then replaced by the Gaussian noise image. This is, of course, compatible with the operation of the majority of commands, such as *neg*. Reading an image from a disc file is also performed in this way.



```
>> cbl;
Number of blobs = 1
>> cwp;
Number of white points = 6375
>> eul;
Euler number = -1
>> mar;
Blob parameters: 9   44  237  175
>> colorbar
>> pev

a =

     1

>>
```

QT - Prototyping Industrial Machine Vision Systems

Home Page | QT Commands | QT Images | QT Tutorial | Information | Stand-alone | Applications

Command: avg; Results: 169 0 0 0 0 0

Current Image

Alternate Image

Next command: Submit

■ Fig. 21.1

QT control/display screens. (a) The Current Image is the large image on the *left*. The Alternate Image is on the *right*. The image stack is displayed, in part, as a set of thumbnails. (b) Window mode provides control buttons to read standard images and perform popular functions. Notice too the slide controls for thresholding and gamma adjustment

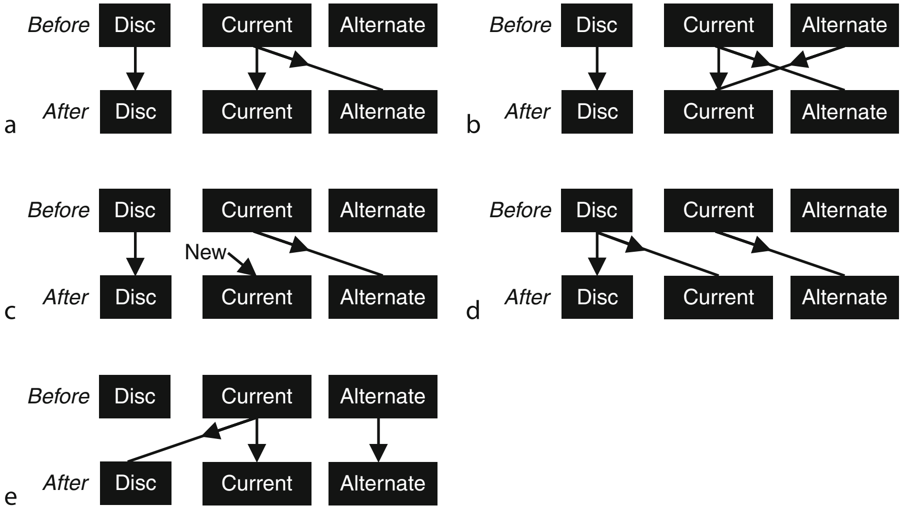

Fig. 21.2
Mapping the Current and Alternate Images during execution of QT functions. (a) Most commands behave in this way (e.g., *neg, thr, caf, chu*). (b) Image generators. (e.g., *gsn, hic, wgx*). (c) Dyadic operators (e.g., *adi, sub, mxi, mni*). (d) Reading images (e.g., *rei, rni, rci*). (e) Saving images (e.g., *wri*)

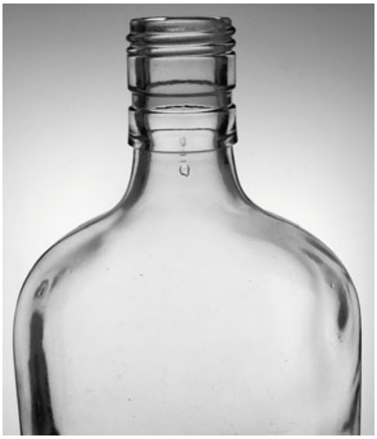

Fig. 21.3
Glass bottle, viewed with back lighting

(c) Commands that write images to a disc file do not alter either image.
(d) A few commands, such as *scp* (plot RGB scattergram) generate a new display window (MATLAB refers to this as Figure 4), without altering either the *Current* or *Alternate* Image.

> *Note*: The user should close MATLAB's Figure 4 before typing the next command, otherwise the results will be placed there, rather than the customary display window: MATLAB's Figure 1.

(e) A few commands combine the *Current* and *Alternate* Images. For example, function *adi* adds the intensities of pixels at corresponding addresses in the *Current* and *Alternate* Images. In such cases, the result is placed in the *Current* Image and the original *Current* Image is copied into the *Alternate* Image, whose original contents are discarded.

21.3 Command Syntax

QT commands can be concatenated as in the following example:

- ► wri(100), dil, ero, rei(100), sub, enc% Performs grey-scale edge detection using morphology

Alternatively, when writing new MATLAB scripts or functions, individual commands can be written on separate lines, with optional comments added as illustrated below:

```
wri(100)        % Write the Current Image to disc file 100.jpg
dil,            % Dilation using default parameters
ero             % Erosion using default parameters
rei(100),       % Read image file 100.jpg
sub,            % Subtract the Alternate Image from the Current Image
enc             % Enhance contrast
```

Notice that commas can be included at the end of each line but are not necessary. (Semicolons, which will be considered next, would have no effect in this example.)

Some commands generate numerical results. For example *avg* calculates the average intensity, which can be used by a later command. The following command sequence shows how this is achieved:

$$x = avg,\ \ thr(x)$$

avg calculates the average intensity and *thr* performs simple thresholding. Notice the comma separating these two commands. The effect of this comma is to allow MATLAB to display the value of the newly assigned variable (x). This is a design feature of MATLAB. To suppress the display of this variable, we must use a semi-colon instead:

$$x = avg;\ \ thr(x)$$

If we wish to place these commands on separate lines to make reading easier, the semi-colon again suppresses the display of the values for x:

```
x = avg;                 % The value of x is not displayed
thr(x)                   % Threshold at level x
```

Whole images can be assigned using a construction of the form

$$\text{current} = \text{original}$$

> *Warning*: This displays the intensities for the whole image, pixel by pixel. For a colour image, there are three values displayed for each pixel. This is a lot of data and the command takes a long time to execute!

To suppress the output display, use a semi-colon:

$$\text{current} = \text{original};$$

Some commands generate several output values, as the following example shows (This is the heart of the function *nxy*, which normalises the position of a blob so that its centroid lies at the centre of the image.)

```
[x1,y1] = cim          % No semi-colon, so the values of x1 and y1 are
                         displayed.
[x2,y2] = cgr          % No semi-colon, so the values of 2x and y2 are
                         displayed.
q = round(x1-x2);      % Standard MATLAB rounding functions. Output is
                         suppressed.
p = round(y1-y2);      % Standard MATLAB rounding functions. Output is
                         suppressed.
current = original;    % Take care to place a semi-colon here to avoid long
                         delays.
psw(p,q)               % Shift image horizontally by p pixels and
                         vertically by q pixels.
```

21.4 Image Formats

QT uses the following image representations:

Monochrome images (i.e., grey-scale images): 2-dimensional MATLAB arrays of 8 bit integers. Black is 0 (zero) and white is 255. Individual pixels in the *Current* Image can be accessed thus;

$$x = \text{current}(y - \text{address},\ x - \text{address})$$

> *Warning*: This is contrary to conventional mathematical notation. QT and its predecessors follow the normal convention that the *x*-address precedes the *y*-address. Hence, it is better to use the QT functions *civ* and *siv* when accessing individual pixels; we can use
> $x = \mathit{civ}\ (x - \text{address},\ y - \text{address})$
> and
> $\mathit{siv}\ (x - \text{address},\ y - \text{address},\ \text{intensity})$
> to read and set individual pixels in the Current Image. Also note that the image must be declared as being *global* in the *Command Window*, before we can access the pixels directly. Again, to avoid confusion, it is better to use *dgw* to determine the image size, instead of MATLAB's *size* function:
> $[\text{width},\ \text{height}] = \mathit{dgw}$

Binary images are represented in QT as special cases of monochrome images. Black is zero and white is 255. MATLAB has a special structure for binary images but this is not used in QT, to maintain consistency. (It is advantageous to use grey-scale operators to process binary images. For example, *neg* (grey-scale negation) performs logical inversion (*NOT*) on binary images.)

Colour images are represented by 3-dimensional arrays. The pixels can be accessed, using MATLAB's addressing convention, thus:

$$\text{current}\,(y-\text{address},\ x-\text{address},\ \text{colour\_plane})$$

where *colour_plane* is an integer in the range 1–3. Plane 1 is the *R*-channel; plane 2 is the *G*-channel and plane 3 is the *B*-channel. Again, it is preferable to use *civ* and *siv* to maintain a consistent addressing format.

Image files held on disc in JPEG and TIFF formats can be read using the function *rei*. (Also see functions *rea*, *rim*, *rni* and *rci*.) Other file formats, including BMP, GIF and BMP, can be read by MATLAB, so it is a straightforward matter to extend this range, as necessary.

> *Note*: The JPEG format is liable to produce artefacts if it is used to save images that are later compared to the original (➤ *Table 21.5*). The reason is that reading an image file with JPEG coding regenerates an approximation to the original image. Furthermore, when a binary image is saved in JPEG format, the image read back from the disc is not binary. Hence, it is necessary to apply the threshold function *thr* before applying any of the binary operators. The TIFF format, which is forced to be loss-less, regenerates an exact copy of the original image and hence avoids these problems altogether.

21.5 Writing M-Files

QT commands are implemented as MATLAB functions (*M-functions*), which are stored in M-files. It is quite easy for the user to extend the QT command repertoire, by adding his/her own M-functions. This section shows how this can be done and also explains how MATLAB scripts can be used. It is assumed that the reader is already familiar with MATLAB programming but not necessarily its Image Processing Tool-box.

21.5.1 Defining Simple QT Command Sequences (MATLAB Scripts)

Consider the following command sequence, which will form the body for a new script, called *crack_detector*.

```
rni(41)                                % Read file number 41 (Crack image)
crk(5)                                 % Apply the crack detector
thr(140)                               % Threshold
kgr(100)                               % Keep only those blobs with area
                                         > 100 pixels
```

```
x = cbl;                                    % Count the blobs
y = cwp;                                    % Count the white pixels
if x > 0                                    % Test number of blobs
  s = ['Crack detected; total no. of        % Construct message string
    white pixels = ', int2str(y)];
  display(s)                                % Display it
else
  s = ['No crack found'];                   % Construct a message string
  display(s)                                % Display it
end
```

First, the user defines a new M-file and enters the command sequence listed above. To incorporate the new script in QT, *crack_detector* can then be saved in any folder that lies on MATLAB's search path. The resulting script can then be executed by typing *crack_detector* in MATLAB's *Command Window.*

Notice that scripts cannot refer explicitly to the *Current* or *Alternate* Images. To do so, we must define a new MATLAB function. It is also better to use M-functions, rather than scripts, when we need to define input variables to control the processing, or calculate values that can be used in subsequent commands.

21.5.2 Adding New QT Functions

Here is an annotated listing of the function *ftm* (Log-magnitude of the Fourier transform), which shows the structure that is shared by many of the QT functions:

```
function ftm                        % Function name
% Fourier transform (log magnitude) [0/1]
global current                     % Defines the Current Image to be global
global alternate                   % Defines the Current Image to be global
original = current;                % Save Current Image until the end
a = log(abs(fft2(current)));       % Specific to this function
b = max(max(a))                    % Specific to this function
c = min(min(a))                    % Specific to this function
d = double(255/(b-c));             % Specific to this function
current = uint8(d*(a-c));          % Specific to this function
[e,f] = cim;                       % Specific to this function
psw(e,f)                           % Specific to this function
alternate = original;              % Original Current Image now in Alternate
                                     Image
subplot(1,2,1),                    % Display Current Image in frame of
  imshow(current)                    Figure 1
subplot(1,2,2),                    % Display Alternate Image in frame 2
  imshow(alternate)
```

Notice that QT functions (*cim* and *psw* in this case) can be incorporated within the definitions of other QT functions. QT functions can also be recursive. Also, note that MATLAB functions (e.g., *log*, *abs*, *min*, *max*, *double*, *uint8* in this example) can also be used freely.

Writing new QT functions that use control parameters and/or return values follows the MATLAB convention. Here is the listing of the QT function *eul*, which has one input (*b*) and one output (*a*).

```
function a = eul(b)               % b is the input parameter and a is the
                                    output
% Euler number for 4- or 8-connected blobs [1/1]
global current                    % Defines the Current Image to be global
global alternate                  % Defines the Current Image to be global
if nargin == 0                    % Tests number of arguments (nargin)
  b = 8;                          % Set b to value 8, Orders 8-connectivity
end
level = graythresh(current);      % Specific to this function
working = im2bw(current,          % Specific to this function
level);
a = bweuler(working,b)            % Assigns a value to the output variable a
```

Functions, such as *eul*, with both input and output parameters can be invoked in a number of ways:

- `eul`   Default value for input. Prints Euler number.
- `eul(4)`   Prints 4-connected Euler number.
- `a = eul`   Default value for input. Assigns a to the Euler number.
- `a = eul(8)` Assigns a to value of the 8-connected Euler number.

Functions can use several input arguments and several output arguments. Here is an example that has no inputs and four outputs.

```
function [a, b, c, d] = bbx
% BoundingBox – Smallest rectangle containing the blob [4/0]
q = blob_parameters        % Uses an auxiliary M-file ‘‘blob_parameters’’
  (‘BoundingBox’);
a = q(1);                  % Assigns a value to the output variable a
b = q(2);                  % Assigns a value to the output variable b
c = q(3) + q(1);           % Assigns a value to the output variable c
d = q(4) + q(2);           % Assigns a value to the output variable d
```

bbx may be called with zero to four outputs. The following function has five inputs and no outputs.

```
function vpl(x1,y1,x2,y2,v)
% Draw a straight line given two points [0/5]
global current              % Defines the Current Image to be global
global alternate            % Defines the Current Image to be global
original = current;         % Save Current Image until the end
[h,w] = size(current);
if nargin == 4              % Default: only four inputs
  v = 255;                  % Draw a white line
end
x1 = double(x1);
```

```
x2 = double(x2);
for i = 0:0.0001:1
  p = round(x1 + i*(x2 – x1));
  q = round(y1 + i*(y2 – y1));
  if p >= 1 & p <= w & q >= 1 & q <= h
    current(q,p) = v;
    working(q,p) = v;
  end
end
subplot(1,2,1),                  % Display Current Image in frame of
  imshow(current)                  ➜ Fig. 21.1
subplot(1,2,2),                  % Display Alternate Image in frame of
  imshow(alternate)                ➜ Fig. 21.1
```

21.5.3 Updating QT

QT uses four folders:

(a) *BGB_new_mfunctions* (Holds updates to standard QT functions, down-loaded from the author's web site.)
(b) *BGB_MATLAB_work_files* (The user can add new scripts/functions to QT or define new functions, by placing the appropriate M-files in this folder.)
(c) *BGB_MATLAB_Scripts* (Contains QT's standard library of M-files.)
(d) *BGB_MATLAB_Images* (Contains numbered image files in JPEG or TIFF format. Users can add extra files at will.)

MATLAB's search path should be set up, so that these folders are visited in the order listed above, viz *(a,b,c,d)*. Updated QT functions can be switched ON/OFF, using *qtp*:

qtp(0)	Updated functions in *BGB_new_mfunctions* are disabled
qtp(1)	Updated functions in *BGB_new_mfunctions* are enabled
qtp	Updates are toggled ON/OFF

With the search path set up as described above, any function defined in *BGB_new_mfunctions* is executed in preference to the standard function with the same name held in *BGB_MATLAB_Scripts*.

21.6 User Interface and Utilities

Several factors determine the effectiveness of an interactive image processing system. Of these, the ease of use is critical. The choice of short mnemonic commands, coupled with the *Current-Alternate* operating paradigm have been crucial in making this approach highly successful. QT is the latest development in a series of similar systems that has been evolving for over 30 years. QT possesses a number of operational features that make it significantly easier to use and hence more powerful than even its most recent antecedents.

21.6.1 Modes of Operation

QT has been provided with three modes of operation:

- *Window Mode* (➲ *Fig. 21.1b*)
  Novice users (Author uses this mode for teaching university students.)
  Single window, fixed format display
  Shows only current and alternate pictures
  Buttons, loading standard test images
  Buttons, executing commonly used functions
  Sliders for adjusting threshold and gamma
  Text box for command-line operation
  Restricted functionality (It is difficult to use with functions requiring additional windows)
  Unsuitable for editing M-files
- *Stack Mode* (➲ *Fig. 21.1a*)
  Intermediate level users
  User can reformat/resize image display
  Displays current and alternate pictures
  Displays thumbnails of images in the stack (User clicks on a thumbnail to read the corresponding image from the stack.)
  Buttons to load standard test images
  Buttons to execute commonly used functions
  Keyboard short cuts for common operations (e.g., *pop* and *push* the stack)
  Sliders for adjusting threshold and gamma.
  Most MATLAB features are available (e.g., History Window, cursor, 3D plots, etc.)
  Does not permit editing of M-files
- *Terminal Mode* (➲ *Fig. 21.1a*)
  Experienced users (used for software development)
  As Stack mode in most respects but more functions are available
  Stack display is used to show saved images (accessible at random)
  Permits M-files to be added/edited

➲ *Table 21.1* indicates the features available in these different modes.

21.6.2 Help

There are several ways to obtain help in QT.

- *hlp* lists the names and *H1* comment lines in all M-files in the folder *BGB_MATLAB_Scripts*. The list of QT commands given in Table 21.10 was created in this way.
- *hlp topic* lists the names and *H1* comment lines of all M-files that contain the character sequence *topic*. For example, typing
  hlp median
  produced the following output

```
cmd.m:% Column median [0/0]
mdf.m:% Median filter based on a window of size u*v [0/2]
```

Table 21.1
Comparing QT operating modes. Features marked with an asterisk (*) can be performed via command line control

Function	Window mode	Stack mode	Terminal mode
Cursor	Limited functionality	Yes	Yes
Interactive thresholding and gamma adjustment	Yes	Yes	Yes

MEDIAN Median value.
MEDFILT2 Perform 2-D median filtering.
MEDFILT1 One dimensional median filter.
NANMEDIAN NaN protected median value.
SIGNRANK Wilcoxon signed rank test of equality of medians.

The first two lines here refer to QT functions and the remainder to standard MATLAB M-files. Notice that the numbers within square brackets indicate the number of outputs and inputs for that function. So, *mdf* has no outputs and two inputs.

Updating help When writing a new QT function, insert a comment line immediately after the declaration of the function name. MATLAB refers to this as the *H1* line. When the user types *hlp*, the *H1* lines of all the M-files in the folder *BGB_MATLAB_scripts* are listed.

- *doc qt_ function* downloads and displays the PDF file containing the documentation for the QT function *qt_function*. A complete set of QT documentation files is provided on the CD provided with this Handbook and can also be found by visiting the author's web site:
- http://www.springer.com
- *img* displays a web page containing thumb-nail versions of each of QT's standard images. When the user clicks on one of these thumb-nails, the image is displayed at full resolution. This facility is useful when loading images with the QT command *rni*, which requires a number

21.6.3 Other Special Functions

QT also provides a series of other information and control functions

- *author* Details about the author of QT
- *dab* Do specified command for all blobs in a binary image
- *doc qtfunction* Read the documentation file describing QT's M-function called *qtfunction*
- *dtx* Toggle the text-display switch
- *esr* Evaluate a specified command sequence, save results for display via WWW
- *hub* Visit the author's main web page. This includes a lot of information about QT
- *img* View thumbnails of the standard images provided with QT
- *lvm* Illustrated catalogue of lighting-viewing methods (see ➔ Chaps. 8 and ➔ 40)
- *mmb* Operate the MMB interface unit
- *news* Latest news about QT updates, errors reported, etc.
- *prolog* Ask SWI-Prolog to satisfy a given goal returning a list of integers to QT
- *qt* Start the QT interactive image processing environment. (➔ *Fig. 21.1*)
- *qto* Go to the QT on-line web site. (Run QT on-line within QT stand-alone)
- *qtp* Add/remove path to QT update folder. Enable/disable updates
- *qtr* Evaluate remote command file and save results for display via world-wide web
- *qtu* Read a remote file and save it as an M-file
- *startup* Executed automatically when QT software is loaded

21.7 Applications

During a period of more than 30 years, QT and its precursors have been applied to a wide range of industrial vision tasks. A chapter such as this can do little more that discuss a few representative examples. In doing so, we will inevitably lose one essential feature of QT, the dynamics of the human-computer dialogue. One type of question can never be answered properly in a static paper-based description of QT: "*How did solution XXX emerge?*" The user of an interactive image processing system like QT can never explain how new algorithms were invented in response to a new inspection requirement. The reader is strongly urged to.

21.7.1 Analysing the Shape of a Glass Bottle

Inspection task: Examine the silhouette of a bottle, checking it for symmetry, radius of curvature of the neck-shoulder region, vertical posture (when standing on a horizontal surface), parallel sides. The physical strength of a bottle is determined in large part by the curvature of the neck-shoulder region.

Related tasks: Inspection of symmetrical components, made of glass, plastic, metal, wood, rubber, etc.

Lighting: Back illumination.

Sample image: ➋ *Figure 21.3* shows the image of a glass milk-bottle, with embossing on the front and rear faces. There is a crack in the neck and some surface imperfections which create dark smudge-like patches.

Measuring radius of curvature: To begin, three edge points on the neck are found, by scanning the binary image of the bottle from left to right, along the following rows, which were identified manually:

$$y = 49$$
$$y = 49 + 30 = 79$$
$$y = 49 + 30 + 30 = 109$$

The following command sequence converts this image to binary form. The function *fce* then locates the left-most white point on each of these rows and computes the circle parameters, *[x,y,r]:*

```
enc                              % Enhance contrast
thr(0,127)                       % Threshold
[x,y,r] = fce(49,30,30)          % Fit circle to three edge points
```

In a similar way, a circle can be fitted to the shoulder, simply by selecting three lower scan lines. These two circles are shown in ➋ *Figs. 21.4* and ➋ *21.5*.

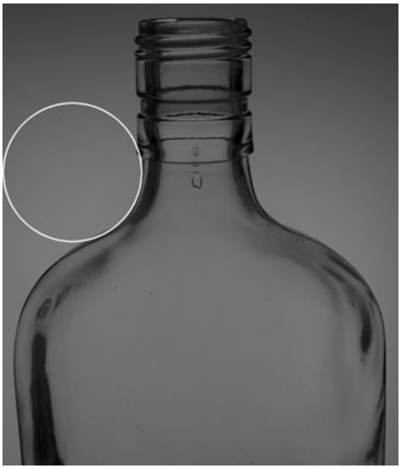

Fig. 21.4
***Circle* fitted to the neck of the bottle**

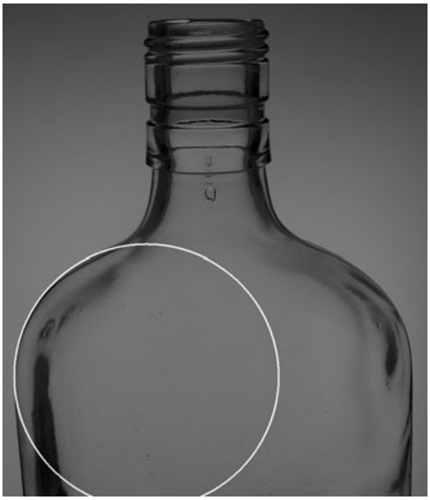

Fig. 21.5
***Circle* fitted to the neck of the bottle**

Fitting a polynomial curve: The following function fits a polynomial of order *n* to a set of edge points, found using *hzs*.

```
function p = fit_polynomial(y1,y2, delta_y, n)
% Fit a polynomial of order n (n ≥ 1) to a binary edge [1/4]
global current
global alternate
original = current;                    % Save image for later
[x,y] = hzs(y1,y2, delta_y);           % Pivotal points
p = polyfit(y,x,n);                    % Calculate polynomial parameters
q = polyval(p,y);                      % Evaluate polynomial
Zer                                    % Black image
[u,v] = size(y);                       % How many pivotal points?
for i = 2:v
vpl(round(q(i)),round(y(i)), round(q(i-1)),round(y(i-1)),255)
                                       % Piece-wise linear plot
end
alternate = original;                  % Recover original image
subplot(1,2,1), imshow(current)        % Draw Current Image
subplot(1,2,2), imshow(alternate)      % Draw Alternate Image
```

The result of applying *fit_polynomial* to the image of the bottle is shown in ➋ *Fig. 21.6*.

21.7.2 Calibrating a Spirit Level

21.7.2.1 Spirit Levels

A spirit level (or bubble) level, is a device that indicates whether a surface is truly horizontal, or vertical. Spirit levels are commonly used by building-trade workers and are often incorporated

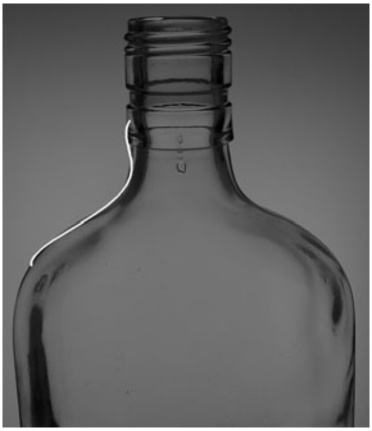

Fig. 21.6

A fourth-order polynomial fitted to the neck–shoulder region, by *fit_polynomial*. The original bottle image was superimposed to emphasise the good fit. Fitting a higher-order polynomial does not improve the fit

into surveying instruments and camera tripods. A common form consists of a slightly curved glass tube that is nearly, but not completely, filled with spirit or alcohol, creating a single bubble, which appears as an ellipse when viewed from above. The ends of the bubble coincide with two calibration lines when the instrument rests on a perfectly level surface. When the device is inclined slightly, the bubble moves away from the centre position. Other forms of spirit levels exist but, for this demonstration of QT, we shall limit ourselves to considering only tube spirit levels.

To make viewing easier, fluorescene is often added to the liquid, making it yellow-green. Preliminary experiments showed that colour filtering (➲ Chap. 16) can assist in separating the bubble from the background. Front lighting, with a localised light source, produces bright highlights by reflection from the tube. This may cause local optical overload in the camera and will certainly complicate the image processing. The bubble acts as an ellipsoidal “hole” in the water. The bubble therefore acts as a crude lens and also creates highlights by reflection. Back illumination produces high contrast images that do not require colour analysis.

21.7.2.2 Locating the Bubble and Calibration Lines

➲ *Figure 21.7* shows a sample grey-scale image, obtained using back-lighting. The back-lit image serves our present purpose, which is to demonstrate the use of QT, rather than offering a solution to a pressing industrial problem. The task we set ourselves is to locate the bubble and calibration lines (A, B, C, D in ➲ *Fig. 21.7*). The “ghost” is the image of calibration line B from the rear of the glass tube. Its displacement is due to the lensing effect of the bubble. ➲ *Figure 21.7* was obtained using a camera placed well away from the spirit level. As a result, the calibration marks appear as single lines, unless the bubble produces a ghost. If a wide angle lens were to be used on a camera located close to the tube, lines A, C and D would split. A telecentric lens would avoid this and allow the camera to be placed closer to the spirit level.

A useful first step when confronted with a new image is to examine its intensity profile along relevant scan lines (➲ *Fig. 21.8*). QT command *plt* does this rapidly but the profile trace is

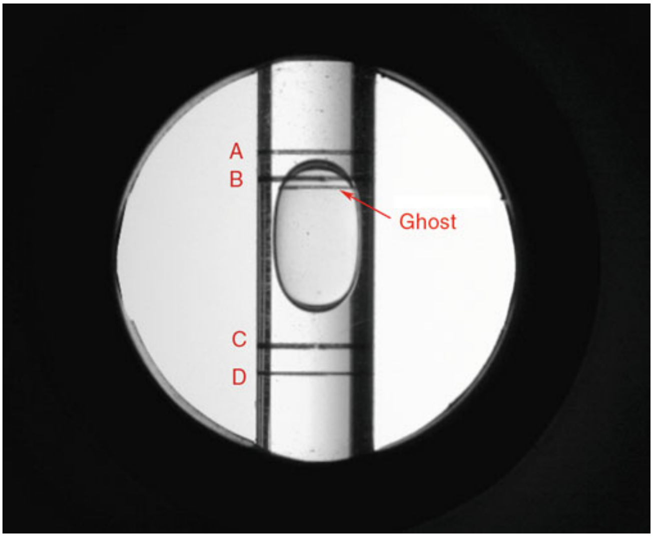

Fig. 21.7
Spirit level, viewed with back illumination. Lines A, B, C and D are genuine calibration marks, while the line labelled "ghost" is an artifact caused by the lensing effect of the bubble. It is an image of line B at the rear of the glass tube. Text was added using Photoshop™

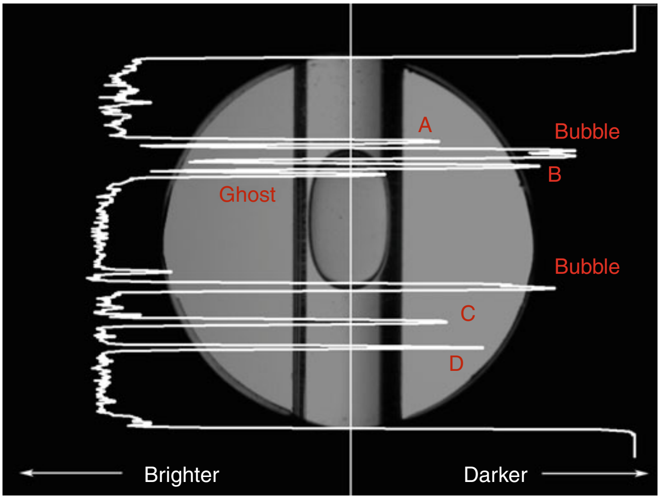

Fig. 21.8
Intensity profile along a vertical line through the centre of the bubble. Notice that the intensity of the ghost is about mid-way between the intensities of the bright back-ground and the dark edge of the bubble and the calibration lines. Text was added using Photoshop™.
[QT: *psh(680,0), csh, wgx, sub, thr, bed, vpl(680,1,680,960,255, lrt, dil(2), rei(original), swi, adi, mxi*]

not permanent; it is not possible to process it as an image. An alternative is to use the following QT command sequence. The parameter *p* controls the position of the vertical scan line.

```
[w,h] = dgw;     % Width height of image
psh(w-p,0)       % Shift right so desired scan line is on RHS of image
csh              % Make all columns same as RHS
wgx              % Intensity wedge
sub              % Subtract Current & Alternate Images
thr              % Threshold at mid grey (level 128)
bed              % Binary edge
dil(2)           % Optional: dilates the trace slightly to improve clarity
```

The resulting image is the same size as the original and hence can be combined with it, as was done in ❯ *Fig. 21.8*.

In almost applications studies, another useful preliminary step is to draw the intensity histogram. (❯ *Fig. 21.9*). There are two strong peaks, corresponding to the bright circular disc and the dark surround but the calibration marks and bubble contribute very few pixels whose contribution to the histogram is not obvious.

As we shall see a little later, it is advantageous to separate the bright central disc from the very dark surrounding area For this reason, the histogram happens to be useful, after all. The centre of the "valley" in a bimodal histogram is often a useful indicator for the threshold parameter needed to separate a figure from its background. An easy way to do this is to use the following QT command sequence:

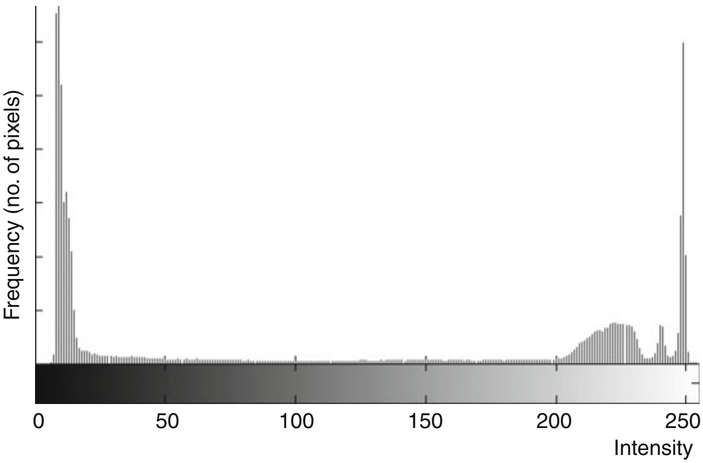

Fig. 21.9
Intensity histogram for the image in ❯ *Fig. 21.7*. Notice that there are two distinct peaks, corresponding to the bright central disc and the very dark background. A bimodal histogram, such as this, often indicates that it is reasonable to apply thresholding to separate a figure from its background. However, in this application, the features of interest make only a very small contribution to the form of the histogram [QT: *hpi*. Axes were relabelled using Photoshop™]

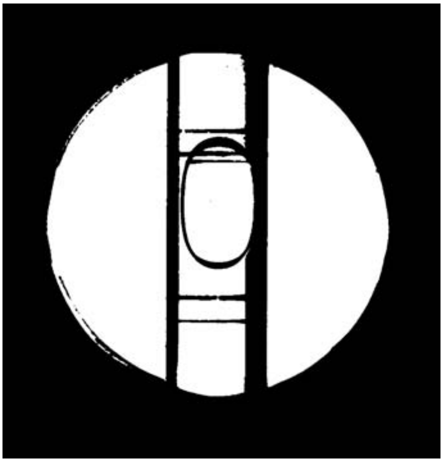

Fig. 21.10
Thesholding applied to the image in *Fig. 21.7*. *[QT: enc, thr]*

```
enc            % Enhance contrast. Darkest pixel becomes black. Brightest
                 becomes white
thr            % Theshold at mid-grey
```

This effectively thesholds at a level corresponding to the mid-point between the brightest and darkest pixels. (See *Fig. 21.10*)

It is now a simple matter to define a Region of Interest (ROI) All further operations will be performed on pixels within the ROI, while those outside will be ignored. This has two advantages. Firstly, it reduces the computation load and thereby improve the execution time. (*Fig. 21.11*(a)) Secondly, unimportant features outside the ROI will be ignored and hence cannot confuse an analysis program, by distracting it from the important parts of the image. The interesting parts of the spirit level image occupy only a very small part of the original image. Hence, it is desirable to make the ROI even smaller, by using the dark vertical stripes to define its left and right limits. (*Fig. 21.11*(b)) For obvious reasons, a spirit level is made to close tolerance. Since the glass tube is held in a well-defined position relative to the frame, it is not unreasonable to expect that the tube can be placed accurately relative to the camera during calibration. This means that it is likely that we can define a small ROI by "dead reckoning". Another ploy is to use well-defined image features in pairs, to locate a ROI whose limits lie between them. In *Fig. 21.11*, the top and bottom limits of the bright disc were used to calculate the height of a ROI that is much smaller than the gap between them. In this case, the processing load is reduced to less than 8% of that originally envisaged. Of course, such a saving is only worthwhile if the processing necessary to calculate the ROI position is straightforward.

From this point on, we shall process only ROI images. It happens that simple thresholding produces a binary image that can then be analysed in a satisfactory manner using binary morphology. To make the thresholding more tolerant of lighting variations, we again use the QT sequence *[enc, thr]*. Binary erosion with vertical line structuring element then detects the calibration lines, top and bottom of the bubble. (*Fig. 21.12*) Here is the command sequence used so far (excluding ROI selection)

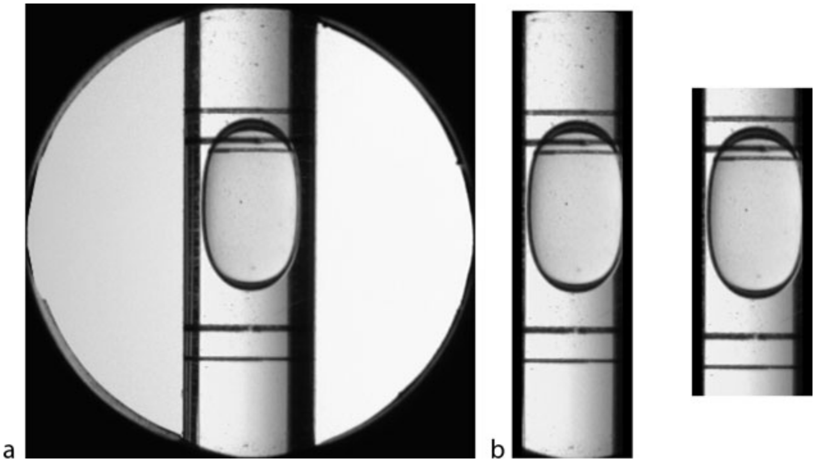

Fig. 21.11

Region-of-interest (ROI). (**a**) ROI defined by the minimum-area box bounding the central bright disc. The computational load for point-by-point calculations (e.g. negation, thresholding and convolution filtering) is reduced to 43.5%. [QT: *wri, enc, thr, [a,b,c,d] = exm(0), rni(126), crp(a,c,b-a, d-c)*] (**b**) The left and right edges of the ROI are defined by those of the vertical dark bands. The computational load is reduced to 11.5%. [QT: *wri, enc, thr*, *big(2), x = cwp; swi, kgr(x), exr, kgr(100), [a,b,c,d] = exm(0), rei, crp(a,c,b-a,d-c), pad(16,0,0)*] (**c**) Minimal ROI, allowing for some uncertainty in the vertical position. The computational load is reduced to 7.9%

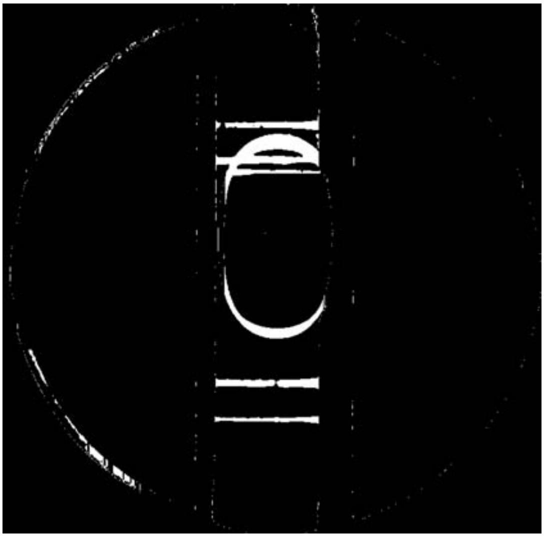

Fig. 21.12

Thresholding (See ➋ *Fig. 21.15b*) and binary erosion with a vertical line structuring element

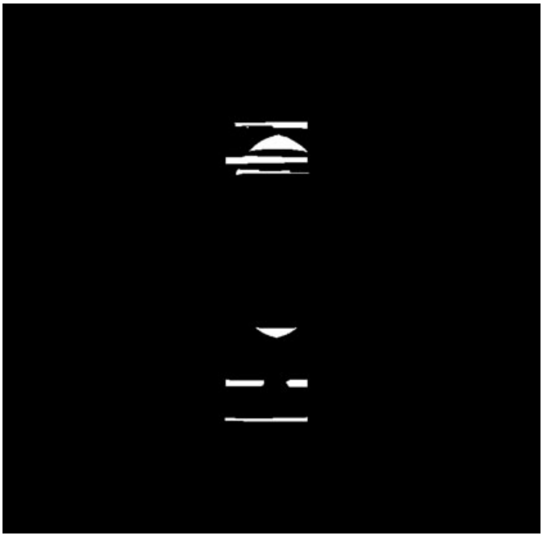

Fig. 21.13
Binary erosion applied to *Fig. 21.12*. The structuring element was a horizontal line, 30 pixels long

```
enc                % Enhance contrast
thr                % Threshold at mid-grey
x = cse(2,50)      % Construct a vertical line structuring element, x, 1*50
                     pixels
gbd(x)             % Dilation. This following operator together implement
                     closing with SE x
gbe(x)             % Erosion. This preceedingoperator together implement
                     closing
rei(original)      % Recover original ROI image
exr                % Exclusive OR of Current and Alternate Images
```

Notice that the top edge of the bubble produces a thick white arc that overlaps calibration line B and the ghost. Horizontal features in this image can be detected using binary erosion with a horizontal line structuring element. (Chap. 19) Here is the command sequence used to generate *Fig. 21.13*:

```
y = cse(1,30)     % Construct a horizontal line structuring element, y,
                    30*1 pixels
gbe(y)            % Erode with structuring element y
```

The y-coordinates of the centroids of these blobs provides the numeric result that we need to complete the calibration. Intepreting this data is an issue that need not bother us here. Let it suffice to say that some intelligent reasoning is needed, since the bubble moves unpredictably. Instead, we shall show visually that the results appear to be reasonable, compared to what we expect. Instead of using the centroid, we use an approximation based on the thinning operator, *thn*.

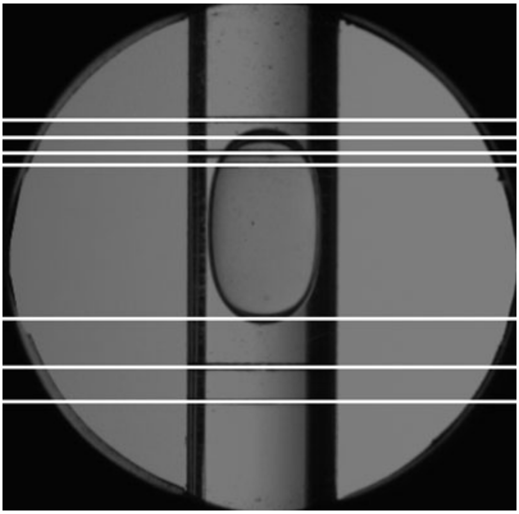

Fig. 21.14

Locating features of interest on the spirit level. Clearly, the bubble can move to overlap one or both of the lower pair of calibration lines (C and D), or not be visible at all. As the bubble moves, the ghost will also move, or not be present at all

```
rox               % Row maximum
csh               % Make all columns the same as the RHS (produces horizontal
                    stripes)
thn               % Thin the stripes to be horizontal lines one pixel wide
dil(2)            % Dilate slightly, to make the resulting lines more obvious
rni(original)     % Read the original ROI image
swi               % Swtch images
adi               % Add Current and Alternate Images
mxi               % Point-by-point maximum intensity between Current
                    Alternate Images
```

The result is shown in *Fig. 21.14*

21.7.2.3 Tracing the edge of the bubble

Finally, we explain how the edge of the bubble can be traced. (*Fig. 21.15*) While this task is not strictly part of the calibration process, it does show that QT can implement complex scene analysis procedures. Since the following QT command sequence was developed interactively, it is not possible to justify why every processing step was chosen. As with many other manifestations of human intuition, rationalisation fails to explain why the mystery remains. An important point worth noting is that the sequence listed below has been shown to produce the desired result on a single image; it has not yet been tested and refined using a large set of images, derived from a range of spirit levels.

```
crp(305,105,731,721)   % Crop parameters were chosen as described earlier
wri('a')               % Save image - see Figure 21.15(a)
```

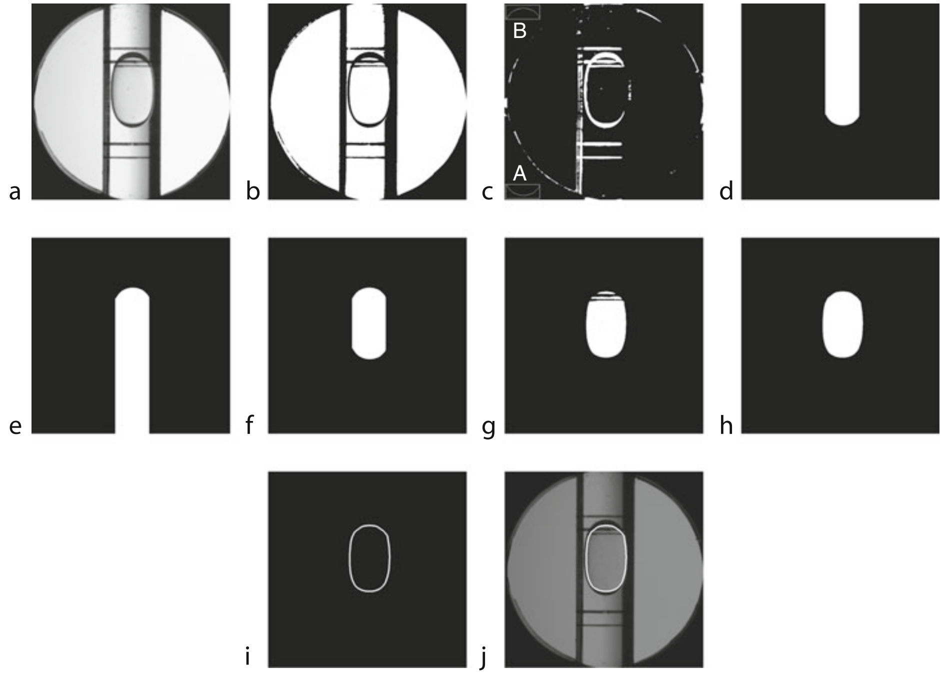

Fig. 21.15

Tracing the edge of the bubble. (a) Original image after cropping. *[crp]* (b) Contrast enhancement and thresholding. *[enc, thr]* (c) Crack detection and thresholding applied to *(b)*. Inserts *A* and *B* are structuring elements. (d) Structuring element A was used to erode image *(c)*. (Structuring element A is represented by *y* in the QT program.) This resulted in single very small blob, which was then shrunk to a single point *[shk]* and dilated [*gbd(y)*], using structuring element *A*. This creates a white arc identical to the structuring element *A*. Following this, a "shadow" (upwards from this arc) was created. *[tbt, cox, tbt]* (e) Similar processing to (d) but using structuring element *B* and creating a "shadow" going downwards. [cox] (f) Images (d) and (e) ANDed together. *[mni]* (g) Blobs in *(b)* that overlap the blob in *(f)*. *[kob]* (h) The previous image was closed. (i.e. dilation followed by erosion) The convex hull *[chu]* was drawn around the resulting blob. (i) Edge of the previous image. *[bed]* (j) Edge contour superimposed on the original image. *[rei('a'), swi, adi, mxi]*

wri('j')            % Save image - see Figure 21.15(j)
```

21.7.3 Robot Vision

In the limited space available, it is only possible to introduce a few of the important issues encountered when designing robot vision systems. Hence, our aim in this section is simply to show that QT posseses appropriate tools for this type of task. We begin by considering one of the simplest: locating and picking up rigid objects lying in random position and orientation on a flat featureless table. An overhead camera views the object. *Figure 21.16a* shows a typical scene: a set of objects lying on an $[X, Y, \theta]$-table. To simplify matters, we shall assume that each of the objects presents a high visual contrast, when viewed against the table surface. This enables the digital image to be segmented easily, perhaps using a simple QT command sequence such as

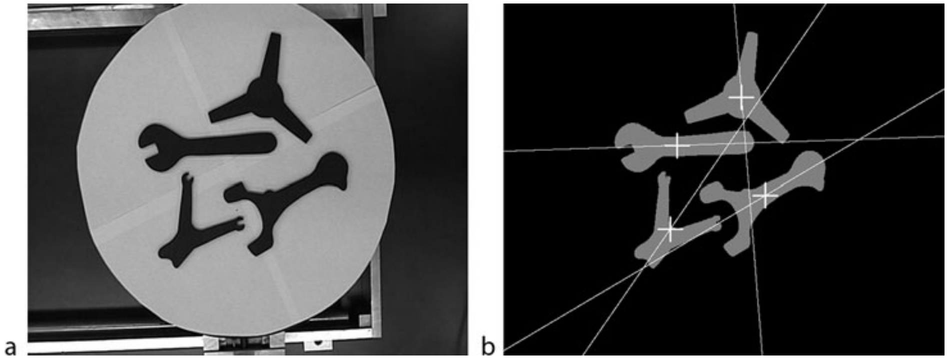

Fig. 21.16
Simple robot vision scene. A common requirement is to isolate each object in turn, then calculate its position and orientation coordinates. These parameters are then translated into robot coordinates. The robot will pick up each object in turn, then place it in a fixed position and orientation, perhaps for packing, assembly, or machining. (a) *Original image*: four objects lying on an [*X,Y,θ*]-table, as seen by an overhead camera. (b) Each object has been isolated, its centroid (cross) and principal axis (*white line*) have been calculated. Notice that the orientation of the principal axis for the three-pointed star is not a reliable indicator of its orientation but is for the other three objects. The centroid of the Y-shaped object is not a good place to position a suction or magnetic gripper, as it lies too close to the object edge to ensure secure lifting

[enc, thr]. For now, we shall assume that a binary image is available and that any background detail, such as the frame of the [X,Y,θ]-table, has been eliminated. Initially, we shall assume that there is only one object in the camera's field of view, although we shall remove this restriction later.

For the sake of brevity, we shall ignore the essential task of calibrating a robot vision system (often referred to as *hand-eye coordination*). Few general principles can be given, since the process depends on the type of robot and gripper, how the system is used, where and how the camera is set up. Let it suffice to say that, by observing the robot as it performs a set of pre-defined movements, QT can calculate the transformation matrices needed to convert the vision system coordinates into the robot coordinates, and vice versa [3]. Calibration is almost always necessary, particularly when the camera and robot are set up independently of each other. Normally, neither "knows" exactly where the other is. Since, the camera's optical magnification (zoom) and focus are best adjusted interactively when it is *in situ*, prior calculations, based upon exact design drawings of the robot-camera cell, are unlikely to provide the necessary accuracy.

21.7.3.1 Picking up Isolated Rigid Objects

Locating most objects is performed easily using the centroid. (➋ *Fig. 21.16*) In QT,

$$[x, y] = cgr$$

calculates the centroid position, [x,y]. However, this may not be best place to put the robot gripper, which we shall, for the moment, ssume is of suction type. A U-shaped object cannot be

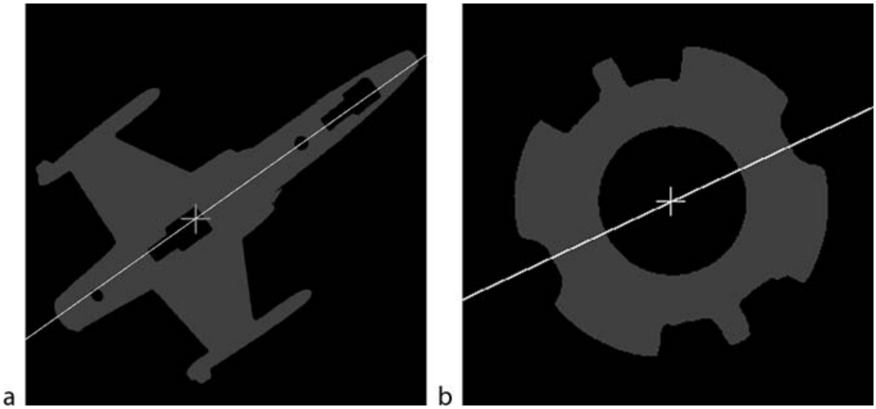

Fig. 21.17

Positioning the gripper when the centroid does not lie within the object bondary. (a) Casting for a model aeroplane. The centroid lies within a lake and is therefore not a good place to put a suction or magnetic gripper. However, placing the gripper at some point along the principal axis, part-way towards the second largest lake will ensure secure lifting. (b) Cam. Although the centroid lies within a lake, this is an ideal place to put a three-finger gripper that expands to grasp the component

lifted at the centroid, since it lies outside the object boundary. The metal casting in *Fig. 21.17a* clearly cannot be lifted by placing the gripper at its centroid. *Figure 21.17b* emphasises the point that the type of gripper is important when calculating grasping positions. The cam cannot be lifted by a suction, or magnetic, gripper placed at the centroid, although it could be held securely by a self-centering 3-finger *expanding* gripper. (Like a drill chuck except that it grips when the fingers are separated.) However for the moment, we shall continue to use a suction gripper. If it is not sensible to place the gripper at the centroid, it may be reasonable to place it at some point defined with reference to the centroid and some measurement of the orientation. A simple rule might be applied in the case of the Y-shaped object in *Fig. 21.16d* or the casting in *Fig. 21.17a*:

- Starting at the centroid, move Q millimetres/pixels along the principal axis, travelling towards/away from the centroid of the largest bay.

Finding the orientation is even more problematical. The principal axis works well for the conrod, spanner (wrench) and even the Y-shaped object in *Fig. 21.16*. It is also satisfactory for the cam, despite there being no obvious "long axis" (*Fig. 21.17b*). However, it does not produce a useful measure of orientation for certain objects, so other methods are sometimes needed. One possibility is to use a line joining two bays, or two lakes. For example, the orientation of a pair of scissors can be derived from the line joining the centroids of the finger-holes (*Fig. 21.18a*). Here is the command sequence for this calculation:

```
blf                             % Fill lakes
exr                             % Exclusive OR – isolates the lakes
big(1)                          % Choose the largest lake
[x1,y1] = cgr;                  % Centroid of the largest lake
```

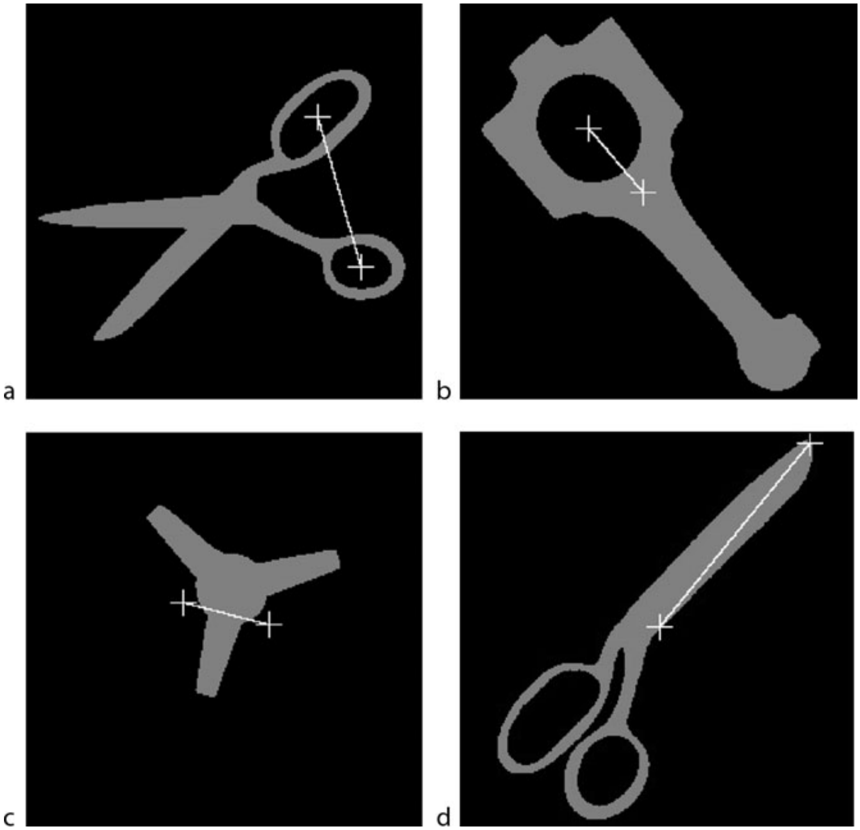

Fig. 21.18

Alternative methods for finding orientation. (a) Scissors (*open*). The lakes (*finger holes*) provide a robust way to determine the position, orientation and the angle of opening. (b) Unfinished forging for an automobile conrod. The centroid and the centroid of the lake determine the orientation. (c) Metal stamping (*three pointed star*). The centroids of two bays determine the orientation. (d) Scissors (*closed*). The centroid and the furthest edge point from the centroid provide a method for determining the orientation

```
swi                              % Switch images
big(2)                           % Choose the second largest lake
[x2,y2] = cgr;                   % Centroid of the largest lake
z = atan2((y1-y2),(x1-x2))       % Orientation (radians)
```

This method work well, whether the scissors are open wide or fully closed.

The following sequence finds the orientation of an object using the line joining its centroid and the centroid of its Nth largest lake (➋ *Fig. 21.18b*, $N = 1$).

```
[x1,y1] = cgr;                   % Centroid of the object
blf                              % Fill lakes
exr                              % Exclusive OR - isolates the lakes
big(N)                           % Select the N-th largest lake
```

```
[x2,y2] = cgr;                    % Centroid of the N-th largest lake
z = atan2((y1-y2),(x1-x2))        % Orientation (radians)
```

Sometimes we might use two bays instead (➲ *Fig. 21.18c*).

```
[x1,y1] = cgr;                    % Centroid of the object
blf                               % Fill the lakes first
chu                               % Convex hull
exr                               % Exclusive OR – isolates the bays
big(N)                            % Select the N-th largest bay
[x2,y2] = cgr;                    % Centroid of the N-th largest bay
z = atan2((y1-y2),(x1-x2))        % Orientation (radians)
```

Another possibility is to find the edge point that is furthest from the centroid. This method for finding orientation is appropriate when the object has a single, long, sharply pointed "limb" (➲ *Fig. 21.18d*).

21.7.3.2 Finding Orientation by Pattern Matching

The methods described above do not produce accurate results when applied to convex shapes, or those that have only small bays, no lakes and no well-defined principal axis. For objects like this, a completely different approach is necessary. The operator *fbl*, defined below, is based on the following procedure (see ➲ *Fig. 21.19*):

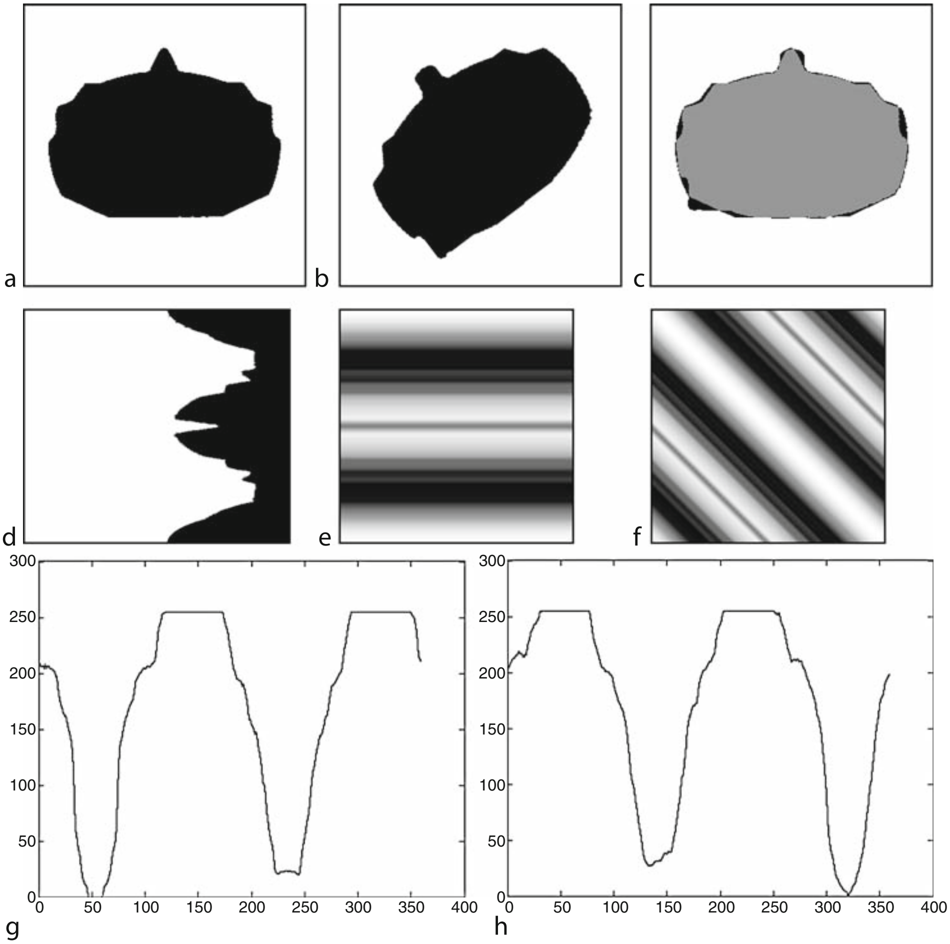
1. Analyse the Current Image and calculate the distribution of "mass" along a series of 360 lines radiating from the object centroid. This is achieved using the operator sequence *[ptc,rin]*. This generates a 360-element, 1-dimensional array, *x*, describing the object shape. (The shape cannot be reconstructed exactly from array *x*.)
2. Contruct an image containing 360 copies of *x*. The operator sequence *csh, crp(1,1,360,360)* does this (➲ *Fig. 21.19e*). Call this image *X*.
3. Repeat step (i) for the Alternate Image, thereby generating another 360-element, 1-dimensional array, *y*.
4. Generate an image in which column *i* is a copy of *y* that has been subjected to a circular shift of *i* pixels (see ➲ *Fig. 21.19f*). Call this image *Y*.
5. Find which column of image *Y* most accurately fits the pattern stored in each column of *X*. This implements a simple pattern matching algorithm based on minimising the quantity.

$$D(i) = \sum_{j=1}^{\text{height}} |(X(i,j) - Y(i,j)|$$

The summation is performed along the columns of the image. *D(i)* is called the *City Block Distance* between two column vectors, one representing the test object (the original Current Image) and the other a reference object (Alternate Image), after it has been rotated by *i* degrees. Hence, *n* where

$$D(n) \leq D(i) \quad \text{for} \quad i = 1, 2, \ldots, 360$$

indicates how far the object in the Current Image has to be rotated to match the reference object best.



◘ **Fig. 21.19**

Finding orientation by matching a vector describing the radial distribution of mass to a set of similar vectors derived from a standard object in different rotations. (a) ***Binary image*****: metal base-plate for an automobile brake pad. Call this** ***Part A*****. (b) Binary image from another slightly different object,** ***Part B*****. (c) After applying** ***[rei('B'), rei('A'), fbl]*****, Part B has been rotated and shifted so that it ''fits'' Part A. Black areas indicate the differences between the two objects. (d) [*****ptc*****] applied to part A. (e) [*****ptc,neg,rin*****] applied to part A. (f) Result of the shear warping. (This is image** ***Y*** **mentioned in the text.) (g) Array of distance scores, [*****D(1), D(2),...*****], when Part A is compared to another image of Part A rotated by 55°. Notice that the minimum value of D_i occurs when i = 55. (h) Array of distance scores, [*****D(1), D(2),...*****], when Part A is compared to an image of Part B. The minimum value of D_i (*****i*** **=321°) indicates how far the image of Part B must be rotated so that it fits Part A. When Part B is rotated by this amount, it fits well onto Part A (➋** ***Fig. 21.19c*****)**

Here is the listing for *fbl*:

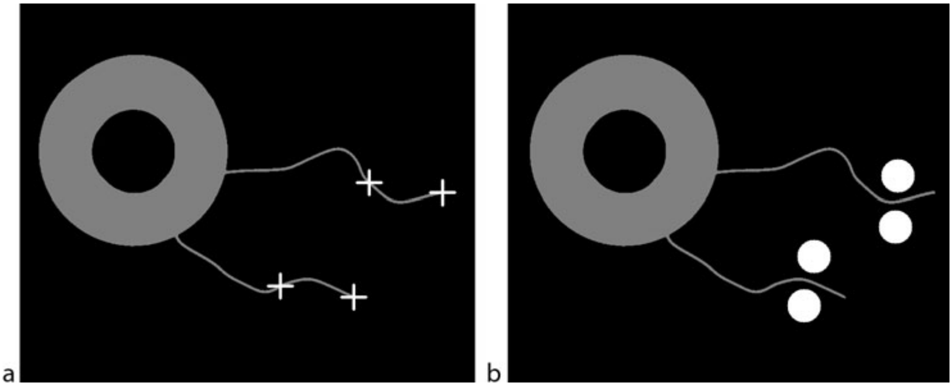
subplot(1,2,2)          % Getting ready to display another image
imshow(alternate)       % Finally, display the new Alternate Image
```

No attempt has been made to optimise this program. To improve the speed of execution, image Y (➲ *Fig. 21.19e*) should be computed once and then stored for future use.

Notice that *fbl* is invariant of position changes for both objects. Scale invariance is also possible by normalising the object size before *fbl* is invoked. Finally, notice that, when *fbl* is executed, the Alternate Image (i.e. the reference image) remains unchanged, while the Current Image is rotated. Hence, *fbl* does not follow the convention established for QT operators.

21.7.3.3 Gripping Flexible Wires

➲ *Figure 21.20* shows the silhouette of a small inductor (coil) with flying leads. Our task is to construct a visual guidance system for a robot that will, in turn, grasp the two free ends of the



■ Fig. 21.20
Grasping flexible wires. (a) Original image, coil with two flying leads. The points marked with crosses indicate the ends of the wires and, on each wire, a point N pixels from its end. N is determined by the size of the gripper. (b) Gripper finger positions in the "open" configuration

wires and then solder them onto connecting pins. This is quite a complicated task, as it requires the calculation of three positional and two angular coordinates for each wire. In practice, the wires can overlap, or even become twisted together. To achieve a complete solution to this problem, we require at least four cameras: one overhead and three providing side views. Moreover, a high level of intelligent image interpretation is needed, particularly to resolve situations where the wires are entwined. For the sake of clarity, we shall consider the simplified task of analysing plan-view images like that shown in *Fig. 21.20a*, considering only two dimensions. This yields three values: *[X,Y]* position coordinates and one angle. We shall explain the processing steps required, by concentrating on just one wire.

Once the image of the coil has been reduced to binary form, a skeletonisation/thinning operator is applied. (*ske* or *thn*) The pixel at the very end of the skeleton limb is then isolated, using the operator *lmb* and its position, $[x_1,y_1]$, is found using *gap*. Next, the skeleton is "pruned", by removing the pixel from the tip of the limb. This process is repeated iteratively, say, *N* times. (*N* is chosen to suit the size of the robot gripper.) The position of the last pixel removed is then found. Call this $[x_2,y_2]$. Here is the code to calculate these values.

```
t2 = current; zer, t1 = current; swi;
for i = 1:N
   current = t2; lmb, alternate = t1; mxi, t1 = current;
   current = t2; lmb, exr,temp2 = current;
end
current = t1; big(1), lmb, [x1,y1] = gap;
current = t1; big(2), lmb, [x2,y2] = gap;
```

The points $[x_1,y_1]$ and $[x_2,y_2]$ enable us to calculate the position coordinates *[x,y]* and the angular coordinate in the XY plane, *theta*, required by the robot:

```
x = (x_1 + x_2)/2;             % [x,y] is approximately N/2 pixels from end of
                                 the wire
y = (y_1 + y_2)/2;
theta = atan2((y_1-y_2)        % Angle of wire at end
  /(x_1-x_2));
```

(Notice that *atan2(.)* is MATLAB's four-quadrant inverse tangent function.)

21.7.3.4 Ensuring Safe Lifting

Consider the scene shown in *Fig. 21.16b*, which shows four objects lying close to each other but not overlapping. Suppose we wish to direct the robot to pick up the conrod. In order to do so, the robot must place its fingers on opposite sides of the object. The robot lowers its gripper onto the work table in the "open" configuration. How can we be sure that the robot will not bump into another object lying nearby. One solution is to superimpose a diagrammatic representation of the robot's "fingerprint" onto the (binary) image. If the number of binary objects is increased by exactly two, it is safe to lower the gripper. If the gripper fingerprint overlaps either the object that is to be picked up, or some other nearby object, the Euler number will not be increased by 2. In this case, it is not safe to lower the gripper, as a crash would occur.

Here is a QT program which can be used to check the safety for a 2-finger gripper used to grasp one of the flying leads of a coil. The input parameters are as follows:

```
function [x,y,z] = grip2(x1,y1,x2,y2,N1,N2)
% [x1,y1]                    Cartesian coordinates of the end of the
                               end of the wire
% [x2,y2]                    Cartesian coordinates of a point N pixels
                               from the end of the wire
% N1                         Length of the gripper finger
% N2                         Width of the finger
global current
global alternate
original = current;
x = (x1 + x2)/2;
y = (y1 + y2)/2;
z = atan2((y1-y2),(x1-x2)) + pi/2;
s = sin(z);
c = cos(z);
u1 = x1 + N1*c;
v1 = y1 + N1*s;
u2 = x1 + (N1 + N2)*c;
v2 = y1 + (N1 + N2)*s;
u3 = x2 + N1*c;
v3 = y2 + N1*s;
u4 = x2 + (N1 + N2)*c;
v4 = y2 + (N1 + N2)*s;
vpl(u1,v1,u2,v2,255)         % Draw a line from [u1,v1] to [u2,v2]
vpl(u3,v3,u4,v4,255);        % Draw a line from [u3,v3] to [u4,v4]
vpl(u3,v3,u1,v1,255);        % Draw a line from [u3,v3] to [u1,v1]
vpl(u4,v4,u2,v2,255);        % Draw a line from [u4,v4] to [u2,v2]
u1 = x1-N1*c;
v1 = y1-N1*s;
u2 = x1-(N1 + N2)*c;
v2 = y1-(N1 + N2)*s;
u3 = x2-N1*c;
v3 = y2-N1*s;
u4 = x2-(N1 + N2)*c;
v4 = y2-(N1 + N2)*s;
vpl(u1,v1,u2,v2,255)         % Draw a line from [u1,v1] to [u2,v2]
vpl(u3,v3,u4,v4,255);        % Draw a line from [u3,v3] to [u4,v4]
vpl(u3,v3,u1,v1,255);        % Draw a line from [u3,v3] to [u1,v1]
vpl(u4,v4,u2,v2,255);        % Draw a line from [u4,v4] to [u2,v2]
blf                          % We now have two open rectangles, so we
                               fill them
alternate = original;
subplot(1,2,1), imshow(current)
subplot(1,2,2), imshow(alternate)
```

The situation shown in Fig. 21.20b is safe.

To save programming effort, the author used another M-function (*grip1*) to prepare data for *grip2*, so that it can accept arguments in a form that is more suitable for handling discrete parts. The input parameters for *grip1* are then as follows:

```
function grip1(x,y,z,d,N1,N2)
% [x,y]                         Centroid coordinates
% z                             Orientation (normally use lmi to find)
% d                             Separation of the fingers when the gripper
                                  is ``open''
% N1                            Length of the gripper finger
% N2                            Width of the finger
global current
global alternate
original = current;
z = pi*z/180;
s = sin(z);
c = cos(z);
x1 = x + d*c;
y1 = y + d*s;
x2 = x−d*c;
y2 = y−d*s;
grip2(x1,y1,x2,y2,N1,N2);
alternate = original;
subplot(1,2,1), imshow(current)
subplot(1,2,2), imshow(alternate)
```

Although grip1 is computationally inefficient, it does the necessary calculation with minimal reprogramming effort (➜ *Fig. 21.21*). Notice that we can model a gripper with circular or rectangular fingers. The principle for modelling a vacuum gripper is simple: to avoid air leakage, which would lead to unsafe lifting, the suction pad must not overlap the edge of the object silhouette (➜ *Fig. 21.21d*). A similar principle applies to a magnetic gripper, although a small amount of overlap might be tolerated.

21.8 Controlling External Devices

Practical Machine Vision systems do not operate in isolation from the real world; factory-based visual inspection/control systems require an image processing engine that can be interfaced easily to a variety of external devices, such as:

- *Lamps* (filament bulbs, strobed discharge tubes, LED arrays, etc.)
- *Optical systems* (lens aperture, zoom, focus, camera, pan and tilt, indexed filter wheel)
- *Cameras* (synchronising scanning and image acqusition, as well as setting internal control parameters)
- *Transport mechanisms* (ranging from simple indexed/continuous parts-transport mechanisms to multi-axis robots)
- *Actuators* (relays, solenoids, pneumatic/hydraulic valves, stepper-motors, DC motors, programmable logic controllers (PLCs), heaters, fans, machine tools lathe, drilling, milling machine, etc.)

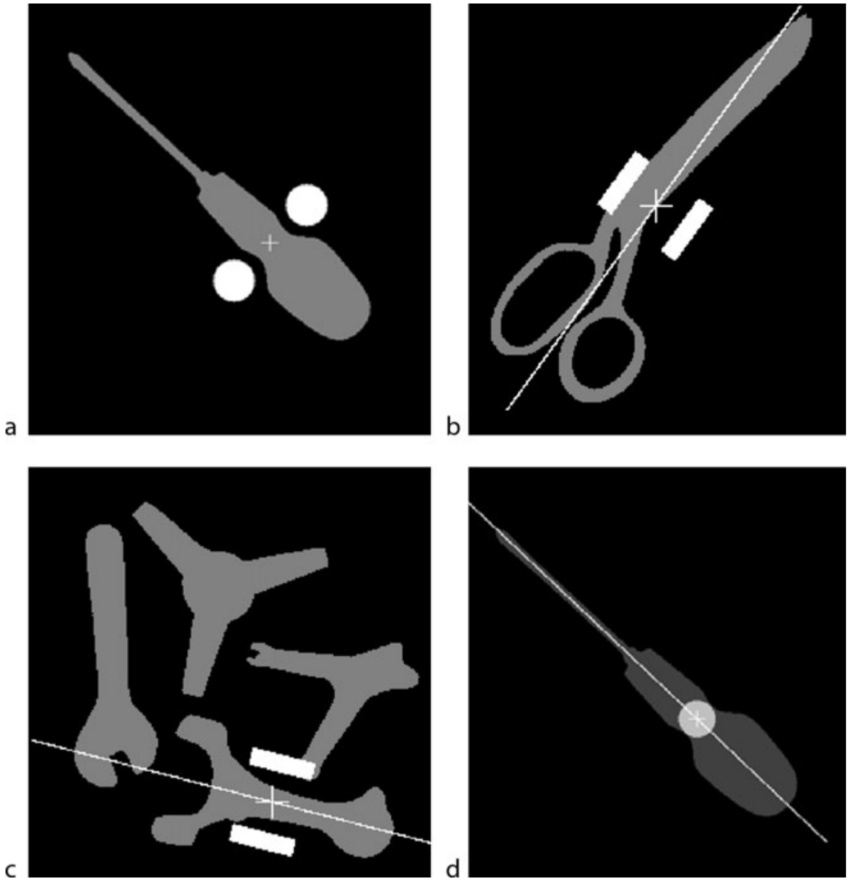


Fig. 21.21
Ensuring safe lifting. In each case, the centroid and principal axis were used to calculate the position and orientation of the gripper. (a) Screwdriver. The gripper has two circular fingers. This is a safe lifting configuration. (b) Scissors (*closed*). The gripper has two rectangular fingers. This is not safe as the upper finger collides with the scissors. (c) Picking up the conrod with other objects nearby. This is not safe as the upper finger collides with the Y-shaped object. (d) Picking up a screwdriver with a circular suction/magnetic gripper. The grass-fire transform (*gft*) was used to estimate the maximum size of gripper that can be used safely

QT's primary function is that of prototyping tool, so, it must be able to operate such devices, if it is to be useful in practical demonstrations and feasibility studies. It should be understood, however, that real-time operation is not an issue that we can address seriously. QT was designed as a multi-function development tool and hence speed has often been sacrificed for versatility.

MATLAB provides several tools for building an interface to external hardware:

(a) Serial port
(b) Reading/writing files on the host computer
(c) Reading files on a remote computer, given an appropriate URL

(d) Communicating with external hardware via custom C or Java programs, running on the same host computer as QT

To date, QT has been provided with facilities for (a), (b) and (c) but not (d). The last mentoned remains an option for improving the speed of dedicated control systems but does not represent a serious loss for our present requirements.

Since MATLAB can operate a serial port, an obvious approach is to connect the host computer to another machine that has the required I/O capability (➲ *Fig. 21.22*). This is very convenient but inherently slow, since all I/O traffic flows via the serial port. However, we argue that this is not normally important in QT's intended role. Suppose, for example, that we want to set up a prototype automated visual inspection system in a factory. Clearly, we cannot expect QT to perform 100% inspection in any but the least demanding of applications. It might, for example, be possible to perform the appropriate processing on only 1% of all product samples. If the limited I/O capabilities reduce this to, say, 0.5%, the experiment will simply take a little longer! It is much more important that the equipment and software can be set up and adjusted quickly and easily, so that the customer is able to assess the benefits of using vision, whilst incurring minimal cost and causing little disturbance to the smooth running of the factory.

Serial port There are several available options for the I/O control processor, including. The authors have used a low-cost system designed and built by one of their colleagues,

Control/data input from host computer (RS232, 9600 Baud)
Video multiplexor
Video output to host computer
Eight CCIR video inputs (with power for cameras)
PV
Switched air lines 4 *ON/OFF*, 2 "push/pull"
Compressed air supply
b

Fig. 21.22
QT controlling external hardware via a serial interface. (a) System organisation. This does not normally create a communications bottle-neck, since the opto-electro-mechanical devices are all slow. However, these must be located close to QT's host computer (site 1). Since it is possible to operate QT remotely via a web browser (site 2) and to digitise images from a remote webcam (site 3), this arrangement can be limiting. (b) Details of the MMB architecture (Designed by Michael Daley, Cardiff University)

Michael Daley. This is called MMB [9, 12] (➜ *Fig. 21.22b*). This is built around a slow processor (Intel 8086). There is only a very small amount of RAM, one ROM chip for firm-ware written in assembly code. MMB provides the following I/O facilities:

(a) One serial port, which exercises control over the function of the MMB unit and passes all I/O traffic to/from QT.
(b) Seven serial ports, any of which can be multiplexed to receive data from the control port. These can operate at different speeds, with run different protocols.
(c) Eight 8-way parallel I/O ports.
(d) 8-way video multi-plexor.
(e) Four *ON/OFF* compressed air lines.
(f) Two complementary-pair compressed-air ports, each allowing forward/reverse operation of a pneumatic cylinder.
(g) Ten *ON/OFF* mains-power lines, each capable of supplying 2.5 A at 240 V, 50 Hz. (Total load must not exceed 13 A.)

Notice that the MMB unit and other devices interfaced via the serial port must be located close to the QT host processor. That is, QT must be running on a computer that is physically close to the object being inspected. Therefore, we cannot use the serial-port interfacing option for running QT on a computer that is far removed from the point of inspection.

USB Port The Velleman *K8055 USB Experiment Interface Board* [Velleman K8055 USB Interface Board, URL http://www.velleman.eu/, accessed 13th December 2010] is a low-cost micro-controller device that is able to control the following input/output channels, via a single USB port:

Five digital input channels
Eight digital output channels

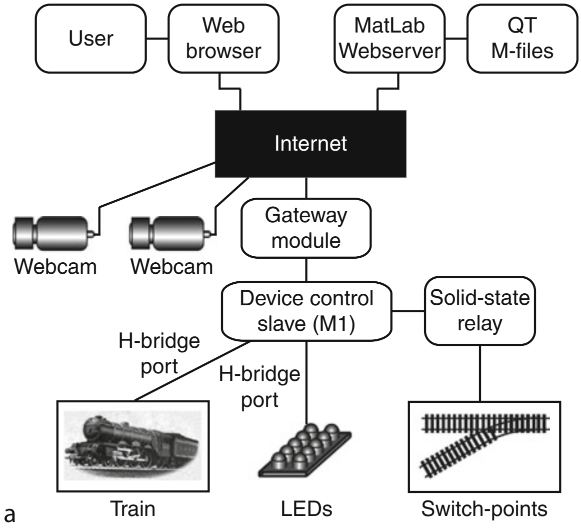

Fig. 21.23

Fig. 21.24
Operating QT via the Internet

Two pulse-width modulated (PWM) digital outputs
Two analogue inputs
Two analogue outputs

The board derives its power from the host computer's USB port. Details of the driver software for the Windows XP version of QT are given in Appendix J. Up to a maximum of four K8055 boards can be connected together, thereby increasing the number of I/O channels available. The K8061 module is similar to the K8055 board and provides more I/O channels, with a higher resolution. A similar range of devices is available from Arduino.

Ethernet/Web-based I/O Control Web-friendly hardware is now readily available for controlling devices such as those listed above. For example, a flexible family of devices is available from [J43 *Designs*, Neath, West Glamorgan SA10 7TG, UK] (➔ *Fig. 21.23*). Overall control is exercised via the so-called *Gateway* board, which can be controlled from its Ethernet port. Each *Gateway* board is assigned a unique URL and can control up to 16 slave modules, which are connected directly to the external equipment. The company provides slave modules with the following output facilities:

(a) Parallel ports.
(b) Serial ports. (RS485/RS232)

(c) Switched *H-bridge* ports. (These provide a succession of reversible, variable pulse-width, fixed-level pulses. An *H-bridge* port is ideal for controlling the speed/direction of a DC motor and can also be used to control the brightness of low power lighting modules.)
(d) Stepper motor driver.

Since the Gateway board is web-based, an unlimited number of them, with their attendant slave modules, can be controlled by single QT processor. These do not have to be located close to the QT-host computer. This provides an important advantage over the serial-port and USB interfaces and allows us to build a distributed prototyping system (➋ *Fig 21.24*).

21.9 Concluding Remarks

The authors remain convinced that a command-line system, with abbreviated mnemonic names and short argument lists provides the best way to study Machine Vision applications interactively. Some other worker taken a different approach. (See, for example, ➋ Chap. 22.) While a certain investment of time is needed to master QT's cryptic mnemonics, the present author asserts that this is well worthwhile, in the long term. He was an early and enthusiastic advocate of the Macintosh operating environment (long before MS-WINDOWS appeared) but he never felt that a GUI was the appropriate way to operate an interactive image processor. Pull-down menus were made available in PIP, QT's immediate predecessor, but were never found to provide an adequate substitute for command-line control. Similarly, a set of MATLAB short-cuts was established for QT. (A short-cut is a labelled icon residing at the top of the Command Window and executes a predefined command sequence with a single click.) Short-cuts have never been found to be really useful, except as a means of selecting standard images by name, rather than index number.

MATLAB, with its Image Processing Tool-box (IPT), provides a very versatile system for processing and analysing images. The fact that QT is implemented using MATLAB provides testimony to this. MATLAB is capable of handling a wide variety of image and data types and it has a very rich command repertoire. As a result, it has found application in a wide range of engineering and scientific disciplines. It is therefore worth asking why the authors felt it was necessary to add the QT M-functions to it; why not use "raw" MATLAB instead? (This term includes "core" MATLAB, plus the IPT, but without the M-files that constitute QT.) After all, everything that QT can accomplish, MATLAB can also do. There are several reasons:

- Individual MATLAB commands are often quite long and demand far greater mental effort on the part of the user than QT does. This is distracting from the real task: analysing images/designing algorithms.
- The source and destination images must both be specified for each operation. (QT always processes the *Current* Image.)
- Full path names are required when images are read from, or written to disc. (QT allows the use of image files to be specified more simply, by numbers or single-letter names, without recourse to file-name extensions, or path names.)
- Certain MATLAB functions provide unnecessary options. (Many operations, or command options, provided by MATLAB have no foreseeable use in Machine Vision applications.)
- Machine Vision can make good use of special image processing operators that have been programmed in MATLAB but which do not exist in its "raw" form.

- It is necessary to order the display of images explicitly. (QT displays results automatically.)
- There is no facility for normalising image intensity after each operation. (➜ Chap. 14. Normalisation is an important and integral feature of QT.)
- The distinction between grey-scale and binary images often hinders user interaction. (It is often helpful to be able to regard, and process, a binary image as if it it were an ordinary grey-scale image.)
- MATLAB encourages new images to be generated. These are very easily forgotten, leading to progressive increase in memory usage. (QT retains only two "permanent" images (*Current* and *Alternate*). In addition, it occasionally generates a few (usually no more than two) working images that are deleted immdiately after use.)
- Many MATLAB functions can be applied to only a limited group of image types. There are several different types of image and it is not obvious which type is currently being processed/displayed. (This makes the operation of "raw" MATLAB intellectually challenging for the user. When processing grey-scale images, QT has only two data types, so this problem does not arise.)
- Writing valid and effective MATLAB function sequences is far from straightforward, as each operation is liable to change the data type. QT always leaves the result in a form that can be processed by *any* other QT function. (Colour image processing operators do not conform to this convention.)
- Input and output images are sometimes of different sizes. (Certain functions, such as *conv2*, generate images that are of a different size from the original. Some other functions crop the output image, to remove "redundant" pixels. QT avoids this awkward situation.)

MATLAB is an excellent platform on which to build more specialised facilities. In its "raw" form, its versatility mitigates against rapid user interaction.

21.10 QT User Guide

21.10.1 What Is QT?

QT is a software package for interactive image processing. It provides an experimental tool-kit for application analysis and algorithm selection and was specifically designed to assist in the development of prototype industrial Machine Vision systems. It allows rapid selection and testing of image processing algorithms. QT has a large repertoire of easily executable operators: simply type the name of the appropriate function and, if necessary, a short list of control parameters. (➜ section 21.11 provides a list of QT commands.) This section concludes with an explanation of how a typical algorithm is developed using QT (➜ Sect. 21.10.7) and some graded exercises (➜ Sect. 21.10.8).

The QT software, a set of standard images and a number of other utilities for Machine Vision system design, can be accessed by visiting the author's web site at

http://bruce.cs.cf.ac.uk/index.html

21.10.2 Choose the Right Version

The following versions of QT are currently available:

- Single-user version, written and executed as a series on MATLAB M-files.

- Single-user stand-alone executable file, running under LINUX or WINDOWS.
- Multi-user, multi-processor version.
- PQT using SWI-Prolog [URL: www.swi-prolog.org/] as the top-level controller.

21.10.3 Getting Started

Visit the following web site:

http://www.springer.com
News and updates are made available from time to time at the author's web site:
http://bruce.cs.cf.ac.uk/bruce/

21.10.4 Modes of Operation

QT has been provided with three modes of operation:

- Window Mode (➔ *Fig. 21.25a*)
  Novice users (The author uses this mode for teaching degree-level and post-graduate students.)
  Single window, fixed format display
  Shows only current and alternate pictures
  Buttons, loading standard test images
  Buttons, executing commonly used functions
  Sliders for adjusting threshold and gamma
  Text box for command-line operation
  Restricted functionality (It is difficult to use with functions requiring additional windows)
  Unsuitable for editing M-files
- Stack Mode (➔ *Fig. 21.25b*)
  Intermediate level users
  User can reformat/resize image display
  Displays current and alternate pictures
  Displays thumbnails of images in the stack (User clicks on a thumbnail to read thecorresponding image from the stack.)
  Keyboard short cuts for common operations (e.g., *pop* and *push* the stack)
  Most MATLAB features are available (e.g., History Window, cursor, 3D plots, etc.)
  Does not permit editing of M-files
- Terminal Mode (➔ *Fig. 21.25b*)
  Experienced users (used for software development)
  As Stack mode in most respects but more functions are available
  Stack display is used to show saved images (accessible at random)
  Permits M-files to be added/edited

➔ *Table 21.2* summarises the features available in these different modes.

Table 21.2
QT operating modes. Features marked with an asterisk (*) can be controlled via command line

Function	Window mode	Stack mode	Terminal mode
Cursor	Limited functionality	Yes	Yes
Interactive thresholding and gamma adjustment	Yes	Yes	Yes
Reading standard images	Buttons or command line	Command *rti* loads nine popular images into image stack. User then clicks on thumbnail to read image. Can also read images using command line	
Read images	Button* (single image store available)	CLICK on thumbnail, or via command line (nine thumbnails are displayed in the image stack)	
Save images		CNTRL/CLICK on thumbnail* (storage for eight images available)	
Extra windows (e.g., 3D plots and multi-image display)	No	Yes	Yes
User prompt	Flashing vertical line in *Command* box	QT:	>>
Commands (single)	Buttons or command line	Command line only	Command line only
Command sequences	No (results not displayed)	Yes	Yes
Keyboard short cuts	No	Yes	No
Automatic saving of images during interaction (*push* onto stack)	No	Yes	No (stack can be operated via command line)
Sound playback	Yes	Yes	Yes
Error message reporting	Limited	Limited	Full
MATLAB History Window	Present but not visible	Yes	Yes
On-line help and documentation	No	Yes	Yes
On-line review of standard images	No	Yes	Yes
Editing M-files	No	No	Yes
MATLAB debug tools	No	No	Yes

21.10.5 Operating QT

Except where stated, the notes in this section refer to Stack and Terminal modes.

21.10.5.1 Basics

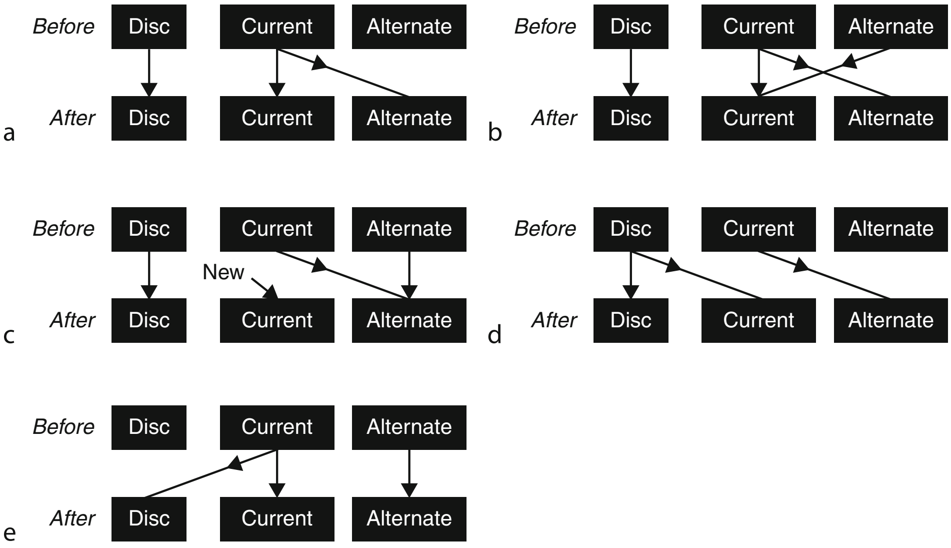
QT uses and displays only two images, called the Current and Alternate Images. The Current Image is always displayed on the left and the Alternate Image on the right. When a typical command, such as *neg* (negate) is typed, the following happens:

1. The Current Image is copied into the Alternate Image. The original contents of the Alternate Image are discarded.
2. The specified operation is performed on the Current Image.
3. The result (negative image) is then stored in the Current Image.
4. The revised Alternate Image is also displayed alongside the Current Image.

For example, thesholding (function *thr*) requires zero, one or two parameters; the following are typical commands:

• *thr(123,234)*	Two arguments supplied
• *thr(156)*	Second argument is, by default, assumed to be 255 (white)
• *thr*	First argument default value is 128. Second is 255.

Functions *thr* (with and without arguments), *neg* and most other QT commands employ the Current and Alternate Images in the same way. However, there are some deviations from this model, reflecting the different types of operators. There are five other situations to consider. (See ➲ *Fig. 21.26*.)



◘ Fig. 21.26

Mapping the Current and Alternate Images during the execution of QT commands. (a) Monadic operators, local operators and other functions that use a single input image behave in this way. (b) Dyadic operators. (c) Image generators. (d) Reading images from a disc file. Functions that down-load images from the web behave in a similar way. (e) Writing images to disc

(a) Some commands return values calculated from the Current Image but do not alter it, nor the Alternate Image. For example, *avg* computes the average grey level in the Current Image. The result(s) can be used to define variables that will be used later to define input values for other commands, or simply printed.

(b) Some commands generate images. For example, *gsn* generates a random image from a Gaussian noise source. In this case, the Current Image is first copied to the Alternate Image. The Current Image is then replaced by the Gaussian noise image. Notice that this process is compatible with the operation of the majority of commands, such as *neg*. Reading an image from a disc file is also performed in this way. Popping an image from the Image Stack also behaves in a similar manner. (Operations involving the Image Stack will be discussed later.)

(c) Writing an image to disc and pushing an image onto the Image Stack do not alter either image.

(d) A few commands, such as *rgb*(show RGB channels separately), *hsi* (show HSI channels separately) and *plot3d* (plot intensity as a function of X and Y coordinates) generate a new display window (MATLAB refers to this Figure 4), without altering either the Current or Alternate Image.

Note: After executing *rgb*, *hsi*, *hpi*, plot3d, click anywhere on Figure 4, to close it

(e) A few commands combine the Current and Alternate Images. For example, function *adi* adds the intensities of pixels at corresponding addresses in the Current and Alternate Images. In such cases, the result is placed in the Current Image and the original Current Image is copied into the Alternate Image, *w*hose original contents are discarded.

21.10.5.2 Combining Commands

QT commands can be concatenated as shown in the following example:

wri(100), *dil*, *ero*, *rei*(100), *sub*, *enc*

Alternatively, when writing new MATLAB scripts or functions, individual commands can be written on separate lines, with optional comments added as illustrated below:

```
wri(100)       % Write the Current Image to disc file 100.jpg
dil,           % Dilation using default parameters
ero            % Erosion using default parameters
rei(100),      % Read image file 100.jpg
sub,           % Subtract the Alternate Image from the Current Image
enc            % Enhance contrast
```

Notice that commas can be included at the end of each line but are not necessary. (Semicolons, which will be considered next, would have no effect in this example.)

Some commands generate numerical results. For example, *avg* calculates the average intensity, which can be used by a later command. The following command sequence illustrates this is.

$$x = avg,\ \ thr(x)$$

avg calculates the average intensity and *thr* performs simple thresholding. Notice the comma separating these two commands. The effect of this comma is to allow MATLAB to display the value of the newly assigned variable *(x)*. This is a design feature of MATLAB. To suppress the display of this variable, we must use a semi-colon instead:

$$x = avg;\ \ thr(x)$$

If we wish to place these commands on separate lines to make reading easier, the semi-colon again suppresses the display of the values for *x*:

```
x = avg;                         % The value of x is not displayed
thr(x)                           % Threshold at level x
```

Whole images can be assigned using a construction of the form

$$\text{current} = \text{original}$$

Warning: This displays the intensities for the whole image, pixel by pixel. For a colour image, there are three values displayed for each pixel. This is a lot of data and the command takes a long time to execute!

To suppress the output display, use a semi-colon:

$$\text{current} = \text{original};$$

Some commands generate several output values, as the following example shows (This is the heart of the function *nxy*, which normalises the position of a blob so that its centroid lies at the centre of the image.)

```
[x1,y1] = cim        % No semi-colon, so the values of x1 and y1
                       are displayed.
[x2,y2] = cgr        % No semi-colon, so the values of 2x and y2 are displayed.
q = round(x1-x2);    % Standard MATLAB rounding functions. Output is
                       suppressed.
p = round(y1-y2);    % Standard MATLAB rounding functions. Output is
                       suppressed.
current =            % Take care to place a semi-colon here to avoid
  original;            long delays.
psw(p,q)             % Shift image horizontally by p pixels and vertically
                       by q pixels.
```

21.10.5.3 Special Features

- Switching Current and Alternate Images
  Terminal Mode — *swi* or *z* (single letter command)
  Window and Stack Modes — *swi*, *z* or simply press the ENTER key
- Interactive investigation of features (position and intensity/colour)
  pxv

- Dynamic thresholding
  - Window mode
    - Slider (Click on radio button labelled "*Threshold*" first)
    - Note: Result is left in the *Alternate Image*
  - Stack and Terminal modes
    - Use command *dth*
- Dynamic gamma adjustment
  - Window mode
    - Slider (Click on radio button labelled "*Gamma*" first)
    - Note: Result is left in the Alternate Image
  - Stack and terminal modes
    - Use command *dgm*
- Display standard images (Stack and terminal modes)
  - *img* Displays all of QT standard images via MATLAB web browser
  - *rti* Loads most popular images into the image stack. (Click on the thumbnail to load into the Current Image)
- Help (Stack and terminal modes)
  - *hlp* Lists all QT functions with a brief description of each one
  - *hlp text* List QT function "text" if it exists

  Otherwise search for all occurences of "*text*" in the abbreviated QT descriptions
- Documentation of individual image processing functions
  - *doc* Same as *hlp*
  - *doc cmd* Display documentation file for QT command "*cmd*"
- Presentation of results
  - *dtx* Switch between minimal and verbose presentation of results
- Mode switching
  - *qt*/*qt(0)* Switch to Terminal Mode
  - *qt(1)* Switch to Stack Mode

  Note: *end*, *halt*, *quit*, etc. switch from Stack to Terminal Mode
  - *qt(2)* Switch to Window Mode. Close QT window to switch to re-enter Terminal Mode
- Interactive drawing of a polygon
  - *pgn* Double click to exit. (Useful for drawing masks.)
- Cursor
  - *cur* Double click to exit
  - *pxv* Fast investigation of position and intensity. Does not return usable numeric results
  - *cob* Choose one blob using cursor
- Calibration of grey-scale
  - *cbr* Display colour bar. Dispappears when next command is executed
- Pseudo-color
  - *psc* Result is an RGB image
- Getting web command sequence
  - *ersf* Execute a remote script file. (Repeats process with time limit.)
- Acquiring image from web camera
  - *gwi* Argument is URL of the camera image

Table 21.3
Relating thumbnail labels to the Image Stack

Screen label	Image no.	Image
−1	*stack_pointer* – 1 (mod *stack_size*)	Image at the bottom of the stack. This is the image that was previously at the top of the stack, i.e., just before the most recent *pop* operation
0	*stack_pointer*	Image at the top of the stack
1	*stack_pointer* + 1 (mod *stack_size*)	Image next to the top of the stack
2	stack_pointer + 2 (mod *stack_size*)	Second image from the top of the stack
N (1 ≤ N ≤ 7)	stack_pointer + N (mod *stack_size*)	Nth image from the top of the stack

- Controlling simple electronic hardware
  See Appendix J
- Viewing/searching the Catalogue of Lighting-Viewing methods
  lvm View the catalogue or perform a simple search
  lvs Multi-term search of the catalogue

Table 21.4

Stack and Terminal Modes. The behaviour of some standard QT commands is slightly different in Stack and Terminal Modes. (Indicated by "*")

Command/Action	Mode	Function
*end**	S	Exit *Stack Mode*; return to *Terminal Mode*
exit		
stop		
*quit**		
halt		
qt(0)	S	Enter Terminal Mode
qt(1)	T	Enter Stack Mode
*qt(2)**	S/T	Enter Window Mode
spon/spof	S	Stack enabled/disabled
sdon sdof	S	Stack display on/off
Null *(CR only)*	S	Interchange Current and Alternate Images. Current Image is put on the stack
pop/push	S	Pop/push the image stack
b	S	Rotate the stack array back one step.
c	S	Grab an image from same the camera as was last used by the *grb* command
f	S	Rotate the stack array forward one step
h	S	Help: display command list
r	S	Read image from temporary file. (See command "w".)
s	S	Read same standard QT image as the last time *rni* was used
t	S	Get image from the top of the stack but do not alter the stack
w	S	Write image to a temporary file. (See command "r". No option which one.)
w	T	*w(N)* writes an image to the Nth stack image. Display the thumbnail in Figure 2.
z	S/T	Interchange Current and Alternate Images. Stack is not changed
*csk**	S	Clear the stack. Fill it with images generated by a Gaussian noise source
dtx	S/T	Display text ON/OFF
img	S/T	Display QT's standard images
rti	T	Load image stack with most popular test images
ssk	S/T	Show (part of) the stack array
*Other QT commands**	S	Execute command as normal, then push Current Image onto the stack
Failed command	S	*Warning*: That command was not recognised – try again
Click on thumbnail in Figure 2	S/T	Selected image is copied from the stack to Current Image
CNTRL/click on thumbnail in Figure 2	T	Copy image to selected stack image

21.10.6 Image Stack

The Image Stack display is used in different ways in Stack and Terminal Modes. The stack consists of *stack_size* images arranged in a circular array. The position of the top of the stack is indicated internally by the software by an integer variable, called *stack_pointer*, which is incremented/decremented (modulo *stack_size*) during *pop* and *push* operations. Eight images residing at or near the top of the stack on the screen are displayed as thumbnails, in a window labelled "➋ *Figure 21.2*" (see ➋ *Fig. 21.27*). In addition, the image at the bottom of the stack is displayed on the screen and is labelled "−1". Its use will be come clear later. The numeric labels in this window should be interpreted as shown in ➋ *Table 21.3*.

21.10.6.1 Stack Mode (➋ *Table 21.4*)

As each command is entered, the result (i.e., the Current Image) is pushed automatically onto the stack and the screen display updated. QT allows the user to revert quickly and easily to an earlier stage in the algorithm development process by

(a) Using command *rsi(N)*, where N ∈ {1,0,2,3,. . .,7}.
(b) Using command *r(N)*, where N ∈ {1,0,2,3,. . .,7}.
(c) Using command *pop* to pop the stack. The screen display is updated automatically.
(d) Using the single-letter command '*b*' (for backwards) to pop the stack. (Use the single-letter "*f*" to correct a mistake if you type "*b*" too often.)
(a) Clicking on a thumbnail in the stack display window (➋ *Fig. 21.25b*) copies the corresponding (full-size) image into the Current Image.

Functions *pop*, *push* and *tsk* (top of the stack), csk (clear stack) and *rsk*(fill stack with images chosen at random) are also available. *rti* fills the stack with popular test images. This is done automatically at start-up.

It is possible to pop the stack using a single-letter command (*b*). Hence, it is easy to go too far and move *stack_pointer* past the desired image, by mistake. Since the bottom of the stack (thumbnail "−1") is visible, the user can easily remedy the error by reversing the last pop operation, using command *f*.

21.10.6.2 Terminal Mode (➋ *Table 21.4*)

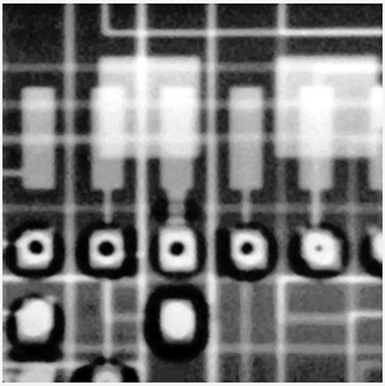
In this mode, the stack is not normally updated automatically, as it is in Stack Mode. (This is possible but the user must work without the benefit of the visual display of the stack contents.) Instead, the stack display can be used to see (some of) the images that have been saved to disc. To save an image so that a thumbnail is visible in the stack display window (labelled "Figure 2"), use one of the following:

(a) Command *wis(N)*, where N ∈ {1,0,2,3,. . .,7}.
(b) Command *w(N)*, where N ∈ {1,0,2,3,. . .,7}. (N.B. *w(N)* and *wis(N)* are synonymous.)
(c) Clicking on the thumbnail while holding the CONTROL key down.

Notice that *wis/w* serves the same purpose as *wri*, except that the latter does not provide a visual display of the saved image. Hence, the stack display effectively provides a 9-picture

Table 21.5

Developing an algorithm for locating the centres of the holes in the component mounting pads

QT	Function	Result
rni(135)	Read the original JPEG image from disc. The intensity histogram is shown below	
rni(135);
heq;
mdf
	Reduce camera noise.
	Composite image, showing the effects of the median filter.
	Histogram equalisation was applied to make the differences appear more pronounced to the reader; it is not used elsewhere in the processing sequence.
	Top-left: *heq* (i.e., no filtering)
	Bottom-right: *heq; mdf* (i.e., after filtering)
		


rni(135);
mdf;
sqr
	Square all intensities. Provides greater contrast in dark regions.	
Table 21.5 (continued)

QT	Function	Result

rni(135);
mdf;
sqr;
ero
	Grey-scale erosion: shrink all bright regions	
rni(135);
mdf;
sqr;
ero;
crk(7)
	Crack detector: grey-scale morphological closing operator	
rni(135);
mdf;
sqr;
ero;
crk(7);
thr(180)
	Threshold at level 180 (light grey). The value of this parameter was chosen by examining the intensity histogram of the image above. This histogram is shown below.	
Table 21.5 (continued)

QT	Function	Result

rni(135);
mdf;
sqr;
ero;
crk(7);
thr(180);
rbe
	Remove all blobs that touch the edge of the image. (Erosion and closing operators produce anomolous effects around the border.)	
rni(135);
mdf;
sqr;
ero;
crk(7);
thr(180);
rbe;
shk;
crs
	Shrink all blobs to a single point (shk).
	Then, draw a white cross at each white pixel.
	The XY-coordinates of the pads can be obtained using the following command sequence. (The array *z* is redundant.)
	rni(135);
	mdf;
	sqr;
	ero;
	crk(7);
	thr(180);
	rbe;
	[x,y,z] = gap

mdf;
sqr;
ero;
crk(7);
thr(180);
rbe;
shk;
crs;
rni(135);
swi;
adi;
mxi
	Superimpose the crosses onto the original image. This is helpful, so that the user can verify that the processing produces sensible results	
Table 21.5 (continued)

QT	Function	Result
rni(135); *hpi*	Intensity histogram of the original image. This comb-like structure is an artifact of the JPEG coding process. The histogram derived from the image obtained directly from the camera resembles that shown below	
rni(135);
caf;
hpi
	Intensity histogram of a low-pass filtered (i.e., blurred) image	
rni(135);
mdf;
sqr;
ero;
crk(7);
hpi
	Histogram of the difference image (i.e., after *sub*) is useful for determining an appropriate threshold value	
random access store with visual feed-back. The command sequence *[wis(n),ssk]* can be used to provide a dynamic display during computation.

- ► Notice that clicking on a thumbnail in the stack display window does not update MATLAB's History file.

21.10.7 Developing an Algorithm Using QT

The development of a simple algorithm is illustrated in ➋ *Table 21.5*. In practice, the user normally explores a multi-branch search tree. For clarity, dead-end branches have been eliminated here.

21.10.8 Exercises

21.10.8.1 Locating Pads on a Printed Circuit Board

Perform the steps in ➋ *Table 21.5*, one at a time. Check that you obtain the same images.

21.10.8.2 Crack Detection

Command	Explain the action and the significance of the result Take account of the Current Image and results in the Command Window
rni(41)	
crk(5)	
enc	
thr(220)	
kgr(100)	
cbl	
rni(41)	
mxi	

21.10.8.3 Telling the Time

Command	Explain the action and the significance of the result Take account of the Current Image and results in the Command Window
rni(141)	
rni(142)	
mxi	
dil	
rni(143)	

sub	
enc	
thr(64)	

- Confirm that the centre of the clock face is at [280.1380, 234.5614]. (*Hint:* first fill the circular contour around the outer edge and then find the centroid.)
- Estimate the radius of the clock face using:
  (a) mar
  (b) cwp
- Explain how *scc* might be used to locate the hour and minute hands.
- Draw a small cross at the centre of the face automatically and then superimpose it onto image # 141.

21.10.8.4 Analysing the Image of a Cog

Execute the following commands one at a time but ignoring the first line (i.e., *function [x,y] = cog*).

Then, execute *cog*.

Command	Explain the action and the significance of the result Take account of the Current Image and results in the Command Window
function [x,y] = cog	How many inputs? How many outputs?
% Analyse the image of a cog [2/0]	This is the H1 line. What is the significance of that? (Read MATLAB documentation.)
global current	Needed to gain direct access to the Current and Alternate Images
global alternate	
rni(210)	
original = current;	Why is the semi-colon there?
enc	
thr	
kgr(50)	
wri(1)	
blf	
chu	
exr	
ero	
shk	
[x,y,z] = gap;	What happens if we replace the semi-colon by a comma?
crs	
wri(2)	
rei(1)	

blf	
exr	
big	
a = cwp;	Will processing take much longer if we remove the semi-colon?
b = round(0.9*a);	Is the semi-colon needed?
swi	
kgr(b)	
str	
rei(2)	
mxi	
alternate = original;	What happens if we replace the semi-colon by a comma?
adi	
swi	
mxi	
alternate = original;	
subplot(1,2,1)	MATLAB functions for image display
imshow(current)	
subplot(1,2,2)	
imshow(alternate)	

21.10.8.5 Analysing the Creasing of Fabric

Obtain a plain white handkerchief and crease it in your hands. Place it gently on a flat-bed scanner. (If you do not have a scanner to hand, use image number 309.) Then, apply the processing steps described in ❯ Chap. 38 to the resulting image. They may need to be adapted to take account of the different image size.

21.10.8.6 Counting Teeth on a Comb

Analyse QT standard image 317 or, to count the teeth and place a cross at the tip of each one. Assume first that the orientation of the comb could be fixed to within a few degrees before image acquisition? Then, repeat the exercise without this benefit.

21.10.8.7 Inspecting a Coding Disc

QT standard image 162 is derived from a shaft-angle coding disc. This is to be assembled using a visually guided robot. Devise a QT command sequence for

(a) Checking that all holes (lakes) have been correctly punched.
(b) Verifying that the outer edge is circular.
(c) Finding the position of the centre of the disc.
(d) Determining the orientation of the disc.

21.10.8.8 Examining a Slice of Bread

Standard image number 45 shows the silhouette of a slice of bread from a non-lidded tin loaf. Assume that the orientation of the slice can be fixed approximately by mechanical means before image acquisition and that its nominal size is known.

Measure the radius of curvature of the top surface.

Measure the angles of the two straight sides.

Measure the area of the overspill (The dough expands during baking and bulges out, overspilling the top rim of the baking tin.)

21.11 QT: M-Files for Image Processing and Analysis

The following is a list of the M-files currently available in QT. Further functions are made available from time to time. These and documentation revisions are available from the authors' web site (URL: bruce.cs.cf.ac.uk). The author welcomes contributions by other workers.).

		Arguments	
Name	Function	In	Out
aab	Area of all blobs in a binary image	0	1
abd	Absolute value of difference in intensities twixt Current and Alternate Images	0	0
abv	Absolute value of the intensity in the Current Image	0	0
acf	Autocorrelation applied to an image	0	1
acn	Add a constant to all intensities in the Current Image	1	0
adc	Add the RGB channels of two colour images separately	0	0
adi	Add the Current and Alternate Images	0	0
aeb	Area of each blob in a binary image	0	1
aia	Write an image to an archive folder	1	0
aic	Adjust intensity range for RGB channels	2	0
aid	Aid the user to set up QT	0	0
air	Rescale intensities:	2	0
alg	Antilogarithm of the intensity of each pixel	0	0
ani	Anisotropic diffusion	2	0
apple	Read standard image: apple (colour)	0	0
asi	Average several images derived from a given webcam	2	0
author	Learn about the author of QT	0	0
avg	Average intensity	0	1
bay	Find the bays for a binary object	0	0
bbx	Bounding box, smallest rectangle containing the blob	0	4
bcl	Bit set	1	0
bcp	Bit complement	1	0
bdg	Bridge operator (morphology)	1	0

beans	Read standard image: coffee beans	1	1
bed	Binary edge detector	1	0
bgb	Information about Bruce Batchelor, the author of QT	0	0
big	Select the blob of given rank size	1	0
birds	Read standard image: birds (colour)	0	0
blf	Fill holes in a binary image	0	0
blo	Expand central part of intensity range; [64,192] is mapped to [0, 255]	0	0
blp	Find the bottom-left-most white (i.e., non-black) pixel	0	2
bnb	Bridge between the two closest blobs	0	3
bottle	Demonstration: Fit third order polynomial and circle to the outline of a bottle	0	1
bpa	Calculate shape/size parameters of all blobs in a binary image	1	1
brp	Find the bottom-right-most white (i.e., non-black) pixel	0	2
brx	Barrel rotate by shifting along the X-axis	1	0
bry	Barrel rotate by shifting along the Y-axis	1	0
btt	Bottom hat morphological filter	1	0
bxy	Barrel rotation along X- and Y-axes	2	0
cab	Centroids of all blobs in a binary image	0	1
cae	Find and count points where the intensities at corresponding points in the Current and Alternate Images are similar	1	1
caf	Circular averaging filter	0	1
caliper	Measure object diameter using a virtual caliper gauge	2	1
cam	Read standard image: cam	0	0
car_park	Read standard image: car park	1	0
card	Demonstration: Find suit and value of non-picture playing card	2	0
cav	Column average	0	0
cbd	Chessboard pattern	1	1
cbl	Count 4- or 8-connected blobs	1	1
cbr	Add color bar next to Current Image Does not alter either image	0	0
cct	Read standard image: thin film circuit	0	0
ccv	Get RGB colour values in the Current Image at a defined address	2	3
cdf	Colour difference between two images, applied to RGB channels separately	0	0
ceb	Use the least-squares method to fit a circle to the edge of a blob	1	3
ced	Canny edge detector	1	1
cen	Contrast enhancement applied to the RGB channels separately	0	0
ceo	Edge detector applied to the RGB channels separately	0	0
cfp	Closest white point [u,v] from a given point [x,y]	2	3
cga	Gamma adjustment applied to the RGB channels separately	3	0
cgp	Count points thta have a given intensity	1	1
cgr	Centroid coordinates, calculated from a single blob	0	2
cgr_all	Centroid coordinates, calculated from all blobs	0	2

chk	Generate check pattern	1	1
chq	Histogram equalise the RGB channels separately	0	0
chu	Convex hull – operates on only one blob at a time	0	0
chu_all	Convex hull of all blobs	0	0
cig	Count points with intensity greater than or equal to a	1	1
cim	Centre of the image	1	2
cin	Column integrate	0	0
cir	Draw an open circle	4	0
civ	Get intensity value in the Current Image at a defined address	2	1
cln	Remove isolated white pixels	0	0
clocks	Read standard image: clock face	1	0
cls	Closing with one of four pre-defined structuring elements	2	0
cmd	Column median	0	0
cmn	Column minimum	0	0
cmx	Column maximum	0	0
cnr	Corner detection: dog-on-a-lead, edge-following algorithm	2	0
cnw	Count white neighbours	0	0
cob	Choose one or more a-connected binary objects with the cursor (a = 4 or 8)	1	0
cog	Demonstration: Analyse the image of a cog	0	2
coil	Demonstration: Locate the ends of the flying leads on a small cylindrical coil	0	6
coin	Read standard image: coin	0	0
con	Same as *glc*. (Mac OS X. Causes an error with MATLAB running under Windows)	0	0
cox	Column maximum	0	0
cpy	Copy the Current Image to the Alternate Image	0	0
crack	Demonstration: Detect a crack in a forged ferrous component	0	0
cracked	Read standard image: cracked ferrous component	0	0
crease	Read standard image: creased fabric	0	0
crk	Crack detector with variable structuring element	2	0
crp	Crop the image interactively or by specifying four parameters	4	4
crs	Dilate so that an isolated white point becomes a vertical cross	1	0
csd	Column standard deviation	0	0
cse	Creating structuring elements for *gbd* and *gbe*	2	1
csg	Define polygon within colour image. Plot 3D scattergram of its RGB values	1	0
csh	Copy given column to all other columns	1	0
csi	Crop the image to create a 3-level mask and convolve this with whole image	4	3
csk	Clear the image stack. The stack size is also defined	0	0
csp	Generate a sine-wave intensity pattern that is rotationally symmettrical	3	0

ctp	Convert from Cartesian to polar coordinates	2	0
ctr	Draw intensity contours in the Current Image	0	0
cur	Get position of a point defined by the cursor	0	3
cwp	Count white points	0	1
cxa	Convex area for all blobs	0	1
dab	Do specified command for all blobs in a binary image	1	0
dbn	Direction of brightest neighbour	0	0
dcd	Draw a solid circular disc of radius a	1	0
dcg	Draw a cross at the centroid (of one blob)	0	0
dci	Draw a cross at the centre of the image	1	0
dcl	Draw a cross at a given point	3	0
dcr	Dilate so that an isolated white point becomes a diagonal cross	1	0
dcw	Draw a circular intensity wedge	3	0
dec	Draw equivalent circle (i.e., same area, located at the centroid)	0	0
delay	Delay of a given duration	1	0
demon	Demonstrations: a collection of demonstrations of QT	1	0
dev	Standard deviation of the intensity	0	1
dfc	Shade image so that intensity indicates distance from centroid (for all blobs)	0	0
dfp	Intensity is equal to the Minkowski r-distance from a given point, where r = 0,1,2,3,. . .	3	0
dga	Dynamic gamma adjustment	0	1
dgr	Diagonal gradient	0	0
dgw	Find the size of the image,	0	2
dic	Draw an intensity cone	2	0
did	Dynamic image display	0	2
dil	Dilate with one of four pre-defined structuring elements	2	0
dim	Find the size of the image	0	2
din	Double all intensities	0	0
div	Divide Current by Alternate Image	0	0
dla	Draw a line at a given angle from a given point	3	0
dlr	Draw one line identified from a peak in the Radon transform image	4	0
dls	Find the closest point along that line at a given angle from a given point	3	0
dmg	Direction of maximum gradient	0	0
doc	Read the documentation file describing one of QT's M-functions	1	0
dor	DOLP filter, based on rectangle-averaging filters	4	0
dpa	Draw the principal axis (i.e., axis of minimum second moment)	0	3
dps	Picture shift with wraparound Shift parameters are set using the cursor	0	2
drd	set the intensities of all pixels within a defined rectangle to a given value	5	0
dri	Dilate with a rectangular structuring element	2	0
drp	Dominant Radon projection	0	0
dsc	Draw a white disc of radius r centred at a given point [x,y]	3	0

dsq	Dilate so that an isolated white point becomes a square	1	0
dsz	Dynamic size thresholding (Works with blob sizes $<$ 256 pixels)	0	1
dth	Slightly modified version of cur, omitting colorbar generator	0	3
dtx	Toggle the text-display switch	0	0
eab	Euler number for all blobs	0	1
ecc	Exchange colour channels	3	0
ecy	Eccentricity – ratio of and the lengths of the major and minor axes	0	2
edd	Morphological edge detectors	1	0
edg	Set the image border to a predefined level	3	0
edx	Functions lbx and rbx are applied Then, the results are merged using mni	0	0
emn	Extended-minima transform	1	0
emx	Extended-maxima transform	1	0
enc	Contrast enhancement	0	0
epl	Find the extremal white points along a given line	4	4
eqd	Equivalent diameters of all blobs in a binary image	0	1
eri	Erode with a rectangular structuring element	2	0
erl	Erode with an L-shaped structuring element	2	0
ero	Erode with one of four pre-defined structuring elements	2	0
ersf	Repeated execution of a remote script file, with a specified time limit	3	0
esr	Evaluate a specified command sequence Save results for display via the web	2	2
eul	Euler number for 4- or 8-connected blobs	1	1
evo	Grab the latest image saved by the EvoCam image capture software from the iSight camera	1	0
exm	Extremal points in a binary image	1	4
exr	Exclusive OR	0	0
ext	Extent – proportion of pixels in minimum area rectangle that are also in blob	0	1
fap	Set pixels at a list of given addresses to intensity values defined by list z	3	0
far	Filled area – no of white pixels after holes have been filled	0	1
fbl	Fit one blob onto another	0	1
fcc	Freeman or chain code the edge of a solid blob	0	3
fcd	Draw a circle intersecting three given points	6	3
fce	Fit a circle to intersect three edge points found by scanning horizontally	3	3
fcf	Fixed colour filter	0	0
fci	Read Current Image (see *sci*)	0	0
fcl	Fit a circle using the least-squares fit	0	3
fib	Fill isolated black pixels	0	0
fil	Image filtering with one of MatLab’s predefined image filters	1	0
fish	Read standard image: fish	1	3
fll	Fill isolated black pixels	1	0
fov	Field-of view-calculator	0	0

fsl	Find maximum length straight line using the Hough transform	0	0
fsz	Display image at full size Rescale it, if it is too big to fit on screen	0	0
ftd	Fourier transform (direct)	1	0
ftm	Fourier transform (log magnitude)	1	0
fwp	Furthest white point from a given point	2	3
gap	Get position coordinates and intensity values for all non-black pixels	0	3
gbd	General binary dilation	1	0
gbe	General binary erosion	1	0
gbi	Generate a new black image of a given size	3	0
gcc	Gamma adjustment applied to the RGB channels separately	1	0
gear	Read standard image: gear	0	0
gft	Grass-fire transform	1	0
girls	Read standard image: three girls (colour)	0	0
gis	Grab and save a series of images from a webcam given its URL	4	0
git	General intensity transform using a look-up table	1	0
glass	Read standard image: glass bottle	0	0
glc	General linear convolution operator	1	2
gli	Lower and upper intensity limits	0	2
gma	Gamma adjustment	1	0
go	Initialise QT	0	0
gpt	Find the intensity at a given point	2	1
gra	Simple (cross) edge detector	0	0
grb	Grab an image from one of the remote cameras	2	0
grd	Grid pattern	1	1
grip1	Demonstration: Draw robot fingerprint given size and orientation parameters	6	0
grip2	Demonstration: Calculate grasping parameters for a 2-finger gripper	6	3
grip3	Demonstration: Calculate grasping parameters with round fingers	1	4
grip4	Demonstration: Calculate grasping parameters for a suction or magnetic gripper	0	4
grp	Calculate and display gripping points for 2-finger robot gripper	1	4
grs	Calculate and display gripping point for suction or magnetic robot gripper	0	4
gry	Convert a colour image to grey	0	0
gsi	Get image from the stack simply by clicking on the Image Stack display	0	0
gsn	Add Gaussian noise to an image for testing purposes	1	0
gwc	grab web image, retaining colour information	1	0
gwe	Get a sample colour image from the web	1	0
gwi	Get image from a given web site	1	0
gwp	Get window position	1	4
hbt	Local averaging along the Hilbert curve	2	0
hbt1	Maximum intensity along the Hilbert curve	2	0

hbt2	Minimum intensity along the Hilbert curve	2	0
hcd	Harris corner detector	3	2
hcf	Programmable colour filter for detecting variation in hue	1	0
hcp	Plot the cumulative intensity histogram. Display only; neither image is altered	0	0
heq	Equalise the intensity histogram and plot the mapping function	0	0
hgm	Plot the intensity histogram Display only; neither image is altered	0	0
hgr	Horizontal gradient	0	0
hil	Highlight pixels whose intensity is within a given range	3	0
hin	Halve all intensities	0	0
hlp	Help	1	1
hpf	High-pass filter	0	0
hpi	Plot the intensity histogram. Display only; neither image is altered	0	0
hpk	Find and draw the peaks in the Hough transform	1	1
hqx	Apply histogram equalisation mapping function for Alternate Image to Current Image	0	0
hs4	Hysteresis smoothing applied four times: right, left, up, down. Results are added	1	0
hsb	Scan horizontally along a given row until a bright pixel is found	2	2
hsd	Hyteresis smoothing then subtract the original	1	0
hsi	Separate the HSI planes	1	0
hsp	Render the HS plane in glorious colour	0	0
hsr	Hue-saturation reference chart	0	0
hub	Visit the author’s main web page. Upgrades to QT are held here	0	0
hue	Extract hue channel from a colour image	0	0
huf	Hough Transform	3	0
hys	Hysteresis smoothing	1	0
hzs	Scan horizontally along a given set of rows	3	2
icc	Correlation coefficient between the Current and Alternate Images	0	0
idn	Display the Current and Alternate Images immediately	0	0
ihm	Intensity histogram maximum	1	2
imf	Plot scattergram of A(i,j) versus C(i,j), for all (i,j)	0	0
img	View the standard QT images held on the author’s web site	0	0
imn	H-minima transform	1	0
imx	H-maxima transform	1	0
ine	Find pixels that are equal or very nearly equal in intensity	1	1
iob	Isolate that blob which overlaps a given point	3	0
ipc	Intensity profile	1	0
ipl	Intensity profile along a line	4	0
ipp	Find 100*a centile intensity	1	1
ipr	Intensity profile along a selected row	1	0
irt	Inverse Radon Transform	0	0

isight	Read an image obtained from the iSight camera and iStill software (Macintosh only)	1	0
iso	Plot isophotes in a new figure	0	0
itl	Find the point of intersection of two lines, each defined by two points	8	2
itx	Insert text in an image	1	0
ity	Extract intensity channel from a colour image	0	0
jas	Find a skeleton junction and the area surrounding it	3	1
jnt	Find the joints on a match-stick figure, produced by thn or ske	0	0
joy	Play one of several pre-recorded sounds	0	0
kbb	Keep the blob of rank size a and those blobs larger than it	1	0
kgp	Keep all blobs whose area is greater than b times the area of ath largest blob	2	0
kgr	Keep all b-connected blobs (b = 4 or 8) that contain at least a pixels	1	0
lak	Find the lakes in a blob	0	0
las	Find a skeleton limb-end and the area surrounding it	3	1
lbp	Find the left-bottom-most white (i.e., non-black) pixel	0	2
lci	Linear combination (weighted sum) of the Current and Alternate Images	2	0
led	Laplacian of Gaussian edge detector	1	1
lenna	Read standard image: Lenna (History of Lenna: http://en.wikipedia.org/wiki/Lenna)	0	0
ley	Local entropy of the intensities within a rectangle of given size	2	0
lhq	Local histogram equalisation	2	0
lic	Largest inscribed circle	0	3
linescan	Read standard image: derived from a line-scan camera	0	0
lln	Longest line found using the Hough Transform	3	0
lmb	Find the limb ends on a match-stick figure, produced by thn or ske	0	0
lmi	Centroid and orientation of the axis of minimum second moment, single blob	0	1
lmi_all	As *lmi*, calculate from multiple blobs	0	1
lnb	Largest neighbour in each neighbourhood of given size	1	0
lpc	Laplacian	0	0
lpf	Local averaging low-pass filter, 3*3 kernel	0	0
lrt	Invert the horizontal axis	0	0
lrx	L-R row maximum(rox) and R-L row maximum Results are then merged with mni	0	0
ls_cone	Read standard image: loud-speaker cone with loose wires	0	1
lsc	Linear scan; sample the intensity along a line	5	1
lsd	Local standard deviation of the intensities within a rectangle of given size	2	0
lsi	Variable frequency sine-wave generator	4	0
ltp	Find the left-top-most white (i.e., non-black) pixel	0	2
ltw	Left-top white point	0	2
lvm	Browse database of lighting-viewing methods on author’s web site	1	0

lvm_search	Search the Catalogue of Lighting-Viewing Methods for a given string	1	0
lvs	Search the LVM Catalogue for a set of terms	1	0
mab	Take multiple measurements (13) on all blobs	0	1
maj	Majority-vote edge smoothing on a binary image	1	0
mar	Minimum-area enclosing rectangle	0	4
mbc	Minimum bounding circle	1	3
mch	Find the mid-point of each vertical chord	0	0
mci	Mask a coloured image	0	0
mcn	Multiply all intensities by a constant	0	0
mdf	Median filter based on a window of given size	2	0
mdp	Most distant edge points	0	4
mgw	Magic wand operator	1	0
mic	Apply lic recursively; fit many circular discs inside a blob	1	3
mnc	Minimum of the RGB channels of two colour images separately	0	0
mni	Point by point minimum of current and alternate intensities	0	0
moment	Calculate the [p,q]-th moment for small integers p and q	2	4
mrc	Crop image by finding the smallest enclosing rectangle	0	0
mst	Thin white lines, to create a "match-stick" figure	1	0
mul	Multiply two images	0	0
mxi	Point by point maximum of current and alternate intensities	0	0
mxs	Maximum and minimum of several images derived from a given webcam	2	0
nargs	Utility function: No. of arguments and data I/O requirements for given function	0	6
ndo	Numerate distinct binary objects	0	0
neg	Negate	0	0
news	Read the latest news about QT from the author's web site	0	0
nlf	Non-linear filters Function is selectable by first parameter	3	0
nlg	Natural logarithm of the intensity of each pixel	0	0
nlp	Non-linear low-pass filter with one of four pre-defined structuring elements	2	0
npo	Reposition binary object at the centre of the image and normalise orientation	0	0
npo_all	As *npo* but calculated from all blobs	0	0
npv	Find number of pattern vectors	0	1
nrf	Neighbourhood intensity range filter	2	0
nwp	Nearest white point to a given point	2	3
nxy	Reposition binary object at the centre of the image	0	2
nxy_all	Reposition centroid of multiple binary objects at the middle of the image	0	2
oab	Orientation parameters of all blobs in a binary image	0	1
opn	Opening with one of four pre-defined structuring elements	2	0
packer	Demonstration: Packs rectangles into an odd-shaped area	1	0

pad	Pad the image by adding a border of defined width and intensity	3	0
panasonic	Grab an image from a Panasonic Lumix camera	1	0
parts	Read standard image: four metal stampings	0	0
pbi	Perpendicular bisector of the line joining two given points	4	4
pcb	Read standard image: printed circuit board	0	0
pcd	Apply given dyadic operator to RGB channels separately	2	0
pcf	Programmable colour filter	0	0
pci	Process each colour channel separately	3	0
ped	Prewitt edge detector	1	1
pencils	Read standard image: pencils (colour)	0	0
pex	Rescale the spatial resolution along both axes, by a given amount	1	0
pft	Fit a polynomial curve to the edge of a binary object	0	0
pgn	Draw a polygon using the cursor	0	0
pgt	Find the intensity at a given point	2	1
phs	Process each H, S and I channels separately	3	0
pis	Process all image files	3	0
pki	Find coordinates and value of peak intensity and plot it	0	3
plan	Read standard image: plan view of an hydraulics component	0	0
plot3d	Plot intensity in the Current Image as a 3D surface	0	0
plt	Intensity profile, overlaid on the Current Image without changing it	1	0
plv	Plot a vector in the Current Image	1	0
plw	Parallelogram warping	1	0
pmf	Process selected frames of a non-compressed colour AVI movie	4	0
pon	Normalise position and orientation, determined from direction of greatest radius	0	3
pop	Pop a file from the image stack	0	0
pout	Read standard image: girl pouting	0	0
prc	Plot intensity profiles along a row and column selected using the cursor	0	2
prolog	Ask SWI-Prolog to satisfy a given goal, returning a list of integers	1	1
psc	Pseudo-colour display of the Current Image	0	0
psf	Process each image in a given folder and construct an AVI movie	2	0
psh	Picture shift, without wrap-around	2	0
psw	Picture shift with wrap-around	2	0
ptc	Convert from polar to Cartesian coordinates	2	0
pth	Threshold so that a defined proportion of the image is white	1	0
push	Push a file onto the image stack	0	0
pxv	Investigate position and intensity of image features interactively, using the cursor	1	0
qt	Initialisation and starting one of the standard interactive environments	0	0
qtp	Add/remove path to QT update folder. Enables/disables updates	1	0
qtr	Evaluate sequence specified by the command file and save results for web	2	0

qts	Operate QT using the image stack (The stack size is set within qtstart)	0	0
qtu	Read a remote file and save it as an M-file	1	0
r	Synonym for rsi	1	0
raf	Local averaging low-pass filter of given kernel size	2	0
rbe	Remove blobs that touch the edge of the Current Image	2	0
rbi	Restore Current and Alternate Images from disc	0	0
rbk	Remove background intensity by opening and then subtracting the original image	1	0
rbp	Find the right-bottom-most white (i.e. non-black) pixel	0	2
rcf	Rank convolution filter	1	0
rci	Read a numbered image file and do not convert from colour to monochrome	1	0
rdc	Relate distance from centroid of a blob to distance around its circumference	0	2
rdf	Rank difference filter	3	0
rdt	Radon transform	0	0
rea	Read an image file	1	0
red	Roberts edge detector	0	0
rei	Read the image saved previously by wri in a TIFF or JPEG file	2	1
rev	Bit reversal for each intensity value; MSB – > LSB, LSB – > MSB, etc	0	0
rgb	Separate RGB colour planes	1	0
rgb2xyz	Convert RGB to XYZ colour coordinates, single data triple	3	3
rice	Read the standard image file showing a few grains of rice	0	0
rii	Read an image created by the iSight camera and sitting on the desk-top	1	0
rim	Read a numbered or named image available formats: TIF, TIFF, or JPG	1	0
rin	Row integrate	0	0
rip	MATLAB process control, interrupt on timer signal	2	0
rkf	Rank filter Find c-th largest intensity value within each a*b window	3	0
rlc	Run-length code along columns	0	0
rlr	Run-length code along rows	0	0
rmn	Find regional minima	0	0
rmv	Remove interior pixels (Binary edge)	0	0
rmx	Find regional maxima	0	0
rni	Read a numbered RGB or gray image file, with file-name extension "jpg" or "tif"	1	0
road	Read standard image: road scene	1	0
rot	Rotate the image by a given amount (a), with no cropping	1	0
rox	Row maximum	0	0
rpc	"Reversible" pseudo-colour mapping using standard image number #999 as LUT	0	0
rsb	Make all rows same as bottom row of the image	0	0
rsf	Resize the image display windows (labelled Figure 1 and Figure 2)	0	0

rsi	Read numbered stack image	0	0
rsk	Fill the stack with randomly chosen images	0	0
rsz	Resize image/adjust aspect ratio	2	2
rti	Fill the image stack with popular images	0	0
rtp	Find the right-top-most white (i.e., non-black) pixel	0	2
rtx	Convert text file to speech.	1	0
rwo	Repeated web operation	2	0
rwp	Read one of the standard images from the author's web site	2	0
rxm	Relaxed median filter	2	0
sai	Sum all intensities	0	1
sat	Extract saturation channel from a colour image	0	0
saturn	Read standard image: Saturn and its moons	0	0
say	Convert a text string to speech (Macintosh only)	1	0
sbc	Select pixels based on the number of white 8-neighbours of each white pixel	1	0
sbi	Save both Current and Alternate Images on disc	0	0
sca	Bit set	1	0
scc	Scan around a circular path	3	1
sci	Set image to a constant intensity	1	0
scissors	Read standard image: scissors (JPEG not true binary)	0	0
scp	Draw polygon in colour image and plot scattergram of RGB values in 3D space	0	0
scr	Scramble the image by sampling along the Hilbert curve	1	0
scv	Set RGB colour values in the Current Image at a defined address	2	3
sdm	Grey-level spatial dependency matrix	2	0
seb	Shade the edge of a blob according to the distance around the circumference	0	3
sed	Sobel edge detector and variations thereon	1	0
seg	Segment the input image	2	1
sgt	Initiate a given operation. After a given time, the user is given the option to terminate execution.	2	0
shf	Area, perimeter and shape factor	0	3
shh	Shift the Current Image by a given number of rows	1	0
shk	Shrink each white region to a point or to loops, if it has lakes	1	0
shp	Vertical gradient	0	0
shr	Shear warping	1	0
shs	Plot scattergram of saturation versus hue	0	0
sia	Save all image files in the named folder to the folder holding QT's standard images (BGB_MatLab_Images)	1	0
side	Read standard image: side view of an hydraulics component	0	0
sim	Read one of the standard images. The user selects which one by clicking on a menu.	0	0
sir	Set the intensities of all pixels within a defined rectangle to a given value	5	0

sit	Sigmoid function intensity mapping	0	0
siv	Get intensity value in the Current Image at a defined address	3	1
ske	Skeletonisation	0	0
slf	Normalise the orientation of the strongest linear feature	0	1
sly	Solidity – proportion of pixels in convex hull that are also in blob	0	1
sme	Edge smoothing: dog-on-a-lead, edge-following algorithm	1	0
sml	Keep the ath smallest blob	1	0
snb	Smallest neighbour in each square neighbourhood of a given size	1	0
sob	Select one blob with the cursor	0	2
sol	Draw line identified by a single spot in the RT (Radon transform) image	4	0
sony	Grab an image from a Sony Cybershot camera	1	0
speaker	Use the speech synthesiser to play a pre-recorded message (Macintosh only)	1	0
spi	Timed interruption of processing	2	0
spn	Add salt and pepper noise to an image for testing purposes	1	0
spr	Shrink each white region to a point or to N loops, if it has a holes	1	0
sqi	Pad the image to make it square	1	0
sqr	Square of all intensities	0	0
sqt	Square-root of all intensities	0	0
srgb	2D colour scattergram	2	0
ssk	See the images on the image stack	0	0
startup	Initialise the stand-alone version of QT. (MATLAB automatically executes the macro startup.m on start-up.)	0	0
stp	Generate a series of intensity steps	0	0
str	Draw a straight line between the overall centroid and the centroid of each blob	0	0
street	Read standard image: street scene (Times Square, New York City, USA)	0	0
sub	Subtract two images	0	0
suc	Subtract the RGB channels of two colour images separately	0	0
swi	Switch images – interchange the Current and Alternate Images	0	0
swipl	Ask SWI-Prolog to satisfy a given goal. This expected to return a list of integers.	1	1
tav	Threshold at some defined point within the band of occupied intensity values	1	0
tbt	Invert vertical axis of the image	0	0
tbx	T-B column maximum (cox) and B-T column maximum Results are merged with mni	0	0
tha	Threshold at some defined point within the band of occupied intensity values	1	0
thb	Threshold at some defined point within the band of intensity values defined by two centiles	3	0
thc	Threshold at the average intensity plus some defined constant intensity	1	0

thd	Threshold at the most popular intensity value plus some defined constant	1	0
the	Threshold to show those pixels that have the lowest intensity	0	0
thf	Threshold to show those pixels that have the highest intensity	0	0
thg	Threshold to show pixels at the popular intensity value	0	0
thh	Threshold using Otsu's method for choosing the parameter	0	2
thn	Thin white lines	1	0
thr	Threshold	2	0
tim	Operation timer	1	1
tkn	Thicken white areas but do not join them	1	0
tlp	Find the top-left-most white (i.e., non-black) pixel	0	2
tlw	Left-top white point	4	4
tpt	Top-hat morphological filter	1	0
trp	Find the top-right-most white (i.e., non-black) pixel	0	2
tsk	Get a file from the top of the image stack, or	0	0
tur	Rotate the image by a given amount	1	0
txt	Superimpose text temporarily on the Current Image	2	0
udc	Draw circle through two points defined by the user	1	0
udr	Draw rectangle through two points defined by the user	1	0
uds	Move up/down the image stack	0	0
ult	Ultimate erosion of a binary image	0	0
uns	Unsharp masking	0	0
usc	Reverse the scrambling perfomed by sampling along the Hilbert curve	1	0
use	User defines a structuring element using the cursor	1	1
vfs	Variable frequency sine-wave generator for testing 1-dimensional filters	1	0
vgr	Vertical gradient	0	0
vial	Read standard image: glass vial (dark-field illumination)	0	0
vpl	Draw a straight line given two points	5	0
w	Synonym for wis	1	0
wgx	Intensity wedge varying along the X-axis	0	0
wgy	Intensity wedge varying along the Y-axis	0	0
wires	Read standard image: coil with loose wires	0	0
wis	Write the Current Image to the image stack	0	0
wnf	Wiener filter	2	0
wri	Save the Current Image in a TIFF or JPEG file	2	1
wrw	Save the Current and Alternate Images (JPEG files), ready for web	1	0
wsh	Watershed	1	0
wti	Save the Current Image in a TIFF or JPEG timed file	1	1
wtx	Create a new text file/add text to exiting file. Prepare files for "rtx"	2	0
xcf	Cross correlation applied to two images.	1	2
xray	Read the standard image x-ray of a mains plug	0	0
xyl	Minimum-area enclosing rectangle for a single blob	0	4

xyz	Reserved for testing QT software		
xyz2rgb	Convert XYZ to RGB colour coordinates	3	3
yxt	Interchange the vertical and horizontal axes	0	0
z	Switch images; interchange the Current and Alternate Images	0	0
zed	Zero-crossing edge detector	1	1
zer	Set all pixels to black	0	0

Controlling the Velleman K8055 Interface Board (WINDOWS only, See Appendix I)			
		Arguments	
Name	Function	In	Out
vel_start	Start	1	0
vel_close	Close	0	0
vel_set_dig_out	Set given digital output to defined level	2	0
vel_clear_dig_out	Clear given digital output	1	0
vel_read_digital	Read given digital input	1	1
vel_set_analog_out	Set given analogue output to defined volatage	2	0
vel_read_analog	Read given analogue input	1	1
vel_test	Test the board	1	0
vel_wait_dig_input	Wait for given digital input to go "high"	1	1
vel_wait_any_dig_input	Wait for any digital input to go "high"	0	2
vel_wait_analog_input	Wait for given analogue input to go above defined voltage	2	2

Commercial Interactive Image Processing Products

Several commercial products have been based on the same paradigm as QT's progenitor, SUSIE. In addition, several similar systems have been devised for in-house use in companies and universities.

Intelligent Camera, previously a product of Image Industries/Ltd, now part of Cognex Ltd., Epsom, Surrey, England, U.K.

SuperVision, interactive image processing software, previously a product of Image Industries/Ltd, now part of Cognex Ltd., Epsom, Surrey, England, U.K.

VCS (Vision Control System), interactive image processing software, previously a product of Vision Dynamics Ltd., Hemel Hempstead, Herts, U.K.

Autoview Viking, previously a product of British Robotic Systems Ltd., London, U.K.

System 7, previously a product of The 3M Company, St.Paul Minnesota

MATLAB

QT was programmed using the following software:

Image Processing Toolbox, MATLAB, Mathworks, Inc, URL http://www.mathworks.com/, accessed 26th November 2009.

22 NeatVision: Development Environment for Machine Vision Engineers

Paul F. Whelan · Robert Sadleir · Ovidiu Ghita
Dublin City University, Glasnevin, Dublin, Ireland

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_22,

Abstract: This chapter will detail a free image analysis and software development environment for machine vision engineers. The environment provides high-level access to a wide range of image manipulation, processing and analysis algorithms (over 300 to date) through a well-defined and easy to use graphical interface. Users can extend the core library using the developer's interface, a plug-in, which features automatic source code generation, compilation with full error feedback, and dynamic algorithm updates. The chapter will also discuss key features associated with the environment and outline the advantages in adopting such a system for machine vision application development. (http://www.cipa.dcu.ie/)

22.1 Introduction

For many novices to the world of machine vision, the development of automated vision solutions may seem a relatively easy task, as it only requires a computer to understand basic elements such as shape, colour and texture. Of course this is not the case. Extracting useful information from images is a difficult task and as such requires a flexible machine vision application development environment. The design of machine vision systems requires a broad spectrum of techniques and disciplines. These include electronic engineering (hardware and software design), engineering mathematics, physics (optics and lighting), mechanical engineering (since industrial vision systems deal with a mainly mechanical world) as well as the system engineering aspects of developing reliable industrial systems. In this chapter, we will focus on one aspect of the machine vision design cycle, namely the algorithm development environment (referred to as NeatVision [1]). It aims to provide novice and experienced machine vision engineers with access to a multi-platform (realised through the use of Java) visual programming development system.

Java is an interpreted programming language, and as such applications written in Java are not executed directly on the host computer; instead, these applications are interpreted by the Java Virtual Machine. As a result, Java programs generally run slower than native compiled programs written in languages such as C or C++. This performance issue is constantly being addressed and a number of improvements have been made since Java was first released. For example, just-in-time compilers significantly improved the performance of Java applications by removing the need to reinterpret already executed code while the introduction of HotSpot technology further enhances application performance by optimising garbage collection and improving memory management. With the recent release of the Java Standard Edition Version 6 Update 22 the performance of Java is approaching that of native programming languages.

The NeatVision environment provides an intuitive interface which is achieved using a drag and drop block diagram approach. Each image-processing operation is represented by a graphical block with inputs and outputs that can be interconnected, edited and deleted as required. NeatVision (Version 2.1) is available free of charge and can be downloaded directly via the Internet www.NeatVision.com.

22.1.1 Standard Installation

The requirements for the standard NeatVision installation are:

- JRE 1.4.X – The J2SE Java Runtime Environment (JRE) allows end-users to run Java applications. (e.g., *j2re-1_4_2_09-windows-i586-p.exe*)

- JAI 1.X – Java Advanced Imaging (JAI) API. (e.g., *jai-1_1_X-lib-windows-i586-jre.exe*)
- NeatVision Standard Edition (*neatvision.jar*). NeatVision is distributed as a ".jar" file. The contents of this file should not be extracted; any attempt to do this will cause NeatVision to cease functioning

Please insure that the JAI is placed in the same path as the JRE. This only becomes an issue if you have multiple versions of Java on your machine (the default is that JAI will place itself in the most recent version of the Java). Assuming the JRE has been installed in `C:\Program Files \ Java\j2re1.4.2_09` and the NeatVision jar file is in `D:\NV`, then the following single line command (The NeatVision argument **must have** a capital "N" and "V") will enable NeatVision to run from `D:\NV`.

```
"C:\Program Files\Java\j2re1.4.2_09\bin\java.exe" -classpath D:\NV\
neatvision.jar NeatVision
```

22.2 NeatVision: An Interactive Development Environment

NeatVision is just one example of a visual-programming development environment for machine vision [2]; other notable examples include commercial programs such as Khoros [3] and WiT [4]. Visual programming involves defining variables, and specifying operations, which are to be performed on these variables, and their derivatives in order to perform a specific task. This is achieved by creating a structured flow of data using branching, looping and conditional processing. Traditionally, computer programs have been written using textual programming languages. These programs can process data in a complex fashion; unfortunately, the data paths and the overall structure of the program cannot be easily identified from the textual description. This can make it very difficult to appreciate the relationship between the source code and the functionality, which it represents. Although the programmer specifies the data flow in a visual program, the order in which the components execute is defined by the availability of data. Conditional processing concepts are supported in the visual domain by using dedicated flow control components. The main disadvantages of existing visual programming environments includes their cost, lack of cross platform support, and the fact that they tend to be focused on image processing rather than image analysis applications (the latter must be considered a key element of any practical machine vision application).

Text-based programming languages such as MATLAB [5] can be a powerful alternative to visual programming. In addition to the disadvantages outlined with respect to the visual programming languages, text-based approaches require the user to have a higher level of programming skills when compared to visual programming environments. Text-based interactive environments are generally more suitable to experienced users; in fact, experienced users can become frustrated by the visual programming environment as complex programs can take longer to develop (Note: we have recently developed a MATLAB compatible *VSG Image Processing & Analysis Toolbox* toolbox [6] that replicates NeatVision's functionality to allow MATLAB users build machine vision solutions). Hence our aim is to produce a suitable environment for those new to machine vision while retaining the flexibility of program design for the more experienced users. Based on our review of exiting text and visual programming based on machine vision development environments, the key criteria necessary are outlined below:

- Multi-platform: The development environment must be able to run on a wide range of computer platforms.
- Focused on machine vision engineering: The environment should contain a wide range of image processing and analysis techniques necessary to implement practical machine vision engineering applications.
- Easy to use: It should allow users to concentrate on the design of machine vision solutions, as opposed to emphasising the programming task.
- Upgradeable: The environment must contain a mechanism to allow users to develop custom vision modules.

A visual program can be created by defining input data using the input components, then implementing the desired algorithm using the processing and flow control components. The data flow is specified by creating interconnections between the components. The program can be completed by adding output components to view the data resulting from the algorithm execution. Details on the design of the NeatVision development environment appear elsewhere [7].

22.3 NeatVision's Graphical User Interface (GUI)

The NeatVision GUI (➊ *Fig. 22.1*) consists primarily of a workspace where the processing blocks reside. The processing blocks represent the functionality available to the user. Support is provided for the positioning of blocks around the workspace, the creation and registration of interconnections between blocks. The lines connecting each block represent the path of the data through the system. Some of the blocks can generate child windows, which can be used for viewing outputs, setting parameters or selecting areas of interest from an image. If each block is thought of as a function, then the application can be thought of as a visual programming language. The inputs to each block correspond to the arguments of a function and the outputs from a block correspond to the return values. The advantage of this approach is that a block can return more than one value without the added complexity of using C-style pointers. In addition, the path of data through a visual program can be dictated using special flow control components. A visual program can range in complexity from three components upwards and is limited only by the availability of free memory.

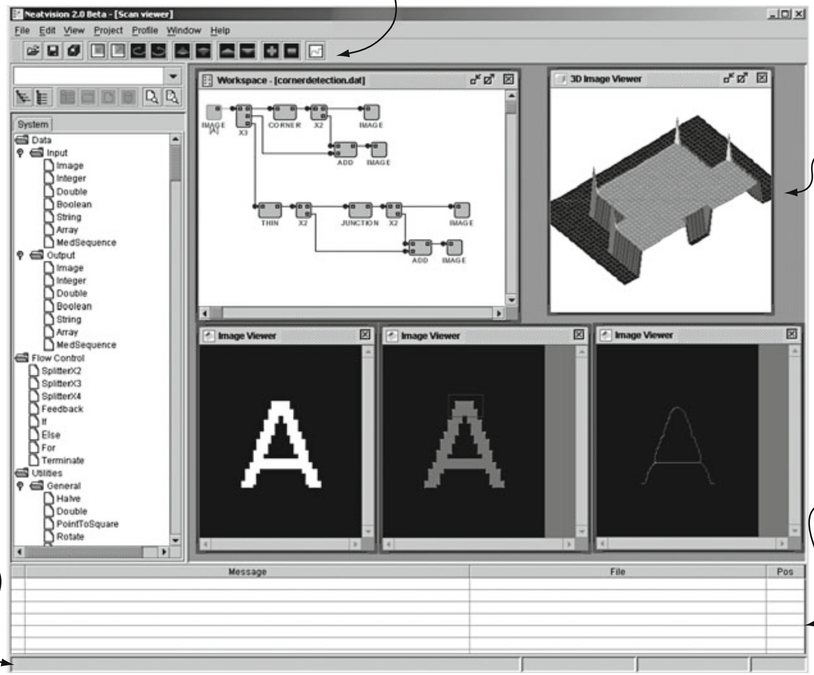
As each block is processed, it is highlighted (in green) to illustrate that it is active. This allows users to see the relevant speeds of parallel data streams within a visual program. This can help identify potential processing bottlenecks within the workspace allowing for a more efficient balanced design. The colour coding of the blocks data connection type and its status also aids in the design process. To aid user operation, each data connection has two colour coded properties, namely the block *data type* and *connection status.* NeatVision currently supports eight data types, i.e., Image (red), Integer/Array data (green), Double precision Floating point data (blue), Boolean data (orange), String data (pink), Fourier data (light blue), Coordinate data (purple) and Undefined data (black). The other connection property relates to its status. There are three main states for a connection, *connected (green), disconnected (red)* and *disconnected but using default value (orange)*.

This approach provides a fast and simple alternative to conventional text-based programming, while still providing much of the power and flexibility. The visual workspace can be compiled and executed as with a conventional programming language. Errors and warnings are

The search utility
due to the vast range of visual components provided by neatvision a search function is provided. Just type the name in here and the relevant component will appear in the workspace.

The controls
the neatvision controls consist of the toolbar and the menubar, these controls adapt to suit the application that is currently selected in the virtual desktop virtual desktop.

The component explorer
The Neatvision component explorer provides access to the currently available components. Components can be dragged directly from the explorer into a visual workspace.



The virtual desktop
any appliaction window such as the visual workspace or the text editor will reside within the virtual desktop of the neatvision application.

The statusbar
The statusbar is used to provide general information for instance compilation success and connection information.

The message window
all java and visual compilation errors and warmings are presented in this window. In order to find out the source of any message just doulble click the messae and the relevant error will be highlighted.

Fig. 22.1
Key features of the NeatVision environment

generated depending on the situation. There is currently support for 15 input graphics file formats and 13 output formats. Some of the main formats are listed below (*R* indicates a read-only file format and *RW* indicates a read/write file format).

- BMP (*RW*) Microsoft Windows Bitmap.
- BYT (*RW*) Raw image data, grey scale only with a maximum pixel depth of 8 bits.
- FPX (*R*) Kodak FlashPix is a multiple-resolution, tiled image file format based on JPEG compression.
- GIF (*R*) Graphics Interchange Format (GIF) is a bitmap file format which utilises Lemple-Zev-Welch (LZW) compression.
- JPEG (JPG) (*RW*) Joint Photographic Experts Group (JPEG) file interchange format is a bitmap file utilising JPEG compression.
- PCX (*RW*) PC Paintbrush (PCX) is a bitmap file using either no compression or Run Length Encoding (RLE).
- PNG (*RW*) PNG is a lossless data compression method for images.
- PBM (*RW*) Portable BitMap is a lowest common denominator monochrome file format.
- PGM (*RW*) Portable Greymap Utilities is a non-compressed bitmap format, hence allowing image data to be left intact.
- PPM (*RW*) Portable PixelMap is a lowest common denominator colour image file format.
- RAS (*RW*) Sun Raster Image (RAS) is a bitmap file format using either no compression or RLE.
- RAW (*RW*) Raw image data is similar to the BYT format described earlier except in this case colour image data is also supported.
- TIFF (TIF) (*RW*) Tagged Image File Format is a bitmapped file format using a wide range of compression techniques.

System parameters can be adjusted and the system may be reset and executed again until the desired response is obtained. At any stage, blocks may be added or removed from the system. NeatVision also contains a built-in web browser to allow easy access to online notes and support tools.

22.4 Design Details

NeatVision is designed to work at two levels. The *user* level allows the design of imaging solutions within the visual programming environment using NeatVisions core set of functions. NeatVision (Version 2.1) contains 300 image manipulation, processing and analysis functions, ranging from pixel manipulation to colour image analysis to data visualisation. To aid novice users, a full introductory tutorial and some sample programs can be found on the NeatVision website. A brief description of the main system (Items in italics are only included in the NeatVision advanced edition.) components [8] is given below; see ➋ Sect. 22.8 for additional details:

- Data types: Image, integer, double, string, Boolean, array, medical image sequences
- Flow control: Path splitting, feedback, if (else), for loop (see ➋ *Fig. 22.2*)
- Utilities: Rotation, pixel manipulation, resize, URL control, additive noise generators, region of interest, masking operations
- Arithmetic operators: Add, subtract, multiply, divide, logical operators

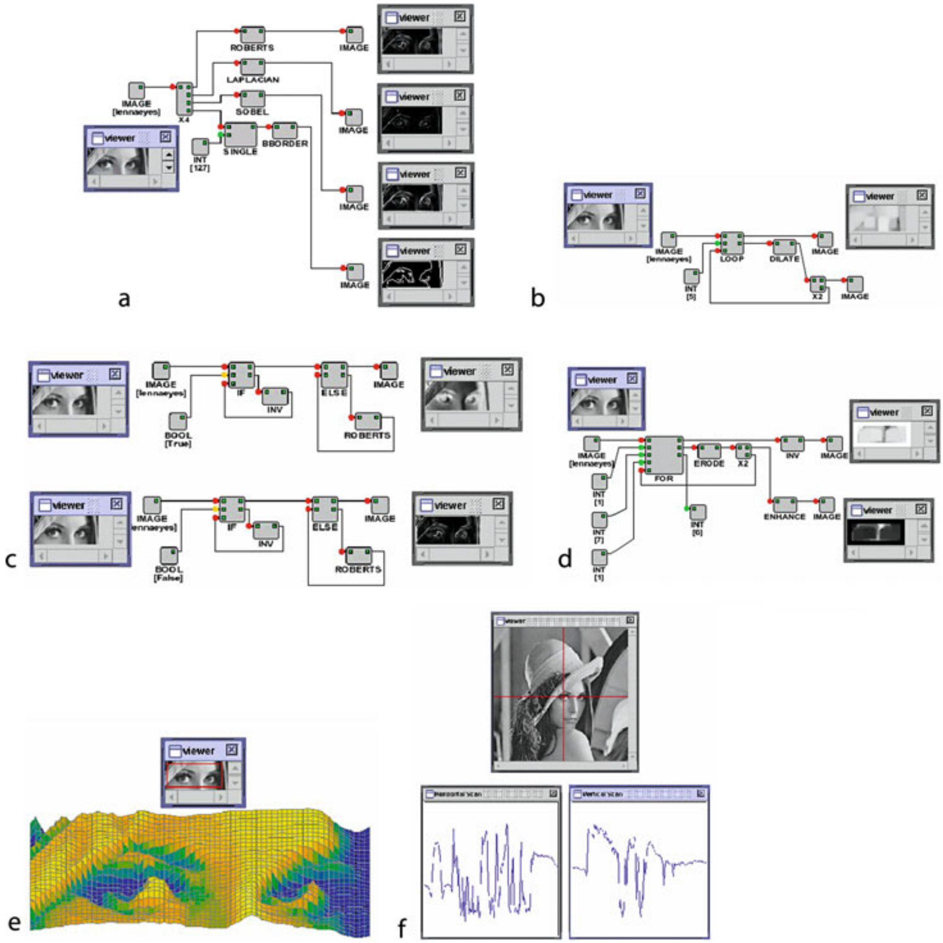


Fig. 22.2
Flow control/graphic utility examples: (a) path splitting, (b) looping feedback, (c) if (else), (d) for loop, (e) 3D viewer, (f) image profiling

- Histogram: General histogram analysis algorithms, local equalisation
- Image Processing: Look-up tables (LUT), threshold, contrast manipulation
- Neighbourhood-based filtering: Lowpass, median, sharpen, DOLPS, convolution, adaptive smoothing (or filtering)
- Edge detection: Roberts, Laplacian, Sobel, zero crossing, Canny
- Edge features: Line/arc fitting, edge labelling and linking
- Analysis: Thinning, binary detection, blob analysis, labelling, shape feature measures, bounding regions, grey-scale corner detectors
- Clustering: K-means (grey scale and colour), unsupervised colour clustering
- Image transforms: Hough (line and circle), Medial Axis, DCT, Cooccurrance, Fourier, distance transforms
- Morphology: Several 2D morphological operators, including erosion, dilation, opening, closing, top-hat, hit-and-miss, watershed

- Colour: Colour space conversion algorithms, RGB, HSI, XYZ, YIQ, Lab
- 3D Volume: 3D operators (thinning, Sobel, threshold, labelling), maximum and average intensity projections, rendering engine (Java and Intel native: wire frame, flat, Gouraud, Phong), *3D to 2D conversion, data scaling, 3D windowing, 3D arithmetic, 3D image processing, 3D labelling, 3D morphological operators, 3D reconstruction, 3D clustering*
- Low Level: Pixel level operators; get pixel value, set pixel value and basic shape generation
- String: String operators, object addition, to upper case and to lower case
- Mathematical: An extensive range of numerical operators and utilities, including constants and random number generation
- JAI Colour: Colour algorithms implemented using JAI (Java Advance Imaging [9]), operators, processing, filters and edge detectors
- OSMIA functions (Wintel native only): NEMA and AIFF image reader, ejection fraction measurement, 2D optical flow (Lucas & Kanasde and Horn & Shcunck courtesy of Barron [10] via the European Union funded OSMIA project [11]), XY normalisation

At the more advanced *developer's* level [12], NeatVision allows experienced application designers to develop and integrate their own functionality through the development and integration of new image-processing/analysis modules.

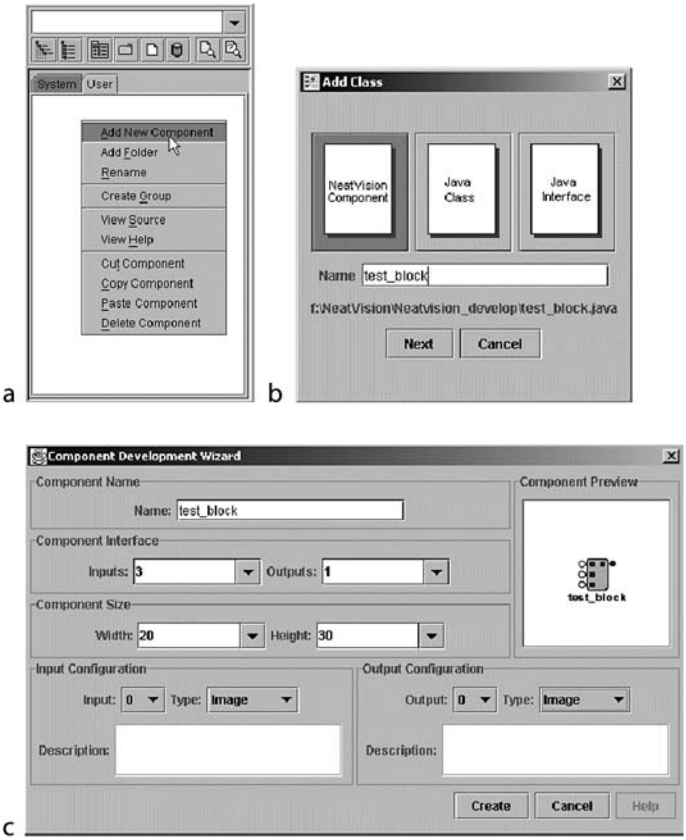
22.5 Developer's Environment

NeatVision was originally designed so that it could be easily extended by building on previously developed algorithms. This feature has been finalised with the release of version 2.1 of the NeatVision visual programming environment. This allows users to:

- Develop new NeatVision components that can ultimately be reused by other NeatVision developers.
- Reuse the core NeatVision components in new user-defined components.
- Submit their component or library of components to wider NeatVision community.

NeatVision development assumes a basic level of familiarity with the Java programming language and the NeatVision developer's plug-in. Additional details on developing for NeatVision [12] and the design concepts behind NeatVision along with detailed explanations of many of the its algorithms are also available [7].

When the developer's interface and the Java Development Kit (JDK) (Installation of the developer plug-in will require you to upgrade the JRE to the JDK. As the JDK compiler is not backward compatible and is frequently modified, we have restricted developer's interface to a specific version of the Java Development Kit – i.e., JDK 1.3.X. To activate the developer's version, you will need the *developer's update file* (*developer.jar*). To install this please close down NeatVision and place *developer.jar* in the classpath. It should be activated the next time you start NeatVision. e.g. `..\java.exe -classpath..\neatvision\neatvision.jar;..\neatvision\developer.jar NeatVision`) (Also be sure to download the latest version of *neatvision.jar*). When the developer's update file is present, a "user" tab appears alongside the "system" tab in the component explorer. The developer can add a new component by right clicking anywhere within the "user" view of the component explorer. After right clicking, a pop-up menu will appear. The "Add New Component" option must be selected from this menu in order to create a new file (➧ *Fig. 22.3*). The user is then queried



Name test_block

f:\NeatVision\Neatvision_develop\test_block.java

Name: test_block

Inputs: 3 Outputs: 1

Width: 20 Height: 30

Input: 0 Type: Image

Description:

Output: 0 Type: Image

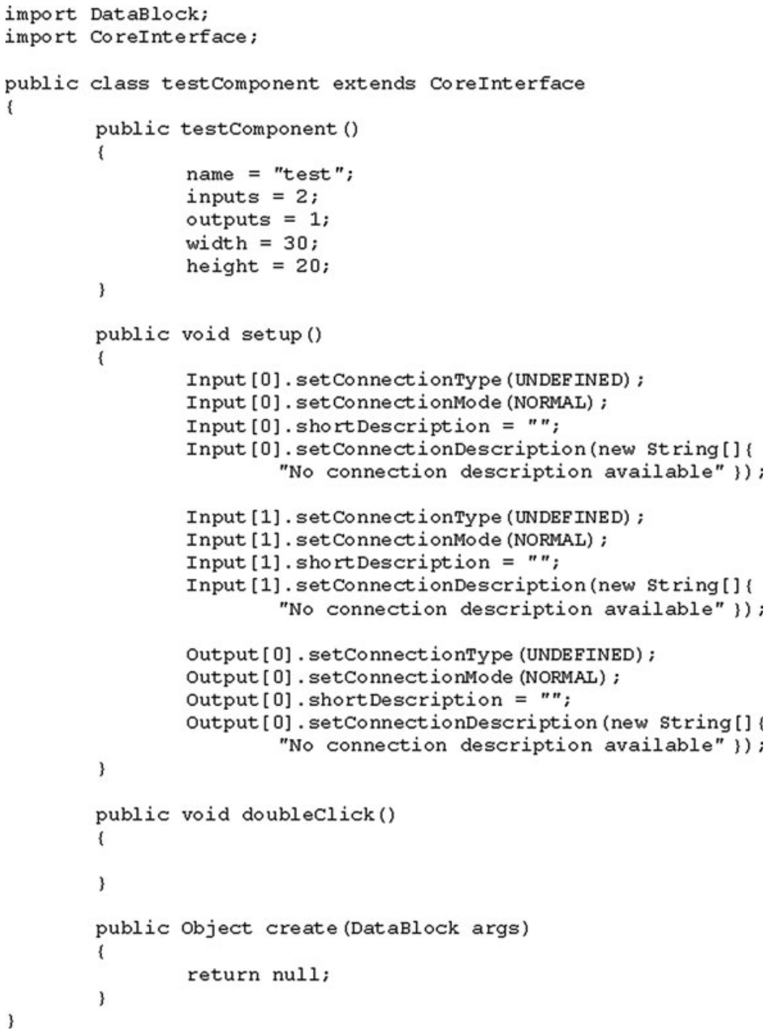
Description:

Fig. 22.3

NeatVision component development wizard. (a) Select *Add New Component* from the pop-up menu of the *user* area of the component explorer. (b) Select component to be added. (c) Define the component skeleton (i.e., the number and type of inputs and outputs for the associated block). This generates the necessary component wrapping code

as to whether they would like to create a NeatVision Component, a Java Class or a Java Interface (Note: a NeatVision Component is just a special type of Java class). A file name for the class or interface must be specified at this point. If a Java Interface or standard Java class is specified, then a text editor window is displayed with the relevant skeleton source code. The developer may edit and compile this code as desired. If a NeatVision component is specified, then a component development wizard is launched.

The wizard allows the developer to specify the visual appearance of the component including width and height in pixels, component name and number of inputs and outputs. The wizard also allows the developer to specify the data type and data description associated with each of the inputs and outputs. Once all of the required information has been entered, the developer need only press the "Create" button to generate to skeleton source code for the desired NeatVision component. The developer can then edit the skeleton source code (➲ *Fig. 22.4*) as required in order to implement the desired component functionality. At any stage, the source code for the component can be compiled. This is achieved by selecting the



```
import DataBlock;
import CoreInterface;

public class testComponent extends CoreInterface
{
        public testComponent()
        {
                name = "test";
                inputs = 2;
                outputs = 1;
                width = 30;
                height = 20;
        }

        public void setup()
        {
                Input[0].setConnectionType(UNDEFINED);
                Input[0].setConnectionMode(NORMAL);
                Input[0].shortDescription = "";
                Input[0].setConnectionDescription(new String[]{
                        "No connection description available" });

                Input[1].setConnectionType(UNDEFINED);
                Input[1].setConnectionMode(NORMAL);
                Input[1].shortDescription = "";
                Input[1].setConnectionDescription(new String[]{
                        "No connection description available" });

                Output[0].setConnectionType(UNDEFINED);
                Output[0].setConnectionMode(NORMAL);
                Output[0].shortDescription = "";
                Output[0].setConnectionDescription(new String[]{
                        "No connection description available" });
        }

        public void doubleClick()
        {

        }

        public Object create(DataBlock args)
        {
                return null;
        }
}
```

Fig. 22.4
The skeleton code for a double input/single output component. Note that the entry point is the `create()` method. This is called whenever the block receives a full complement of input data

relevant compile option from the "Project" menu. Selecting the compile option launches the Java compiler distributed with the JDK, and any errors in the specified file(s) are subsequently listed in the message window at the bottom of the main NeatVision window. For each error a description, file name and line number are provided. The user need only click on an error message to highlight the relevant error in the source code. Once all errors have been corrected, the message "compilation succeeded" is printed in the status bar. Following successful compilation, the block is available for use and can be included in a workspace like any core NeatVision component.

The NeatVision developer's interface extends and complements the visual programming interface by allowing users to develop custom components that can encapsulate the functionality of core NeatVision components, thus extending the already vast NeatVision library of components.

22.5.1 Developing for Reuse

As mentioned previously, the skeleton code for a new NeatVision component is generated using the component development wizard (see ➲ *Fig. 22.4*). In previous versions of NeatVision, the entry point for a component was the `main()` method and the programmer was responsible for interfacing directly with component inputs and outputs to read and write the associated data values. In NeatVision 2.1, the `main()` method is replaced by the `create()` method. This revised approach makes the development of new NeatVision components more straightforward and facilitates component reuse. The programmer is no longer required to interface directly with the component inputs and outputs. Instead, when a component becomes active, NeatVision automatically reads the data values at the inputs to a component and passes the associated data to the `create()` method in the form of a populated `DataBlock` object. Each entry in the `DataBlock` object corresponds to the data at the input with the corresponding index (0, 1, 2, etc. 0 being the topmost input). After the input data has been processed, the results must be stored in a new `DataBlock` object which is returned from the `create()` method upon completion (Note: If only one object is being returned from the `create()` method (i.e. if the block has only one output) then it is not necessary to encapsulate this within a `DataBlock` object. Instead, it can be returned directly and NeatVision will pass the returned object to the single output of the component.) Each entry in the returned `DataBlock` object is then passed to the output with the corresponding index (0, 1, 2, etc. 0 being the topmost output).

22.5.1.1 The `DataBlock` Class

The `DataBlock` class is used to represent the input and output data values associated with a particular NeatVision component. The data associated with a `DataBlock` object is represented as an array of objects. This means that the `DataBlock` class is future proof and will deal with any type of data that may be supported either by the core NeatVision components or any custom components developed by NeatVision users. The specification for the `DataBlock` can be found in the NeatVision developer's guide [12].

22.5.2 How to Reuse

The functionality provided by any of the core NeatVision classes can be called from within custom user-defined classes that are developed using the NeatVision developer's plugin. This is achieved by calling the static `create()` method of the `NeatVision` class.

```
Object NeatVision.create(String class, DataBlock args)
```

The parameters of the `create()` method are a `String` object and `DataBlock` object. The `String` object represents the class name of the desired component, and the `DataBlock` object represents the parameters that will be passed to an off-screen instantiation of the desired component. The `DataBlock` argument must have the same number of entries as the number of inputs connected to the desired component, and each entry must represent the data required by the associated input (0, 1, 2, etc.). The `create()` method then returns a new `DataBlock` object that represents the outputs that were generated after the requested component processed the specified inputs. The `create()` method can also handle up to four arguments that are not encapsulated within a `DataBlock` object, for example:

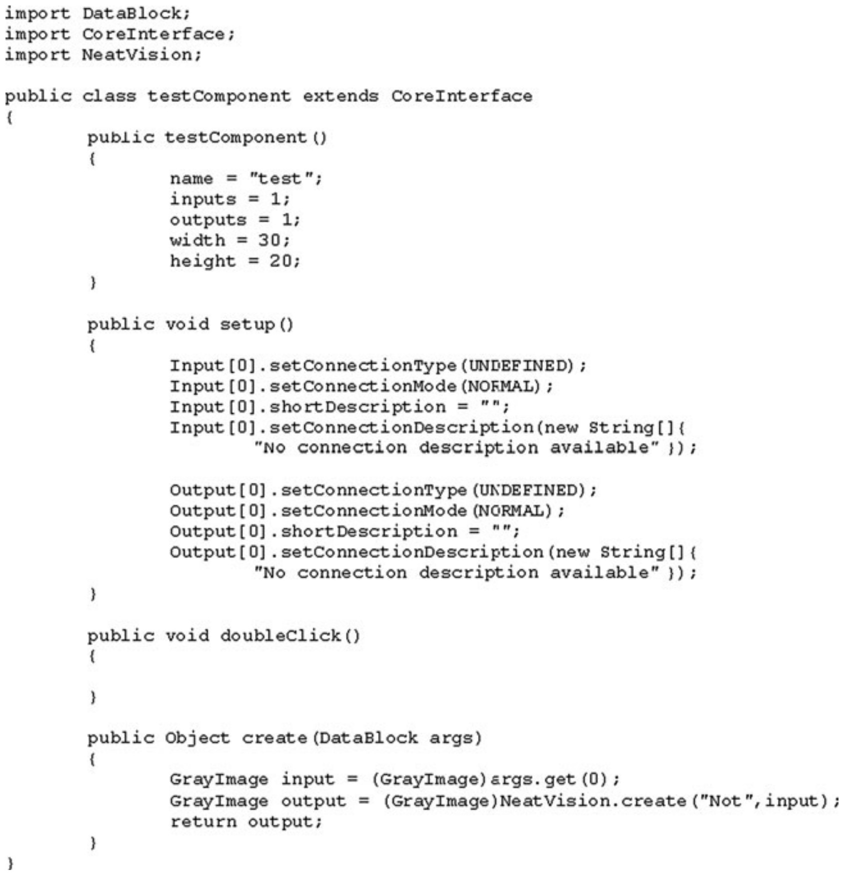
`Object NeatVision.create(String class, Object arg0)`

- Call the create method of the single input component with the specified class name.

`Object NeatVision.create(String class, Object arg0, Object arg1)`

- Call the create method of the dual input component with the specified class name.

All arguments must be represented as objects when using this approach. This means that any primitives must be wrapped before being passed to the `create()` method. Take the integer arguments for the dual threshold operation as an example:



```
import DataBlock;
import CoreInterface;
import NeatVision;

public class testComponent extends CoreInterface
{
        public testComponent()
        {
                name = "test";
                inputs = 1;
                outputs = 1;
                width = 30;
                height = 20;
        }

        public void setup()
        {
                Input[0].setConnectionType(UNDEFINED);
                Input[0].setConnectionMode(NORMAL);
                Input[0].shortDescription = "";
                Input[0].setConnectionDescription(new String[]{
                        "No connection description available" });

                Output[0].setConnectionType(UNDEFINED);
                Output[0].setConnectionMode(NORMAL);
                Output[0].shortDescription = "";
                Output[0].setConnectionDescription(new String[]{
                        "No connection description available" });
        }

        public void doubleClick()
        {

        }

        public Object create(DataBlock args)
        {
                GrayImage input = (GrayImage)args.get(0);
                GrayImage output = (GrayImage)NeatVision.create("Not",input);
                return output;
        }
}
```

Fig. 22.5
A simple example of reuse, calling the `Not` operation from inside a custom user-defined class

```
int hiThresh = 100;
int loThresh = 100;
Integer hiThreshObj = new Integer (hiThresh);
Integer loThreshObj = new Integer (loThresh);
GreyImage output = (GreyImage) NeatVision.create
(``DualThreshold'', input, hiThreshObj, loThreshObj);
```

There are special wrapper classes available for converting all primitive types (`boolean`, `byte`, `short`, `int`, `long`, `double` and `float`) into objects (`Boolean`, `Byte`, `Short`, `Integer`, `Long`, `Double` and `Float`). Objects of these classes can be constructed by simply passing the relevant primitive to the constructor of the relevant class (see int to Integer example above). The static `create()` method of the NeatVision class routes the specified DataBlock object to the `create()` method of the specified class and returns the resulting output DataBlock object.

➤ *Figure 22.5* illustrates a simple example of reuse. This involves calling the `Not` operation from inside a custom user-defined class. ➤ *Figures 22.6* and ➤ *22.7* illustrates the development of the `TestDev` class. This sample program removes boundary regions prior to K-Means clustering. The Canny edge detector is then applied to the original image and keeping only closed structures we find the approximate perimeter of the strong edges. The K-Means and the closed structure overlay images along with the approximate perimeter values are the final block outputs.

22.6 Sample Applications

NeatVision provides an image analysis software development environment that can work at several levels. For example, at a relatively low level, individual pixels can be manipulated. Alternatively, NeatVision's built-in functionality can be used to generate solutions to complex machine vision problems. ➤ *Figure 22.8* illustrates how the *reconstruction by dilation* morphological operator can be used to remove or detect objects that are touching the binary image border. ➤ *Figure 22.9* illustrates how NeatVision can be used to isolate defects in the centre panel of a crown bottle top.

22.7 Application Development Case Study

In this section, we will outline the application of NeatVision to a typical machine vision application, namely the characterisation of surface mount components. We aim to develop a robust *NeatVision* program capable of:

- Automatically counting all components fully within the field of view in the image illustrated in ➤ *Fig. 22.10* (i.e. all elements touching the image boundaries must be removed prior to image analysis).
- Isolate and highlight the largest component within the image.
- Find the approximate area of the largest component within the image.

The system must be robust, and with this in mind it should be capable of automatically determining threshold values from the image data.

    output_b = (GrayImage)NeatVision.create("Add",output_b,inp1);

  // Make the data available to other library functions.
    DataBlock returns = new DataBlock(); returns.add(output_a);
    returns.add(output_b); returns.add(area_1); return(returns);
  }
}
```

Fig. 22.6
Development of the `TestDev` class

22.7.1 Outline Solution

The proposed solution, as summarised in the NeatVision program illustrated in *Fig. 22.11*, consists of a number of distinct stages. This solution is used solely to illustrate the power and flexibility of NeatVision and does not represent the optimal solution for such an application.

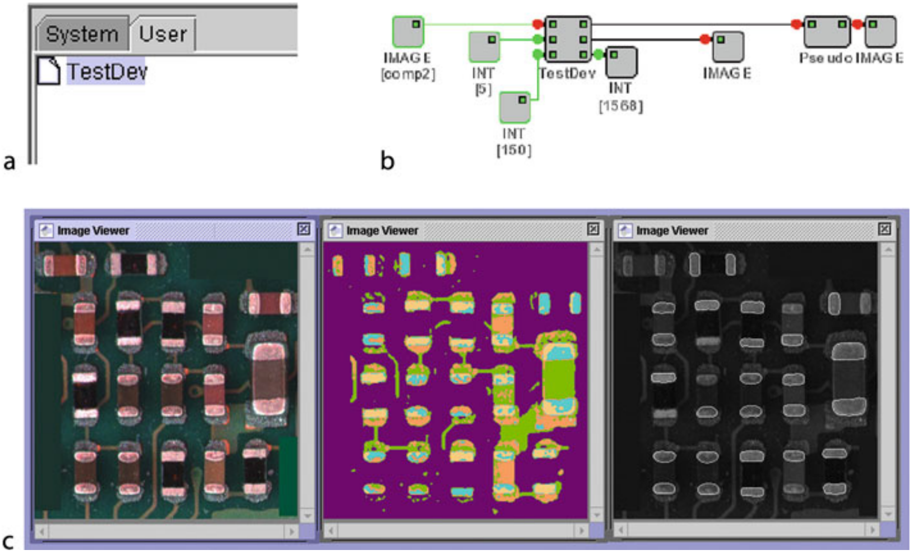

Fig. 22.7
Implementation of the `TestDev` class illustrated in *Fig. 22.6*. (**a**) The associated class file tag in the user area. (**b**) A sample program illustrating the operation of this block. (**c**) Sample images (*left* to *right*): input image, K-Means clustered image and the closed structure overlay image

■ Fig. 22.10
Image segment (pcb_3) containing 15 surface-mounted components fully with in its field of view (Image supplied courtesy of Agilent Technologies (Ireland), acquired using their *sequential colour* technique at 470, 524 and 660 nm (BGR))

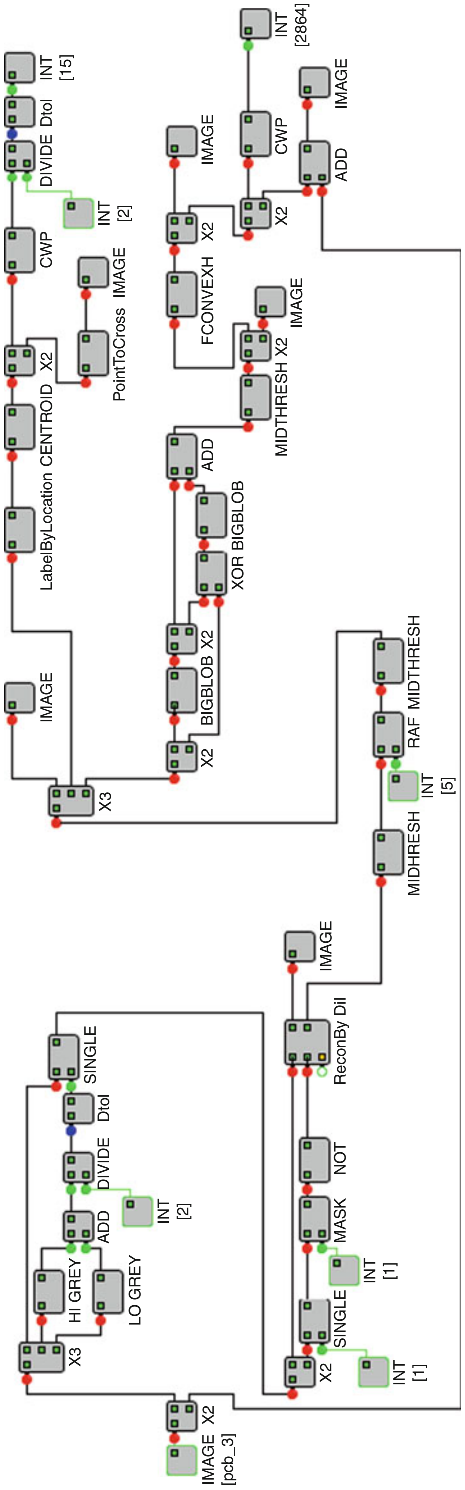

Fig. 22.11
Proposed NeatVision solution

Stage 1: The input colour image (pcb_3.gif) is loaded and converted to grey scale. A binary version of this image is then automatically produced by examining the grey-scale histogram upper and lower values. Due to the high contrast, the automated threshold selection consists of the midpoint between the upper and lower grey scales in the original image (➲ *Fig. 22.12*).

Stage 2: Using the morphological technique *Reconstruction by Dilation*, we isolate any part of the image touching the boundary (➲ *Fig. 22.13*).

Stage 3: Once the incomplete objects touching the image boundary have been removed, we use a 5 × 5 RAF (Rectangular Averaging Filter) to remove any remaining noise (➲ *Fig. 22.14*). Take care to threshold the filtered image at mid-grey as the RAF filter produces a grey-scale image.

Stage 4: Each blob region is now assigned a grey-scale value using labelling by location. These grey patches are then count by finding and marking each grey patch by its centroid. The centroids are then counted and divided by 2 to give the final component count (➲ *Fig. 22.15*).

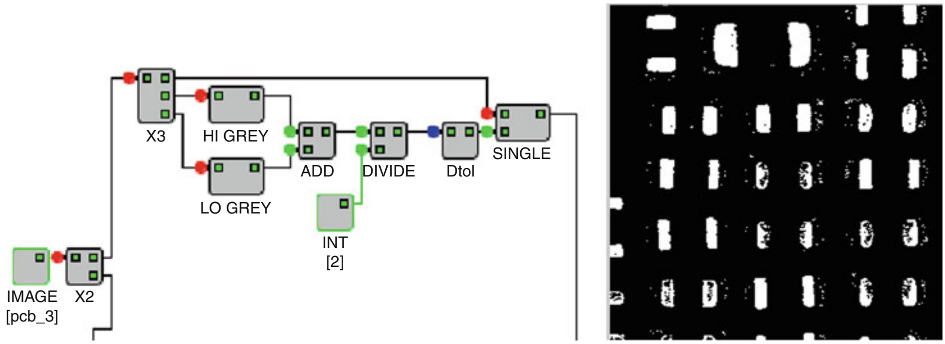

Fig. 22.12
Automated threshold selection stage and the resultant binary image

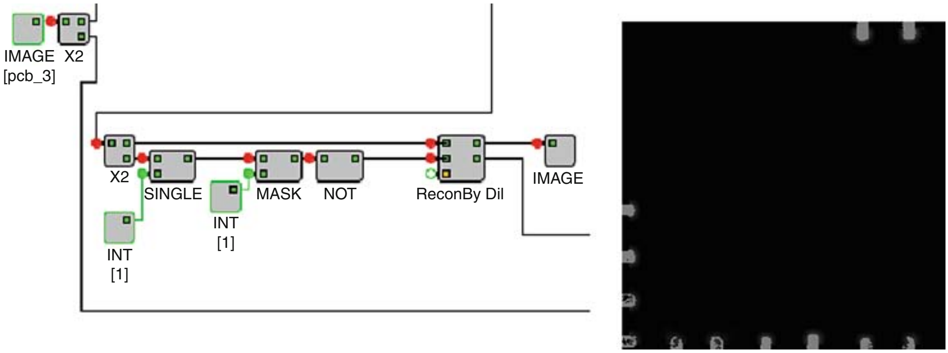

Fig. 22.13
Using reconstruction by dilation to identify the incomplete objects touching the image boundary

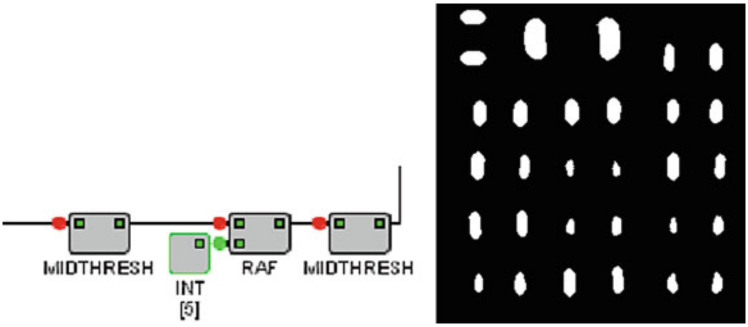

Fig. 22.14

Isolating the components of interest and noise removal

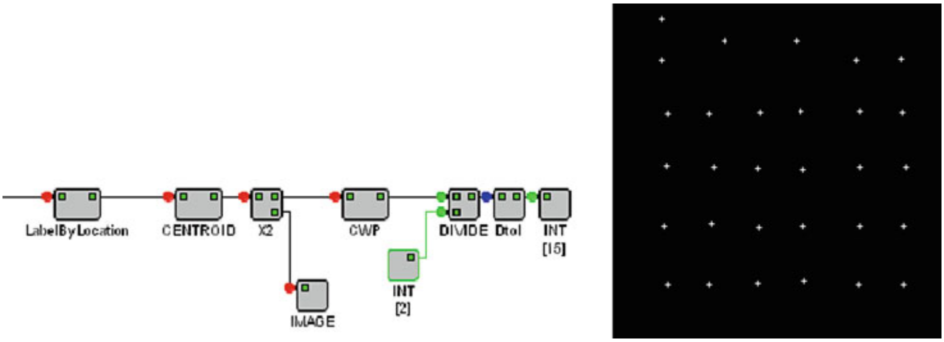

Fig. 22.15

Component counting by isolating and counting the grey patch centroid values (a cross indicates each centroid value)

Stage 5: Using the fact that the largest surface-mounted component is bounded by the two largest blobs in the image, we can identify and extract these blob regions (➲ *Fig. 22.16*).

Stage 6: The final step involves finding the convex hull of the output from the previous stage. This now approximates the largest surface-mounted component. The area of this region is then calculated to determine its size. This convex hull image is then combined with the original image to highlight its location (➲ *Fig. 22.17*).

22.8 Users Summary

The following list summarises some of the main NeatVision methods users may wish to interface too. Many of these are fairly self-explanatory, but if the method you require is not listed or does not have enough information to enable you to use it, drop us an email at

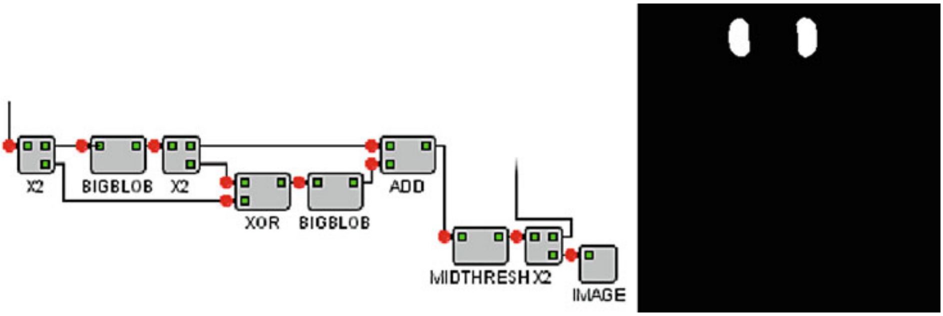

Fig. 22.16
Identifying the bounds of the largest component

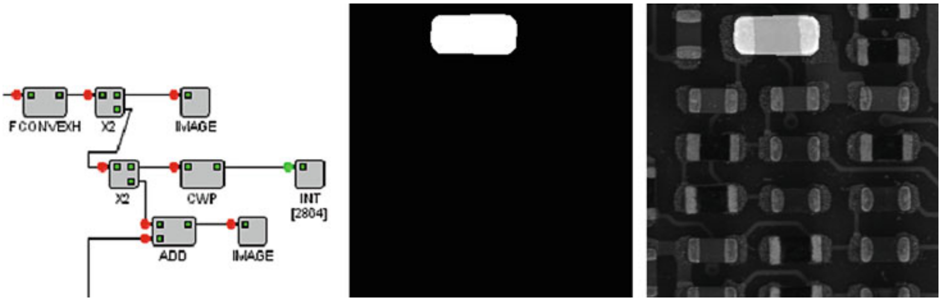

Fig. 22.17
Identifying calculating the area of the largest component. Overlay on original image to highlight its location

tech@neatvision.com with "NeatVision Methods" in the subject line. Additional help can be found in the input/output tags for each block in the NeatVision visual programming interface. Also refer to [2].

Normalisation of grey-scale image operations occurs to keep the output image within grey-scale range 0–255.

22.9 Downloading NeatVision

22.9.1 Overview

NeatVision is a free Java-based image analysis and software development environment, which provides high-level access to a wide range of image-processing algorithms through a well-defined and easy to use graphical interface. NeatVision is in its second major release. New features include: a full developer's guide with method listings and program examples, DICOM and Analyse medical image sequence viewers, URL control, feature fitting, supervised and unsupervised colour clustering, DCT, Improved FFT, 3D volume processing and surface rendering.

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
DATA	Image, Integer, Double, Boolean, String, Array (of integers) and 3D (DICOM, Analyse, Vol, Sequence)		
FLOW CONTROL	SplitterX2, SplitterX3, SplitterX4, Feedback, If, Else, For and Terminate		
UTILITIES			
HalveImageSize	A grey-scale image whose size is halved	0:GrayImage	0:GrayImage
DoubleImageSize	A grey-scale image whose size is doubled	0:GrayImage	0:GrayImage
PointToSquare	A grey-scale image whose white pixels are represented by white squares	0:GrayImage	0:GrayImage
PointToCross	A grey-scale image whose white pixels are represented by white crosses	0:GrayImage	0:GrayImage
Rotate	A grey-scale image is rotated in a clockwise direction by a user specified amount	0:GrayImage 1: Integer [user specified rotation (degrees)]	0:GrayImage
RotatePlus90	A grey-scale image is rotated in a clockwise direction by 90°	0:GrayImage	0:GrayImage
RotateMinus90	A grey-scale image is rotated in an anticlockwise direction by 90°	0:GrayImage	0:GrayImage
ROI[a]	A grey-scale image from which a rectangular region of interest is extracted by the user via the GUI	0:GrayImage	0:GrayImage
PolyROI[a]	A grey-scale image from which a polygon region of interest is extracted by the user via the GUI	0:GrayImage [User interaction]	0:GrayImage
EnhancePolyROI[b]	A grey-scale image from which a polygon region of interest shall be emphasised. User-defined input region	0:GrayImage [User interaction]	0:GrayImage

Measure_Line	An image from which the Euclidean distance between two user selected points is calculated. Must rerun program to generate new line length	0:GrayImage [User interaction]	0:Double [Euclidean distance]
Scale	A grey-scale image is scaled by user-defined dimensions	0:GrayImage 1: Integer [width of the scaled image] 2: Integer [height of the scaled image]	0:GrayImage
Mask	A grey-scale image whose border is masked by a user specified amount	0:GrayImage 1: Integer [Mask size in pixels, Default = 3]	0:GrayImage
Centroid	Replace the grey-scale shapes (Range 0–255) in the original image by their respective centroids (commonly used after the 8-bit labelling operators)	0:GrayImage	0:GrayImage [Binary]
Centroid_16	Replace the grey-scale shapes (Range 0–65535) in the original image by their respective centroids (commonly used after the Label_16 operators)	0:GrayImage	0:GrayImage [Binary]
BinaryToGreyscale	Convert WHITE (255) pixels in a binary image to a given grey scale	0:GrayImage [Binary] 1:Integer [grey scale (0–255)]	0:GrayImage
GreyScalePixelSum	Generates an integer which is the sum of all pixels contained in the input image	0:GrayImage	0:Integer
FirstWhitePixelLocator	Coordinate point representing the location of the first white pixel in the image input image	0:GrayImage	0:Coordinate
RemoveIsolatedWhitePixels	Any white pixels with less than one white pixel (3 × 3) neighbour are set to black. This can be used to remove noise from a binary image	0:GrayImage	0:GrayImage [Binary]
SaltnPepperGenerator	Add salt and pepper noise to the input image	0:GrayImage 1:Double (0–1.0)	0:GrayImage

(Continued)

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
AdditiveWhiteNoiseGenerator	Add a user-defined level of white noise to the input image	0:GrayImage 1:Integer (1–1024)	0:GrayImage
GaussianNoiseGenerator	Add a user-defined quantity of Gaussian noise to the input image	0:GrayImage 1:Double (0–255.0)	0:GrayImage
RayleighNoiseGenerator	Add a user-defined quantity of Rayleigh noise to the input image	0:GrayImage 1:Double (1.0–255.0)	0:GrayImage
PoissonNoiseGenerator	Add a user-defined quantity of Poisson noise to the input image	0:GrayImage 1:Double (0–511.0)	0:GrayImage
HTTPSendScript	Send arguments to a URL	0:String [URL] 1:String [Arguments]	0:String [Return values]
HTTPGetImage	Retrieve image from a URL	0:String [URL]	0:GrayImage [Retrieved Image]
ARITHIMETIC			
Add	Image addition	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = A+B]
Subtract	Image subtraction	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = A – B]
Multiply	Image multiply	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = A*B]
Divide	Image division	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = A/B]

And	Boolean AND operation	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = AND(A,B)]
Or	Boolean OR operation	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = OR(A,B)]
Not	Boolean NOT operation	0:GrayImage [A]	0:GrayImage [C = NOT(A)]
Xor	Boolean Exclusive OR operation	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = XOR(A,B)]
Minimum	Minimum of two images	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = Min(A,B)]
Maximum	Maximum of two images	0:GrayImage [A] 1:GrayImage [B]	0:GrayImage [C = Max(A,B)]
HISTOGRAM			
HighestGreyLevelCalculator	Compute the highest grey level from the input image	0:GrayImage	0:Integer [highest grey level]
LowestGreyLevelCalculator	Compute the lowest grey level from the input image	0:GrayImage	0:Integer [lowest grey level]
MeanSquareError	Compare the input images using the mean square error operation	0:GrayImage 1:GrayImage	0:Double [mean square error]
AverageIntensityCalculator	Compute the average intensity of the input image	0:GrayImage	0:Double [average intensity]
EntropyCalculator	Compute the entropy of the input image	0:GrayImage	0:Double [entropy]
VarienceCalculator	Compute the variance of the input image	0:GrayImage	0:Double [varience]
KurtosisCalculator	Compute the kurtosis of the input image	0:GrayImage	0:Double [kurtosis]
StandardDeviationCalculator	Compute the standard deviation of the input image	0:GrayImage	0:Double [standard deviation]
SkewnessCalculator	Compute the skewness deviation of the input image	0:GrayImage	0:Double [skewness]
LocalEqualisation3 × 3	Local histogram equalisation using a 3 × 3 region	0:GrayImage	0:GrayImage
LocalEqualisation5 × 5	Local histogram equalisation using a 5 × 5 region	0:GrayImage	0:GrayImage

■ **(Continued)**

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
PROCESSING			
Inverse	Inverse the LUT of the input image	0:GrayImage	0:GrayImage
Logarithm	Transform the linear LUT into logarithmic	0:GrayImage	0:GrayImage
Exponential	Transform the linear LUT into exponential	0:GrayImage	0:GrayImage
Power	The linear LUT is raised to a user specified double value	0:GrayImage	0:GrayImage
		1:Integer [power, default = 3.0]	
Square	The linear LUT is raised to power of 2	0:GrayImage	0:GrayImage
SingleThreshold	Single threshold operation	0:GrayImage	0:GrayImage [Binary]
		1:Integer [(1–255): Default = 128]	
MidlevelThreshold	Single threshold operation: threshold level = MIDGREY (127)	0:GrayImage	0:GrayImage [Binary]
DualThreshold	Dual threshold operation. All pixels between the upper and lower thresholds are marked in WHITE (255)	0:GrayImage	0:GrayImage [Binary]
		1:Integer [upper value, default = 128]	
		2:Integer [lower value, default = 1]	
TripleThreshold	This operation produces an LUT in which all pixels below the user specified lower level appear black, all pixels between the user specified lower level and the user specified upper level inclusively appear grey and all pixels above the user specified upper level appear white	0:GrayImage	0:GrayImage
		1:Integer [upper value, default = 128]	
		2:Integer [lower value, default = 1]	

EntropicThreshold	Compute the entropy-based threshold. Relies on maximising the total entropy of both the object and background regions to find the appropriate threshold	0:GrayImage	0:Integer
Threshold3 × 3	Adaptive threshold in a 3 × 3 region	0:GrayImage	0:GrayImage
		1:Integer [constant offset, default = 0]	
Threshold5 × 5	Adaptive threshold in a 5 × 5 region	0:GrayImage	0:GrayImage
		1:Integer [constant offset, default = 0]	
IntensityRangeEnhancer	Stretch the LUT in order to occupy the entire range between BLACK (0) and WHITE (255)	0:GrayImage	0:GrayImage
HistorgramEqualiser	Histogram equalisation	0:GrayImage	0:GrayImage
IntensityRangeStrecher	Stretch the LUT between the lower and upper threshold to occupy the entire range between BLACK (0) and WHITE (255)	0:GrayImage	0:GrayImage
		1:Integer [lower grey level, default = 0]	
		2:Integer [upper grey level, default = 255]	
IntegrateImageRows	Integrate image rows	0:GrayImage	0:GrayImage
IntegrateImageColumns	Integrate Image columns	0:GrayImage	0:GrayImage
LeftToRightSum	Pixel summation along the line	0:GrayImage	0:GrayImage
LeftToRightWashFunction	Left To Right wash function (once a white pixel is found, all pixels to its right are also set to white)	0:GrayImage	0:GrayImage
RightToLeftWashFunction	Right To Left wash function (once a white pixel is found, all pixels to its left are also set to white)	0:GrayImage	0:GrayImage
TopToBottomWashFunction	Top To Bottom wash function (once a white pixel is found, all pixels to its below are also set to white)	0:GrayImage	0:GrayImage

(Continued)

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
BottomToTopWashFunction	Bottom To Top wash function (once a white pixel is found, all pixels to its above are also set to white)	0:GrayImage	0:GrayImage
FILTER			
Convolution	Convolution. This operation requires coefficients to be specified in the form of a square, odd-sized integer array, "null" represents "don't cares"	0:GrayImage 1:Integer [ ] [Array of mask values. No entry default to null. "Don't Care" = null statement]	0:GrayImage
DOLPS	DOLPS – Difference of low pass 3 × 3 filters. Image A results from applying three iterations of the low pass filter. Image B results from applying six iterations of the low pass filter. DOLPS = A−B	0:GrayImage	0:GrayImage
LowPass	Low pass 3 × 3 filter	0:GrayImage	0:GrayImage
Sharpen	High pass 3 × 3 filter	0:GrayImage	0:GrayImage
Median	Median 3 × 3 filter	0:GrayImage	0:GrayImage
Midpoint	Midpoint 3 × 3 filter	0:GrayImage	0:GrayImage
RectangularAverageFilter	Rectangular Average Filter operation. Size of filter is user defined	0:GrayImage 1:Integer [filter size, default = 5]	0:GrayImage
SmallestIntensityNeighbour	Replace the central pixel of the 3 × 3 mask with the minimum value	0:GrayImage	0:GrayImage

LargestIntensityNeighbour	Replace the central pixel of the 3 × 3 mask with the maximum value	0:GrayImage	0:GrayImage
AdaptiveSmooth	Adaptive smoothing of grey-scale images. In order to apply it to colour images, the input image has to be split into RGB components and adaptive smooth has to be applied to each channel. If the colour image is applied directly the algorithm will smooth the average intensity image. (Slow process)	0:GrayImage 1:Integer [number of iterations: possible values: 1 to 10, default = 5] 2:Double [variance strength: possible values: 0.1 −> 0.9, default = 0.2] 3:Double [Diffusion parameter: possible values: 1.0 −> 20.0, default = 10.0]	0:GrayImage
EDGES			
Roberts	Roberts edge detector	0:GrayImage	0:GrayImage
Sobel	Sobel edge detector	0:GrayImage	0:GrayImage
Laplacian	Laplacian edge detector. User-defined 4-connected or 8-connected neighbourhood	0:GrayImage 1:Integer [possible values: 4 or 8, default = 8]	0:GrayImage
Prewitt	Prewitt edge detector	0:GrayImage	0:GrayImage
FreiChen	FreiChen edge detector	0:GrayImage	0:GrayImage
BinaryBorder	Binary Border edge detector	0:GrayImage [Binary]	0:GrayImage [Binary]
NonMaxima	Edge detection using non-maxima suppression	0:GrayImage	0:GrayImage
IntensityGradientDirection	Compute the 3 × 3 intensity gradient direction. Gradients range from 1 to 8	0:GrayImage	0:GrayImage [pixel values from 1 to 8]

■ **(Continued)**

		Inputs	Outputs
Method	Description	(Index #: data type [descriptor])	(Index #: data type [descriptor])
ZeroCrossingsDetector	Zero crossings edge detector	0:GrayImage	0:GrayImage
Canny	Canny edge detector	0:GrayImage 1:Double [standard deviation or spread parameter, possible values: 0.2 –> 20.0, default = 1.0] 2:Integer [lower threshold, default = 1] 3:Integer [upper threshold, default = 255]	0:GrayImage [edge magnitudes] 1:GrayImage [edge directions]
EdgeLabel	Edge labelling operation. Expects a binary image resulting from the application of the Canny edge detector	0:GrayImage 1:Boolean [Set True if you want closed structures]	0:GrayImage [A binary image whose edge pixels are grouped into polygonal shapes]
LineFitting	Line fitting in the edge structure. Expects a binary image resulting from the application of the Canny edge detector	0:GrayImage 1:Boolean [Set True if you want closed structures]	0:GrayImage [A binary image whose edge pixels are grouped into polygonal shapes]

ArcFitting	Arc fitting in the edge structure. Expects a binary image resulting from the application of the Canny edge detector	0:GrayImage 1:Boolean [Set True if you want closed structures] 2:Boolean [Set True if you want display the circles associated with detected arcs] 3:Boolean [Set True if you want display the lines that are not grouped into arcs segments]	0:GrayImage [A binary image whose edge pixels are grouped into polygonal shapes]
EdgeLinking [13]	Edge linking (scanning window is user defined). Expects a binary image resulting from the application of the Canny edge detector	0:GrayImage 1:Integer [The size of scanning window. (5–11)]	0:GrayImage [Edge linked image]
ANALYSIS			
ThinOnce	Full application of the thinning algorithm. Thin *till completion* resulting in a skeleton image	0:GrayImage [Binary]	0:GrayImage [Binary]
Thin	The input binary image is thinned N times as specified by the user	0:GrayImage [Binary] 1:Integer [N – number of iterations]	0:GrayImage [Binary]
CornerPointDetector	Skeleton corner detection from a binary image based on a 3 × 3 region	0:GrayImage [Binary]	0:GrayImage [Binary]
JunctionDetector	Skeleton junction detection from a binary image based on a 3 × 3 region	0:GrayImage [Binary]	0:GrayImage [Binary]
LimbEndDetector	Skeleton limb end detection from a binary image based on a 3 × 3 region	0:GrayImage [Binary]	0:GrayImage [Binary]
BiggestBlob	Extract the biggest white blob from a binary image	0:GrayImage [Binary]	0:GrayImage [Binary]
SmallestBlob	Extract the smallest white blob from a binary image	0:GrayImage [Binary]	0:GrayImage [Binary]

■ **(Continued)**

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
BlobFill	Fill the holes in a binary image	0:GrayImage [Binary]	0:GrayImage [Binary]
Labeller	Label by location unconnected shapes in a binary image (Range 0–255)	0:GrayImage [Binary]	0:GrayImage
LabelByArea	Label the unconnected shapes in a binary image in relation to their size (Range 0–255)	0:GrayImage [Binary]	0:GrayImage
MeasureLabelledObjects	Measure the N (user specified) largest objects in a binary image (Range 0–255)	0:GrayImage [Binary] 1:Integer [limit on the number of labelled objects measured, default = 5]	0:String [contains data describing the measured objects: (Grey Scale, Area, Centroid)]
WhiteBlobCount	Count the number of white bobs in a binary image (Range 0–255)	0:GrayImage [Binary]	0:Integer [Range 0–255] 1:GrayImage [A white cross is overlaid on each blob found]
Label_16	Label by location the unconnected shapes in a binary image (Range 0–65535). Note: This is outside the 8-bit display range. Slow process	0:GrayImage [Binary]	0:GrayImage
WhiteBlobCount_16	Count the number of white bobs in a binary image (Range 0–65535). Slow process	0:GrayImage [Binary]	0:Integer [Range 0–65535] 1:GrayImage [A white cross is overlaid on each blob found]
ConvexHull	Compute the convex hull boundary	0:GrayImage [Binary]	0:GrayImage [Binary]
FilledConvexHull	Compute the filled convex hull	0:GrayImage [Binary]	0:GrayImage [Binary]
CrackDetector	Highlight cracks in the input image	0:GrayImage	0:GrayImage
EulerNumberCalculator	Compute the Euler number from a binary image	0:GrayImage [Binary]	0:Integer [Euler number]

WhitePixelCounter	Compute the number of white pixels	0:GrayImage	0:Integer [pixel count]
IsolateHoles	Isolate holes in a binary image	0:GrayImage [Binary]	0:GrayImage [Binary]
IsolateBays	Isolate bays in a binary image	0:GrayImage [Binary]	0:GrayImage [Binary]
ConnectivityDetector	Connectivity detection in a thinned skeleton binary image. Mark points critical for connectivity in a 3 × 3 region	0:GrayImage [Binary]	0:GrayImage
BoundingBox	Minimum area bounding rectangle.	0:GrayImage	0:GrayImage
FilledBoundingBox	Filled minimum area bounding rectangle	0:GrayImage	0:GrayImage
BoundingBoxTop Coordinate	Compute the top left coordinate of the minimum area bounding rectangle	0:GrayImage	0:Coordinate [top left]
BoundingBoxBottom Coordinate	Compute the bottom right coordinate of the minimum area bounding rectangle	0:GrayImage	0:Coordinate [bottom right]
CornerDetector	Grey-Scale (SUSAN) corner detector	0:GrayImage 1:Integer [Brightness threshold] 2:Integer [Geometric threshold]	0:GrayImage [Corner points]
K-MEANS CLUSTERING			
GrayScaleCluster	Cluster a grey-scale image (number of clusters are user defined) using the k-means algorithm	0:GrayImage 1:Integer [Number of clusters]	0:GrayImage [Grey-scale]
ColourCluster	Cluster a colour image (number of clusters are user defined) using the k-means algorithm	0:Image [Colour Image Input] 1:Integer [Number of clusters]	0:GrayImage [Grey-scale]

■ **(Continued)**

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
Un_ColourCluster	Unsupervised colour clustering using the k-means algorithm	0:Image	0:GrayImage [Grey-scale]
		1:Double [Low threshold (possible values 0.5–1.0), default = 0.6]	1:Image [Colour]
		2:Double [High threshold (possible values 1.0–1.5), default = 1.2]	2:Integer [Number of clusters]
PseudoColour	Pseudo-colour operation	0:Image [grey-scale or colour image]	0:Image [false colour image]
TRANSFORM			
MedialAxisTransform	Medial axis transform operation. Binary image showing the simple skeleton	0:Image [binary]	0:Image [binary]
MedialAxisTransform_GS	Medial axis transform operation. GS image where each point on the skeleton has an intensity which represents its distance to a boundary in the original object	0:Image [binary]	0:GrayImage [grey scale]
FFT	Fast Fourier Transform: FFT	0:GrayImage [Input image dimension must be a power of 2]	0:File [Fourier Data File]
			1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
IFFT	Inverse Fourier Transform	0:File [A Fourier data file which shall be interpreted as an image.]	0:GrayImage [The resulting grey-scale image which represents the interpreted Fourier data]

FFTLowpass	Low pass frequency filter	0:File [Fourier Data File]	0:File [Fourier Data File]
		1:Double [cut-off value (0–1.0)]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTHighpass	High pass frequency filter	0:File	0:File [Fourier Data File]
		1:Double [cut-off value (0–1.0)]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTAdaptiveLowpass	FFT adaptive lowpass filter	0:File	0:File [Fourier Data File]
		1:Double [limit (0–1.0)]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTBandpass	FFT band-pass filter	0:File [Fourier Data File]	0:File [Fourier Data File]
		1:Double [inner limit (0–1.0)]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
		2:Double [outer limit (0–1.0)]	
FFTBandstop	FFT band-stop filter	0:File [Fourier Data File]	0:File [Fourier Data File]
		1:Double [inner limit (0–1.0)]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
		2:Double [outer limit (0–1.0)]	
FFTMultiply	Multiply two Fourier data files	0:File [Fourier Data File]	0:File [Fourier Data File]
		1:File [Fourier Data File]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTDivide	Divide one Fourier data file by another	0:File [Fourier Data File]	0:File [Fourier Data File]
		1:File [Fourier Data File]	1:GrayImage [Grey-scale image transformed to its Fourier coefficients]

■ **(Continued)**

Method	Description	Inputs (Index #: data type [descriptor])	Outputs (Index #: data type [descriptor])
FFTGaussian	FFT Gaussian filter. Input 0 requires an integer value that = 2^n where n is a+ve integer. Note: size = width = height	0:Integer [size of a new Fourier data file which contains Gaussian coefficients] 1:Double [Standard deviation of the Gaussian coefficients (0.1–5.0)]	0:File [Fourier Data File] 1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTSelectivePass	FFT selective frequency filter	0:File [Fourier Data File] 1:Double [The cut-off value of the filter (0–1.0)] 2:Double [The x-offset of the symmetric selective filter (0–1.0)] 3:Double [The y-offset of the symmetric selective filter (0–1.0)]	0:File [Fourier Data File] 1:GrayImage [Grey-scale image transformed to its Fourier coefficients]
FFTSymmetricSelectivePass	FFT selective symmetric frequency filter	0:File [Fourier Data File] 1:Double [The cut-off value of the filter (0–1.0)] 2:Double [The x-offset of the symmetric selective filter (0–1.0)] 3:Double [The y-offset of the symmetric selective filter (0–1.0)]	0:File [Fourier Data File] 1:GrayImage [Grey-scale image transformed to its Fourier coefficients]

DCT2D	Direct Cosine Transform operation	0:GrayImage [Input image dimension must be a power of 2]	0:GrayImage [Real Part] 1:GrayImage [DCT Magnitude]
IDCT2D	Inverse DCT (filtering factor is user defined)	0:GrayImage 1:Double [DCT quality coefficient (0–2.0)]	0:GrayImage [IDCT image]
Hough	Line Hough Transform	0:GrayImage [Binary]	0:GrayImage
InverseHough	Inverse Hough Transform. The integer input specifies how many of the brightest pixels shall be taken into account when performing the Inverse Hough operation	0:GrayImage 1:Integer [Number of bright points to be considered, default = 10]	0:GrayImage
CircHough	Circular Hough Transform	0:GrayImage [binary image to be subjected to the circular Hough transform]	0:GrayImage [Image] 1:GrayImage [Transform space]
CooccurrenceMatrixGenerator	Compute the co-occurrence matrix	0:GrayImage	0:GrayImage
CooccurrenceMatrixEnergyCalculator	Compute the energy of the co-occurrence matrix	0:GrayImage	0:Double
CooccurrenceMatrixEntropyCalculator	Compute the entropy of the co-occurrence matrix	0:GrayImage	0:Double
CooccurrenceMatrixContrastCalculator	Compute the contrast of the co-occurrence matrix	0:GrayImage	0:Double
CooccurrenceMatrixHomogenityCalculator	Compute the homogeneity of the co-occurrence matrix	0:GrayImage	0:Double
DistanceTransform3 × 3	Compute the distance transform in a 3 × 3 window (input binary image)	0:GrayImage [Binary]	0:GrayImage
DistanceTransform5 × 5	Compute the distance transform in a 5 × 5 window (input binary image)	0:GrayImage [Binary]	0:GrayImage
LeftToRightDistanceTransform	Left to right distance transform (input binary image)	0:GrayImage [Binary]	0:GrayImage
RightToLeftDistanceTransform	Right to left distance transform (input binary image)	0:GrayImage [Binary]	0:GrayImage
TopToBottomDistanceTransform	Top to bottom distance transform (input binary image)	0:GrayImage [Binary]	0:GrayImage

■ **(Continued)**

Method	Description	Inputs (Index #: data type [descriptor])	Outputs (Index #: data type [descriptor])
BottomToTopDistanceTransform	Bottom to top distance transform (input binary image)	0:GrayImage [Binary]	0:GrayImage
GrassFireTransform	Grass fire transform (input binary image) [8-connected]	0:Image [Binary]	0:Image [grey-scale]
MORPHOLOGY			
Dilation	Dilation operation (user specify connectivity of the structured element 4 or 8)	0:GrayImage 1:Integer [(4 or 8), default = 8]	0:GrayImage
Erosion	Erosion operation (user specify connectivity of the structured element 4 or 8)	0:GrayImage 1:Integer [(4 or 8), default = 8]	0:GrayImage
Open	Opening operation (user specify connectivity of the structured element 4 or 8)	0:GrayImage 1:Integer [(4 or 8), default = 8]	0:GrayImage
Close	Closing operation (user specify connectivity of the structured element 4 or 8)	0:GrayImage 1:Integer [(4 or 8), default = 8]	0:GrayImage
ErodeNxN	Erosion operation with a user-defined NxN structuring element (X or null = don't cares)	0:GrayImage 1:Integer [Array]	0:GrayImage
DilateNxN	Dilation operation with a user-defined NxN structuring element (X or null = don't cares)	0:GrayImage 1:Integer [Array]	0:GrayImage
MorphologicalValley	Morphological valley operation (user specify connectivity of the structured element 4 or 8) [Default = 8]	0:GrayImage 1:Integer (4 or 8)	0:GrayImage

MorphologicalTophat	Morphological top-hat operation (user specify connectivity of the structured element 4 or 8) [Default = 8]	0:GrayImage 1:Integer (4 or 8)	0:GrayImage
HitAndMiss	Hit-and-miss transformation. Hit and miss array masks must not overlap	0:GrayImage 1:Integer [user-defined hit array, blanks correspond to DON'T CARE)] 2:Integer [user-defined miss array]	0:GrayImage
MorphGradient	Morphological Gradient (user specify connectivity of the structured element 4 or 8) [Default = 8]	0:GrayImage 1:Integer	0:GrayImage
ReconByDil	Reconstruction by dilation	0:GrayImage 1:GrayImage [Seed] 2:Integer [SE size]	0:GrayImage [Reconstructed] 1:GrayImage [Elements removed]
ReconByDil_UI	Reconstruction by dilation via a user selected seed point (8-connected)	0:GrayImage [User interaction]	0:GrayImage [Reconstructed] 1:GrayImage [Elements removed]
DBLT	Double [Hysteresis] Threshold–based reconstruction. Binary Outputs. Seed threshold to reduce noise Mask threshold to maximise signal	0:GrayImage 1:Integer [seed threshold] 2:Integer [mask threshold]	0:GrayImage [Reconstructed] 1:GrayImage [Seed Image] 2:GrayImage [Seed Image]
Watershed	Watershed transform (return the watershed image and the region boundaries image)	0:GrayImage	0:GrayImage [Watershed Image] 1:GrayImage [Binary, Watershed boundaries]
COLOUR			
GreyScaler	Average three colour planes	0:Image [colour]	0:GrayImage

■ **(Continued)**

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
ColourToRGB	Extract the RGB colour planes	0:Image [colour]	0:GrayImage [R]
			1:GrayImage [G]
			2:GrayImage [B]
RGBToColour	Create an image from individual RGB channels	0:GrayImage [R]	0:Image [colour]
		1:GrayImage [G]	
		2:GrayImage [B]	
ColourToHSI	Extract the HSI colour planes	0:Image [colour]	0:GrayImage [H]
			1:GrayImage [S]
			2:GrayImage [I]
HSIToColour	Create an image from individual HSI planes	0:GrayImage [H]	0:Image [colour]
		1:GrayImage [S]	
		2:GrayImage [I]	
ColourToOpponent	Extract the opponent process colour representation	0:Image [colour]	0:GrayImage [Red_Green]
			1:GrayImage [Blue_Yellow]
			2:GrayImage [White_Black]
ViewOpponent	Normalise (0–255) opponent process colour channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [Red_Green]	0:GrayImage [Red_Green]
		1:GrayImage [Blue_Yellow]	1:GrayImage [Blue_Yellow]
		2:GrayImage [White_Black]	2:GrayImage [White_Black]
ColourToCMY	Extract the CMY (Cyan, Magenta, Yellow) colour planes	0:Image [colour]	0:GrayImage [C]
			1:GrayImage [M]
			2:GrayImage [Y]

CMYToColour	Create an image from individual CMY (Cyan, Magenta, Yellow) planes	0:GrayImage [C]	0:Image [colour]
		1:GrayImage [M]	
		2:GrayImage [Y]	
ViewCMY	Normalise (0–255) CMY channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [C]	0:GrayImage [C]
		1:GrayImage [M]	1:GrayImage [M]
		2:GrayImage [Y]	2:GrayImage [Y]
ColourToYUV	Extract the YUV colour planes	0:Image [colour]	0:GrayImage [Y]
			1:GrayImage [U]
			2:GrayImage [V]
YUVToColour	Create an image from individual YUV planes	0:GrayImage [Y]	0:Image [colour]
		1:GrayImage [U]	
		2:GrayImage [V]	
ViewYUV	Normalise (0–255) YUV channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [Y]	0:GrayImage [Y]
		1:GrayImage [U]	1:GrayImage [U]
		2:GrayImage [V]	2:GrayImage [V]
ColourToYIQ	Extract the YIQ colour planes	0:Image [colour]	0:GrayImage [Y]
			1:GrayImage [I]
			2:GrayImage [Q]
YIQToColour	Create an image from individual YIQ planes	0:GrayImage [Y]	0:Image [colour]
		1:GrayImage [I]	
		2:GrayImage [Q]	
ViewYIQ	Normalise (0–255) YIQ channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [Y]	0:GrayImage [Y]
		1:GrayImage [I]	1:GrayImage [I]
		2:GrayImage [Q]	2:GrayImage [Q]

■ **(Continued)**

Method	Description	Inputs (Index #: data type [descriptor])	Outputs (Index #: data type [descriptor])
ColourToXYZ	Extract the XYZ colour planes	0:Image [colour]	0:GrayImage [X]
			1:GrayImage [Y]
			2:GrayImage [Z]
XYZToColour	Create an image from individual XYZ planes	0:GrayImage [X]	0:Image [colour]
		1:GrayImage [Y]	
		2:GrayImage [Z]	
ViewXYZ	Normalise (0–255) XYZ channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [X]	0:GrayImage [X]
		1:GrayImage [Y]	1:GrayImage [Y]
		2:GrayImage [Z]	2:GrayImage [Z]
ColourToLAB	Extract the Lab colour planes	0:Image [colour]	0:GrayImage [L]
			1:GrayImage [a]
			2:GrayImage [b]
LABToColour	Create an image from individual Lab planes	0:GrayImage [L]	0:Image [colour]
		1:GrayImage [a]	
		2:GrayImage [b]	
ViewLAB	Normalise (0–255) Lab channels. Used to view the normalised colour (unsaturated) channels	0:GrayImage [L]	0:GrayImage [L]
		1:GrayImage [a]	1:GrayImage [a]
		2:GrayImage [b]	2:GrayImage [b]
3D VOLUME			
DicomSave	A grey-scale volume image whose pixels shall be saved into DICOM format (*.dcm) (Double-click to activate). Requires the DICOM header file generated by *DicomRead*	0:VolumeImage	
		1:String [Path of the original DICOM header file]	

DicomRead	Extract the grey-scale volume image data from a DICOM image. The header information is also made available to be passed to *DicomSave*		0:VolumeImage 1:String [Path of the original DICOM header file] 2:String [DICOM header]
XYZviewer	Slices in a grey-scale 3D image are viewed from their X, Y and Z directions	0:VolumeImage	
IMGfrom3D	Get a slice from a 3D data set (slice is specified by user). Returns the min max pixel values from within the slice	0:VolumeImage 1:Integer [Range: 1 to the number of slices in the volume, default = 1]	0:GrayImage 1:Integer [minimum pixel value within slice] 2:Integer [maximum value within slice]
Scale3dData	Scale pixel values in a 3D grey-scale image to the range 0 – integer input	0:VolumeImage 1:Integer [Scale range required, (default = 255)]	0:VolumeImage
Thres3D	Threshold the 3D data	0:VolumeImage [Grey-scale] 1:Integer [Threshold value, default = 200]	0:VolumeImage [Binary]
Mask3D	Generate a 3D mask. Zeros a user-defined number of rows, columns and slices	0:VolumeImage [Grey-scale] 1:Integer [size of 3D mask, default = 1]	0:VolumeImage [Grey-scale]
Sobel3D	3D Sobel 3 × 3 × 1 (18-neighbourhood) edge detector	0:VolumeImage [Grey-scale]	0:VolumeImage [Grey-scale]
Blob3D	Extract the 3D blobs from binary 3D image. Each blob is assigned a grey-scale value	0:VolumeImage [Binary]	0:VolumeImage [Binary]

■ **(Continued)**

Method	Description	Inputs	Outputs
		(Index #: data type [descriptor])	(Index #: data type [descriptor])
BigestBlob3D	Extract the N (user-defined) biggest 3D blobs from 3D binary image	0:VolumeImage [Binary]	0:VolumeImage [Binary]
		1:Integer [Number of large blobs required, range 0–255, default = 1]	
Thinning3D	3D thinning operation of a binary 3D data set	0:VolumeImage [Binary]	0:VolumeImage [Binary]
MIP	Maximum intensity projection transform	0:VolumeImage	0:GrayImage
AIP	Average intensity projection transform	0:VolumeImage	0:GrayImage
PushSlice	Push (insert) an image slice into the 3D data set	0:VolumeImage	0:VolumeImage
		1: GrayImage [Image to be inserted]	
		2:Integer [slice number - between 1 and depth (default = 1)]	
		3:Integer [minimum pixel value within slice (default = 1)]	
		4:Integer [maximum pixel value within slice (default = 255)]	
RenderEngine	Surface rendering of a binary image. Image can be displayed as a cloud of points, wire frame, flat shading, Gouraund shading and Phong shading. (Double-click to activate). Allows user to translate, scale and rotate image	0:VolumeImage	0:VolumeImage

LOW LEVEL			
GetPixel	A grey-scale image from which a pixel intensity at a certain coordinate is obtained	0:GrayImage	0: Integer [intensity of the pixel at the specified coordinate]
		1: Coordinate [coordinate of the pixel in question]	
SetPixel	A grey-scale image from which a pixel at a certain coordinate is replaced with one of a user-defined intensity	0:GrayImage	0:GrayImage
		1: Integer [grey-scale intensity of the replacement pixel]	
		2: Coordinate [coordinate of the pixel in question]	
RemovePixel	A grey-scale image from which a pixel at a certain coordinate is removed (removing a pixels sets that pixel to black)	0:GrayImage	0:GrayImage
		1: Coordinate [coordinate of the pixel in question]	
DrawLine	Draw a line in the grey-scale image	0:GrayImage	0:GrayImage
		1: Coordinate [starting coordinate of the line]	
		2: Coordinate [finishing coordinate of the line]	
		3: Integer [grey-scale intensity of the line]	
DrawBox	Draw a hollow box in the grey-scale image	0:GrayImage	0:GrayImage
		1: Coordinate [upper top left]	
		2: Coordinate [lower bottom right]	
		3: Integer [grey-scale intensity]	

■ **(Continued)**

Method	Description	Inputs (Index #: data type [descriptor])	Outputs (Index #: data type [descriptor])
FillBox	Draw a filled box in the grey-scale image	0:GrayImage 1: Coordinate [upper top left] 2: Coordinate [lower bottom right] 3: Integer [fill grey-scale intensity]	0:GrayImage
DrawCircle	Draw a white hollow circle in the grey-scale image	0:GrayImage 1: Coordinate [coordinate of the centre of the circle] 2: Integer [radius]	0:GrayImage
FillCircle	Draw a white filled circle in the grey-scale image	0:GrayImage 1: Coordinate [coordinate of the centre of the circle] 2: Integer [radius]	0:GrayImage
GetImageWidth	Width of the input grey-scale image	0:GrayImage	0: Integer [width of the input grey-scale image]
GetImageHeight	Height of the input grey-scale image	0:GrayImage	0: Integer [height of the input grey-scale image]
GenerateCoordinate	Generate the coordinate value from the (x,y) components	0: Integer [x] 1: Integer [y]	0: Coordinate
GeneratePoints	Generate the (x,y) components of a given coordinate	0: Coordinate	0: Integer [x] 1: Integer [y]

STRING			
StringAdd	Combine two strings (objects)	0: Undefined [first of two strings (objects) which are to be added]	0: String [The resulting string which is made up from the two input strings]
		1: Undefined [second of two strings (objects) which are to be added]	
StringToLowerCase	A string which shall be converted to lower case	0: String	0: String
StringToUpperCase	A string which shall be converted to upper case	0: String	0: String
MATH	Library of standard mathematical operators		
JAIColour	See the Java^{TM} Advanced Imaging website: https://jai.dev.java.net/		
OSMIA – Tina 5 Interface	See http://www.neatvision.com/ for details on interfacing NeatVision with Tina 5.0		

[a] *Left click and hold* to draw the ROI, then release when complete

[b] The user inputs a polygon by *left-clicking* a series of points (marked in red). When the user clicks a point within 4 pixels of the start point or alternatively *right-click* to finalise and close the polygon. Once closed, the polygon will be displayed in green. To begin a new polygon, use *shift-click*.

[c] Some of these functions use data types/variables that are for internal NeatVision use *only*. Access to such data (e.g., pixel access) is can be done directly in Java

NeatVision contains over 300 image manipulation, processing and analysis algorithms. Users can extend the core NeatVision library using the developer's interface, a plug-in which features, automatic source code generation, compilation with full error feedback and dynamic algorithm updates. NeatVision is primarily an image-processing application and offers an extensive range of image analysis and visualisation tools (these include zoom, pseudo colour, intensity scan, histogram and 3D profile mesh). In addition, the ability to read and write a wide range of image file formats is supported.

22.9.2 Downloading

NeatVision can be downloaded and evaluated for 30 days prior to registration. Users can register online and a unique username and password will be automatically issued. To download NeatVision, visit: http://www.neatvision.com/, or the publisher's web site http://extras.springer.com/2012/978-1-84996-169-1.

NeatVision is distributed in two forms. The standard version is distributed as afree full functional product. NeatVision can be downloaded and evaluated for 30 days prior to registration. Users can register online and a unique username and password will be automatically issued.

Registered users can upgrade to the developer's version. This release of NeatVision includes a fully integrated development environment allowing users to to develop their own Java code and image analysis blocks for use within the NeatVision environment, thus extending the extensive range of built-in algorithms. This is achieved using the full power the Java Programming language from Sun Microsystems, the Java AWT Imaging, Java 2D API, Java Advanced Imaging and the basic NeatVision image class approach. This includes a development wizard to allow ease of integration of custom programs or existing JAI programs into the NeatVision environment, providing an open environment for the development, integration and distribution of imaging functions.

22.9.3 Developing Additional NeatVision Components

Registered users can also upgrade to a developer's version, which supports algorithm development based on Java AWT Imaging, Java 2D Imaging and Java Advanced Imaging. The developer's update is compatible with all versions of NeatVision.

22.10 Conclusions

NeatVision was designed to allow novice and experienced users to focus on the machine vision design task rather than concerns about the subtlety of a given programming language. It allows machine vision engineers to implement their ideas in a dynamic and straightforward manner. NeatVision standard and developers versions are freely available via the Internet and are capable of running on a wide range of computer platforms (e.g. Windows, Solaris, Linux).

Acknowledgements

While NeatVision is primarily a collaboration of researchers within the Vision Systems Group in Dublin City University (Ireland), we would also like to acknowledge all those who have supported the NeatVision project through the submission of algorithms for inclusion or for their constructive and useful feedback. Development of the MATLAB compatible *VSG Image Processing & Analysis Toolbox* which offers MATLAB users NeatVision functionality was funded in part by HEA PRTLI IV *National Biophotonics and Imaging Platform Ireland* (NBIPI) [14].

23 Intelligent Image Processing Using Prolog

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_23,

Abstract: Some potential applications of Machine Vision, particularly those involving highly variable objects (➲ Chap. 2), require greater reasoning power than standard image processing languages can provide. This chapter is based on the premise that an intelligent vision system can be made, by the simple expedient of embedding image manipulation and measurement routines, such as those provided by QT (➲ Chap. 21), within the Artificial Intelligence language Prolog. The great strength of Prolog is its ability to perform symbolic reasoning. It is a declarative language. That is, it operates by searching automatically for a solution to a problem, given a description of (part of) the world. The user specifies the desired characteristics that a solution must have. Prolog's search engine then hunts for the specific conditions that must exist to obtain a solution. If the user chooses, or programs Prolog appropriately, it will search for multiple solutions. Unlike a conventional imperative language, Prolog does not have any instructions. Instead, it accepts, a series of statements that are then tested individually for their veracity. It does not possess any of the usual flow-control tools, such as IF ... THEN, FOR, WHILE, CASE, etc. Instead, it relies on back-tracking and recursion. The former allows temporary assumptions that have been made while searching for a solution to be revised before continuing the search. A software interface interconnecting QT with a modern implementation of Prolog (SWI-Prolog) was designed. The result, called PQT, allows image processing operations to be invoked procedurally within a Prolog program, or executed interactively, as in QT. Image measurement values can be used to define temporary values for (i.e. instantiate) Prolog variables. Using PQT, it is possible to define general spatial relationships (left, above, concentric, parallel, etc.), geometric features (T, X, U, V), shape characteristics (round, curved, elongated), colour and texture (yellow, smooth, spotty). These would be much more difficult to define and use in a standard programming language. PQT can also be used effectively to control external peripheral devices but not in real time. PQT inherits Prolog's limited ability to analyse and extract meaning from natural language sentences, such as spoken commands. While PQT was designed to perform vision-based tasks, such as inspecting food products, it is also capable of the high-level reasoning needed to incorporate them into a well-balanced meal.

This chapter is in three parts. In the first, we explain how certain tasks involving abstract symbolic reasoning about images, can be accomplished, using a Prolog program with embedded image processing commands. In the second, we discuss the processing of natural language using Prolog. This allows us to build a vision system that is able to understand spoken commands expressed in English. In addition, such a machine can perform such tasks as operating an array of lights, or controlling a simple robot. In the third part, we describe how Prolog and QT, the image processing software package discussed in ➲ Chap. 21, can be interfaced to one another. This combination implements a convenient, easy-to-use language that has the ability to process and analyse images and then reason logically about them.

23.1 Part 1: Basic Features of Prolog

23.1.1 Adding Intelligence

Many potential applications of machine vision require greater reasoning power than the image processing languages described earlier can provide. This chapter is founded on the premise that an intelligent vision system can be made, by the simple expedient of embedding image manipulation and measurement routines within the AI language Prolog. The top-level control language for such a system will be called *Prolog+*. One of the most recent implementations of Prolog+ was constructed by interfacing QT (➤ Chap. 21) to SWI-Prolog [1] and will therefore be called *PQT*. We shall see later that Prolog+ is able to solve some of the problems that do not yield to standard image processing techniques (➤ Chap. 14) operating alone. (QT should not be confused with Qt which is a cross-platform application and user-interface framework, produced by Nokia. URL http://qt.nokia.com/products/.)

Prolog was devised specifically for developing AI programs and is used extensively for tasks involving Natural Language processing [2], machine learning [3] and for building rule-based and expert systems [4]. The range of applications is impressive in its breadth and includes areas as diverse as financial risk assessment, bridge design, planning health care, designing computer systems, route planning, symbolic mathematical manipulation [3, 5].

Prolog is an unusual computer language and bears no real resemblance to any of the "conventional" languages of Computer Science. In the core language, there are no FOR loops, IF . . . THEN statements, CASE statements, or any of the usual flow-control constructions. There is no variable assignment process; Prolog does not even allow instructions. The reader is, therefore, warned against trying to reconcile the distinctive features of Prolog with his/her prior programming experience. *Prolog is different!* In the following section, we describe this fascinating language for readers with no prior knowledge; we shall try to explain *why* Prolog is important. However, to obtain a more comprehensive understanding, the uninitiated reader is urged to refer to the standard textbooks. [4, 6, 7] Later, we shall attempt to justify the choice of Prolog, by describing and listing PQT programs that solve some interesting vision problems. For the moment, let it suffice to say that many major benefits have been obtained through the use of Prolog that could not have been obtained nearly so easily using other languages.

From his own experience, which now stretches over more than 20 years, the author can report that no serious shortcomings of Prolog+ have come to light. PQT combines SWI-Prolog with the proven set of image processing utilities embodied in QT. In Prolog+, it is possible to define abstract relationships/attributes such as *left_of*, *above*, *bigger*, *between*, *beside*, *near*, *yellow*, *curved*, *spotty*, etc. Representing these concepts in more popular languages, such as Java, C, C++, etc. is much more difficult.

Experienced Prolog programmers will appreciate that Prolog+ is a super-set of standard Prolog, with numerous additional built-in predicates that perform image processing functions. These behave much like the standard *write/1* predicate; by trying to satisfy a goal, the desired effect (e.g., negating, thresholding or filtering an image) is actually achieved. Predicates that calculate numeric values (e.g., Euler number, blob count, etc.) instantiate variables in the normal way. Readers who are familiar with Prolog may wish to omit ➤ Sect. 23.2 and skip directly to ➤ Sect. 23.3.

23.1.2 Introducing Prolog

It took the author 2 years to understand *why* Prolog is important and just 2 weeks to become reasonably proficient at using it! The reason why Prolog is worth further study is simply that it allows a novel and very natural mode of programming to be used. It permits a person to state the nature of an acceptable solution to a given search-based task, rather than *how* to find one. To understand this, consider the task of finding a marriage partner for a given hypothetical man. (*Not the author!*) It is relatively easy to specify the basic "requirements" to a dating agency, in terms such as those listed below. (The following list and Prolog program are intended to illustrate a point about Prolog; they do not constitute any statement about the absolute desirability of any type of religion, or personal/racial characteristics.)

Sex	Female
Age	[45,55]
Height	[150,180]
Weight	[45,75]
Language	English
Desirable characteristics	List might cover personality, faith, interests, hobbies, life-style, etc.

Clearly, this list cannot guarantee success in romance but it is sufficiently detailed to allow us to illustrate the general principles of what is known as *Declarative Programming*. Conventional programming languages are, by contrast, termed *imperative*, since they consist of a sequence of instructions. Prolog "programs" consist of a set of logical tests, rather than commands.

Writing a Prolog program to find a wife/husband is straightforward and has actually been used by at least one commercial dating agency. Here is a program to find a suitable wife, using the very small number of criteria specified above:

```
suitable_wife(X):-
        person(X),                 % Find a person called X
        sex(X,female),             % Is person X female?
        age(X,A),                  % Find age, A, of person X
        A >= 45,                   % 45 or more years old?
        A =< 55,                   % 55 or fewer years old?
        height(X, H),              % Find height, H, of person X
        H >= 150,                  % Is X at least 150 cm tall?
        H =< 180,                  % Is X at most 180 cm tall?
        weight(X,W),               % Find the weight of person X
        W >= 45,                   % Weight >= 45 kg?
        W =< 75,                   % Weight =< 75 kg?
        speaks(X,English).         % Does X speak English?
        must_be(X,[christian,kind, truthful,generous,loving,loyal]).    % Obvious meaning
```

Given such a program and a set of stored data about a collection of people, Prolog will search the database, to find a suitable match. There is no need to tell Prolog how to perform the search. The reader is urged to consider rewriting the program using Basic, C, Fortran, Java, or Pascal. An imperative-language program will take much longer to write, will consist of many more lines of code and be less transparent, because it imposes an unnatural mode of thought on the problem. Declarative (Prolog) programming is very much more natural in its style and allows a person to think directly about the type of solution required, rather than how to find it. Prolog differs from most other computer languages in several very important ways:

(a) Firstly, a Prolog "program" does *not* consist of a sequence of instructions, as routines written in conventional languages do. (The correct term is "application", since a program is, strictly speaking, a sequence of instructions. However, we shall continue to use the term "program", since this is more familiar to most readers.) Instead, it provides a medium for describing (part of) the world. As we have already stated, Prolog is referred to as a *declarative* language, while most other computer languages, military orders, knitting patterns, automobile repair manuals, musical scores and culinary recipes are all examples of *imperative* languages. This is a vital difference, which distinguishes Prolog and a small group of related languages from the better known conventional languages of Computer Science.

(b) The "flow of control" in a Prolog program does not follow the normal convention of running from top to bottom. In a Prolog program, the flow is very likely to be in the reverse direction, through a mechanism called *back-tracking*.

(c) Through the use of back-tracking, it is possible to make and subsequently revise temporary assignments of values to variables. This process is called *instantiation* and is akin to re-evaluating assumptions made earlier. (The word "*instantiation*" is derived from the same linguistic root as "instance". Prolog tries to find an *instance* of some variable(s) which cause the given predicate to be true.) Instantiation is performed, in order to try and prove some postulate, theorem or statement, which may or may not be true. As far as Prolog is concerned, theorem proving (also called *goal satisfaction*) is the equivalent process to running or executing an imperative language program.

(d) It is possible to make very general statements in Prolog in a way that is not possible in most other languages. We shall see more of this feature later, but for the moment, let us illustrate the point with a simple example. In Prolog it is possible to define a relationship, called *right* in terms of another relationship, called *left*.

In English:	"A is to the *right* of B if B is to the *left* of A."
In Prolog:	*right(A,B) :- left(B,A).*

(Read "**:-**" as "*can be proved to be true if*" or more succinctly as "*if*"). Notice that neither A nor B have yet been defined. In other words, we do not need to know what A and B are in order to define the relationship *right*. For example, A and B might be features of an image such as blob centres, or corners. Alternatively, A and B may be objects on a table, people (*Hitler* and *Lenin*) or policies (*National Socialism* and *Marxism*). The point to note is that Prolog+ allows the relationships *left* and *right* to be applied to any such objects, with equal ease. (Is *hitler* to the right of *lenin*? In the political sense, "yes", while the answer is "no", when we consider at the layout of words on this page.)

(e) Prolog makes very extensive use of *recursion*. While, Java, C and many other imperative languages also allow recursion, in Prolog it forms an essential control mechanism.

Prolog is not normally recommended for writing programs requiring a large amount of numerical manipulation. Nor is Prolog appropriate for real-time control, or other computational processes requiring frequent processing of interrupts.

23.1.2.1 Sample Program

The following program deals with the ancestry and ages of members of two fictitious families. (Not the author's!) Remember that ":-" means "*is true if*", while comma (",") means *AND*. Single-line comments are prefixed with %, while multi-line comments begin with /* and are terminated thus */.

```
/*
The following facts specify in which years certain people were born. Interpretation:
            born(roger,1943)
means that
            "roger was born in 1943".
                                                                        */
born(roger,1943).
born(susan,1942).
born(pamela,1969).
born(graham,1972).
born(thomas,1953).
born(angela,1954).
born(elizabeth,1985).
born(john,1986).
born(marion,1912).
born(patricia,1911).
born(gertrude,1870).
born(david,1868).
/*
These facts describe the parent-child relationships that exist in the families. Interpretation:
parent(X,Y) means that
              "X is a parent of Y".
                                                                        */
parent(roger,pamela).
parent(roger,graham).
parent(patricia,roger).
parent(anne,patricia).
parent(david,patricia).
parent(marion,susan).
parent(susan,graham).
parent(susan,pamela).
parent(thomas,john).
parent(angela,john).
parent(thomas,elizabeth).
parent(angela,elizabeth).
/*
Defining a relationship called "child". Read this as follows:
              "A is a child of B if
                          B is a parent of A."
                                                                        */
```

```
child(A,B) :- parent(B,A).
/*
Defining a relationship called "older". Read this as follows:
            "A is older than B if
                      the age of A is X AND
                      the age of B is Y AND
                      X > Y".
                                                                        */
older(A, B) :-
            age(A,X),                   % Age of A is X
            age(B,Y),                   % Age of B is Y
            X > Y.                      % Is X greater than Y?

/*
Defining a relationship "age". Read this as follows:
            "A has age B if
                      A was born in year X AND
                      it is now year Y AND
                      X =< Y AND
                      B is equal to Y – X."
                                                                        */
age(A,B) :-
            born(A,X),
            date(Y,_,_),
            X =< Y,
            B is Y - X.
/*
The definition of "ancestor" has two clauses. Prolog always tries to satisfy the top one first.
If this fails, it then tries to satisfy the second clause.
Interpretation: ancestor(A,B) means that
            "A is an ancestor of B."
The first clause should be interpreted as follows:
            "A is an ancestor of B if A is a parent of B".
                                                                        */
ancestor(A,B) :- parent(A,B).
/*
The second clause should be interpreted as follows:
            "A is an ancestor of B if
                      A is a parent of Z AND
                      Z is an ancestor of B."
Notice the use of recursion here.
                                                                        */
ancestor(A,B) :-
          parent(A,Z),
          ancestor(Z,B).
/*
Definition of "print_descendents".
```

```
This uses backtracking to find all possible solutions.
The first clause always fails but in doing so it prints the descendants and their dates of birth.
____________________________________________________________*/
print_descendents(A) :-
          nl,                              % New line
          write('The known descendants of' ),
                                           % Print a message
          write(A),                        % Print value of A
          write(' are:' ),                 % Print a message
          ancestor(A,Z),                   % A is ancestor of Z
          born(Z,Y),                       % Z was born in year Y
          nl,                              % New line
          tab(10),                         % 10 white spaces
          write(Z),                        % Print value of Z
          write(', born ' ),               % Print a message
          write(Y),                        % Print value of Y
          fail.                            % Force back-tracking
% Second clause always succeeds and prints a new line
print_descendents(_) :- nl.
```

23.1.2.2 Queries

A Prolog program consists of a set of *facts* and *rules* for interpreting them. The user then presents a *query*, which Prolog tries to prove to be true. The following goal was satisfied, because the program contains facts that explicitly state it to be true.

Query: *born(susan, 1942)*
Result: *YES*

In the following query, X is a variable. The query tests the proposition that susan was born some time (X). The goal succeeds, even if we refuse to accept that X = 1942.

Query: *born(susan, X)*
Result: *X = 1942*
YES

It is possible to use a variable for the first argument, to find who was born in 1942.

Query: *born(X, 1942)*
Result: *X = susan*
YES

It is also possible to use two or even more variables to specify very general queries:

Query: *born(X, Y)*

(*X* and *Y* are both variables, since their names have capital initial letters.) There are several possible solutions to this query.

Result: *X = roger*
Y = 1943

X = susan
Y = 1942

X = pamela
Y = 1969

X = graham
Y = 1972

X = thomas
Y = 1953

X = angela
Y = 1954

X = elizabeth
Y = 1985

X = john
Y = 1986

X = marion
Y = 1912

X = patricia
Y = 1911

X = gertude
Y = 1870

X = david
Y = 1868

NO MORE SOLUTIONS
(Notice the alternative solutions generated by this general query.)

The following query is satisfied by using the simple rule for *age/2* given above.

Query: *age(marion, Z)*
Result: *Z = 77*
YES

However, the following query uses a higher-level rule; *older/2* is defined in terms of *age/2* which is itself defined using *born/1*. (It is customary to specify the *arity* (number of arguments) of a Prolog predicate in the following way: *predicate_name/arity.)*

Query: *older(marion, susan)*
Result: *YES*

It is not always possible to satsify a given goal.

Query: *older(susan, marion)*
Result: *NO*
(*NO* should properly be expressed as *NOT PROVEN.*)

Another query which can only be solved by using a rule (*child*), which relies on another explicit relationship (parent):

Query: *child(susan, Z)*
Result: *Z = marion*
YES

The following is an example of a query that is satisfied by using a recursive rule (i.e., *ancestor*, clause 2) This is tantamount to asking who is a descendent of susan.

Query: *ancestor(susan, Z)*
Result: *Z = graham*
Z = pamela
NO MORE SOLUTIONS
(Notice the alternative solutions.)

The following query finds all of the ancestors of a given object (We know that *graham* is likely to be a person, but Prolog does not, as we have not explicitly told it so.)

Query: *ancestor(Z, graham)*
Result: *Z = roger*
Z = susan
Z = patricia
Z = anne
Z = david
Z = marion
NO MORE SOLUTIONS

Finally, here are two queries involving a high-level predicate:

Query: *print_descendents(marion)*
Result: *The known descendants of marion are:*
susan, born 1942
graham, born 1972
pamela, born 1969
YES

Query: *print_descendents(anne)*
Result: *The known descendants of anne are:*
patricia, born 1911

```
            roger, born 1943
            pamela, born 1969
            graham, born 1972
        YES
```

23.1.2.3 Back-tracking

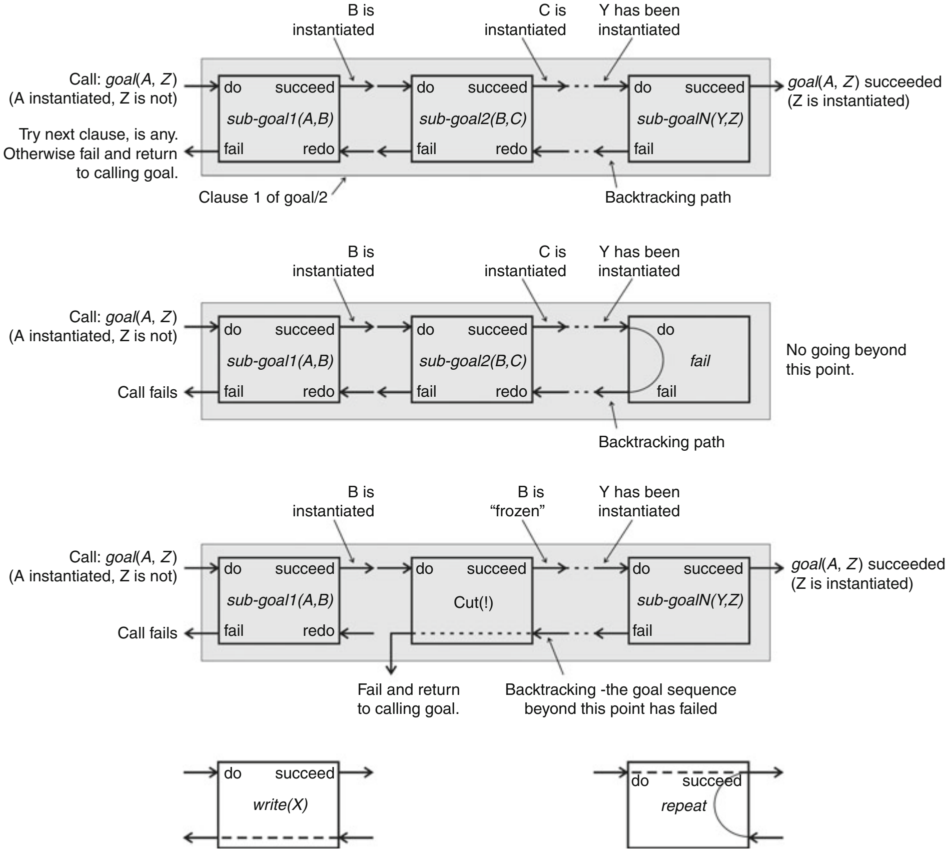
Consider the following program, which prints all of the grandparent-grandchild pairs that can be inferred from a *parent/2* database like that given above.

```
1.  go :-                % Starting the definition of the first clause
2.      parent(A,B),     % parent/2 is defined above. Find one parent-child pair.
3.      parent(B,C),     % Find child of B (i.e., grand-child of A)
4.      write([A,C]),    % Writes one of the solutions i.e., a [grandparent,grandchild] pair.
5.      nl,              % New line
6.      fail.            % First clause ends. It fails after all solutions have been found

7.  go :-                % Second clause. Is tried when clause 1 fails
8.      write('The end'), % Writes a simple message
9.      nl.              % New line. This clause and the goal "go" always succeed here
```

The goal *go* always succeeds. Clause 1 is evaluated first. In line 2, a parent-child pair (A,B) is found. This value of the variable B is used in line 3, as Prolog seeks a child (C) of B. (C is, of course a grandchild of A.) In line 4, the pair [A,C] is printed, while line 5 simply prints a new line. Line 6 always fails. In Prolog, goal failure is not catastrophic; it simply forces Prolog to begin back-tracking, as it continues its search for other possible solutions. Line 5 is then re-evaluated, but the built-in predicate *nl/0* is not resatisified. Back-tracking therefore continues to line 4. The built-in predicate *write/1* is not resatisified either, so back-tracking continues to line 3. If B has more that one child, the variable C is re-instantiated in line 3. In this case, lines 4, 5 and 6 are evaluated next. This cycle is repeated until all of the children of B have been found. Once this happens (i.e., line 3 has exhausted all solutions for a given value of B), back-tracking returns to line 2. Here, a new pair [A,B] is found and the whole process described so far is repeated. (A and/or B may change as a result of this re-instantiation.) Eventually, line 2 runs out of possible solutions. When this happens, clause 2 fails and Prolog begins evaluating clause 2, which in this case always succeeds.

When writing Prolog programs, it is not normally necessary to pay much attention to the possibility of back-tracking. However, an experienced Prolog programmer is often able to structure the program so that it searching is performed efficiently. One way to do this is to "freeze" all instantiations, once one partial solution has been found. This is accomplished using a device known as the *cut*, which is represented in Prolog by the operator "!". ➲ *Figure 23.1* explains the flow of control during backtracking and cut (1) using the so-called Box Model. This is a representation of Prolog execution, in which we think in terms of *procedures* rather than *predicates*. Each sub-goal is represented by a box with four ports:



B is instantiated
C is instantiated
Y has been instantiated
Call: goal(A, Z) (A instantiated, Z is not)
do
succeed
sub-goal1(A,B)
fail
redo
sub-goal2(B,C)
sub-goalN(Y,Z)
goal(A, Z) succeeded (Z is instantiated)
Try next clause, is any. Otherwise fail and return to calling goal.
Clause 1 of goal/2
Backtracking path
Call fails
No going beyond this point.
B is "frozen"
Cut(!)
Fail and return to calling goal.
Backtracking -the goal sequence beyond this point has failed
write(X)
repeat

Fig. 23.1

Box model of flow in a Prolog program. (a) Sequence of sub-goals not containing *fail* or cut (!). (b) Sequence containing *fail* but not cut (!). (c) Sequence containing cut (!) but not *fail*. (d) Model for printing by the built-in predicate *write/1*. The goal is not resatisfied on backtracking. Control continues to flow backwards. (e) Model for the built-in predicate repeat/0. The goal is satisfied on first meeting *repeat* and is always resatisfied on backtracking

Do Input port. This receives data from the previous sub-goal and then tries to satisfy the sub-goal.

Succeed Output port. When the sub-goal succeeds, previously and newly instantiated variables are sent to the next sub-goal.

Fail Output port. No new instantiations have been made. Return to the previous sub-goal. That is back-track one step.

Redo Input port. Receives control when the following subgoal fails.

The box representing the Built-in Predicate *fail* does not have *Succeed* or *Redo* ports. The box representing cut (!) directs the output from its *Fail* port to the calling goal/query, when it receives an input from the following sub-goal, without performing any other action. Any other clauses are ignored. When cut (!) receives a *Do* input, it freezes all instantiations in the clause.

23.1.2.4 Recursion

Prolog provides just two methods of controlling program "flow": back-tracking and recursion. We have already encountered recursion, in the definition of *ancestor/2*. Prolog handles recursion very efficiently and is one of the main reasons why it is so powerful. In the following example, *left_of/2* builds on the predicate *left/2*, whose meaning is obvious and which will be defined later.

```
% A is left_of B if A is to (the immediate) left of B
left_of(A,B) :- left(A,B).                     % Terminating clause

% A is left_of B if A is to (the immediate) left of C and C is left_of B
left_of(A,B) :- left(A,C), left_of(C,B).       % Recursive clause
```

Structurally, this is similar to *ancestor/2*, although it should be understood that there are many other ways to employ recursion. One of the dangers of using recursion is the possibility of creating programs that never halt. However, an experienced programmer avoids this trap by following one simple rule: place a terminating clause above the recursive clause.

Why is recursion so important? The reason is that many operations leading to "intelligent" behaviour are easily naturally expressed in terms of recursion, rather than iteration. The process of packing 2D shapes is a good example; the procedure is simple:

(a) Define the space available for placing an object.
(b) Choose an object to fit in place. This involves optimising its position and possibly its orientation and/or posture ("heads up" or "tails up").
(c) Put the object into its chosen place and calculate the space that is unoccupied.
(d) Apply steps (a) to (d) recursively.

As we shall see later, packing is one of the tasks that Prolog+ is able to perform but which presents major problems for QT, or imperative languages such as C, Java, etc.

23.1.3 Prolog+

The reader is reminded that Prolog+ is an extension of standard Prolog, in which a rich repertoire of image processing functions is made available as a set of built-in predicates. For convenience, we shall employ QT's image processing mnemonics in our description of Prolog+. This results in the language PQT that we shall discuss hereafter in this chapter. In the past, other implementations of Prolog+ have been devised [8]. PQT is simply the latest of these. *Figure 23.2* shows the basic structure of a generic Prolog+ system.

The way that the image processing predicates operate follows the standard pattern established for printing in Prolog (c.f. *nl, write, tab*). That is, they always succeed but are never resatisfied on back-tracking. For example, as a "side effect" of trying to satisfy the goal *neg*, Prolog+ calculates the negative of QT's current image. Similarly, the goal *thr(125,193)* always succeeds and in doing so thresholds the current image. Again, this goal is never resatisfied on back-tracking. When X is initially uninstantiated, the goal *cwp(X)* succeeds and instantiates X to the number of white pixels in the current image. However, the goal *cwp (15294)* will only succeed if there are exactly 15294 white pixels in the current image; it will fail otherwise see (*Fig. 23.3*).

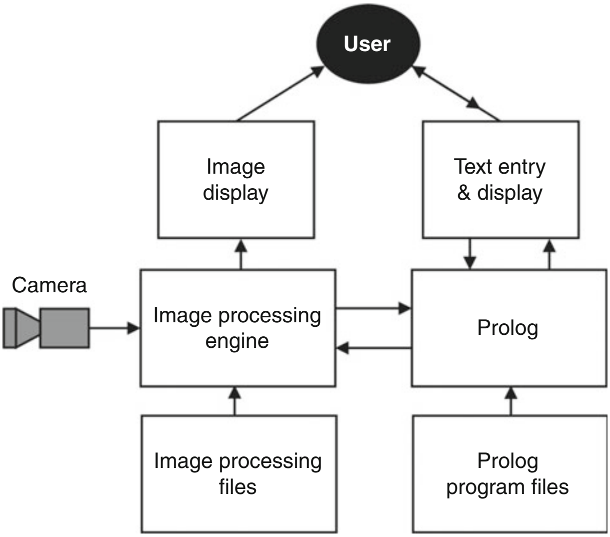


Fig. 23.2
Basic structure of a Prolog+ system. This may be implemented using one, or two, computers, or one computer, hosting Prolog, and a hardware image processing module

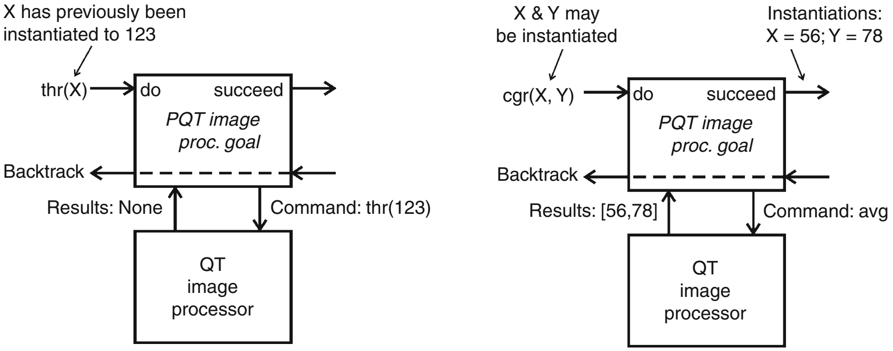

Fig. 23.3
Box model for PQT image processing predicates. (a) Image processing operations (e.g., *thr/1*) that do not return results. The goal is not resatisfied on backtracking. Control continues to flow backwards. (b) Model for PQT image processing operations (e.g., *cgr/2*) that return results. The goal is not resatisfied on backtracking. Control continues to flow backwards. If the results calculated by QT do not match the instantiations of X and Y, the goal will fail and backtrack to the previous goal

The distinction between assignment in an imperative language and instantiation in Prolog is important and must be understood before the merits of Prolog+ can be appreciated.) While PQT is trying to prove the compound goal

avg(Z),thr(Z)

Z is instantiated to the average intensity within the current image (calculated by *avg*). This value is then used to define the threshold parameter required by *thr*. With these points in mind, we are ready to examine our first PQT program.

```
grab_and_threshold :-
        grb,                    % Digitise an image
        caf,                    % Blur (Low-pass filter)
        avg(Z),                 % Calculate average intensity
        thr(Z).                 % Threshold at average intensity
```

Since each sub-goal in this simple program succeeds, the effect is the same as if we had written a sequence of commands using a conventional (i.e., imperative) computer language. Here is the QT equivalent M-function

```
        function grab_and_threshold
        grb                     % Digitise an image
        caf                     % Blur (Low-pass filter)
        Z = avg(Z);             % Calculate average intensity
        thr(Z)                  % Threshold at average intensity
```

The Prolog+ goal *grab_and_threshold* always succeeds. However, the following PQT program is a little more complicated.

```
big_changes(A) :-
        repeat,                 % Always succeeds on backtracking
        grb,                    % Digitise an image from the camera
        raf,                    % Perform raf (low-pass filter)
        sca(3),                 % Retain 3 bits of each intensity value
        rei,                    % Read image stored in previous cycle
        swi,                    % Switch current & alternate images
        wri,                    % Save the image for the next cycle
        sub,                    % Subtract the two images
        abv,                    % Absolute value of intensity
        thr(10),                % Threshold at intensity level 10.
        cwp(A),                 % A is number of white pixels
        A > 100.                % Are image differences significant?
```

The built-in predicate *repeat* succeeds, as does each of the image processing operators, [*grb*, *raf*, . . ., *cwp(A)*]. If the test *A* > *100* then fails, the program back-tracks to *repeat*, since none of the image processing predicates is resatisfied on backtracking. (The predicate *repeat/0* is always resatisfied on backtracking.) Another image is then captured from the camera and the whole image processing sequence is repeated. The loop terminates when *A* exceeds 100. When this happens, the goal *big_changes(A)* succeeds and *A* is instantiated to the number of white pixels in the difference image. The goal *big_changes(A)* performs the processing sequence [*grb*,. . ., *cwp(A)*] an indefinitely large number of times and only succeeds when two consecutive images are found that are significantly different from one another. This program could be used as the basis for a crude intruder alarm that detects when a large object (a person) enters a restricted area. By adjusting the number in the final sub-goal (i.e., *A* > *100*), it is possible to tolerate small changes (e.g., a cat wandering in front of the camera), while still being able to detect large variations due to a person being in view. By now, the reader should be able to write a QT program to perform the same function.

Although image processing commands, such as *grb, thr, cwp* etc. are always satisfied, errors will be signalled if arguments are incorrectly specified. Since *thr(X)* requires one numeric argument, an error condition will arise if X is uninstantiated. On the other hand, the following compound goal is satisfied

```
X is 197, thr(X),
```

as is

```
gli(A,B),                  % Lower & upper intensity limits
C is (A+B)/2,              % Average A and B
thr(C).                    % Threshold at average value
```

The compound goal

```
X is 186, Y is 25, thr(X,Y)
```

fails, since *thr* fails when its second argument is less than the first one. (The image processor signals an error, which causes the failure of the Prolog goal, *thr(186,25).*) The compound goal

```
X is 1587, thr(X)
```

fails, because the parameter (X) is outside the range of acceptable values, i.e., [0,255].

Notice that *thr* has already been used with different numbers of arguments. We can use *thr* with 0, 1 or 2 arguments. Other image processing predicates will be treated in the same way. For example, we have already used *wri/1* (write image to disc) and *rei/1* (read image from disc) without arguments. We can also use arguments instantiated to a string of alpha-numeric characters. Such arguments may be generated according to the usual Prolog conventions. For example, the Prolog symbol generator, *gensym/2*, may be used to create a series of file-names, *image_file1, image_file2,...* as the following illustration shows:

```
process_image_sequence :-
        grb,                            % Digitise an image
        process_image,                  % Process the image
        gensym(image_file,X),           % Generate new symbol name
        wri(X),                         % Write image
        process_image_sequence.         % Repeat processing
```

Notice here that we have "condensed" almost all of the image processing into the subsidiary predicate, *process_image/0.* Using this approach, a simpler, revised version of *big_changes/1* may be defined using the subsidiary predicate, *process/0.*

```
big_changes(A) :-
        process      % Listed below
        cwp(A),      % Instantiate A to number of white pixels
        A > 100.     % Are differences between images large enough? If not, back-track.
```

where *process/0* is defined thus:

```
process :-
        grb,            % Grab an image from the camera
        lpf, lpf, lpf,  % Low pass filter applied three times
```

```
          sca(3),        % Reduce number of bits representing intensity to 3
          rei,           % Read image from disc
          swi,           % Interchange the Current and Alternate images
          wri,           % Save image on disc
          sub,           % Subtract current and alternate images
          abv,           % "Absolute value" (fold intensity scale around mid grey)
          thr(1).        % Threshold at level 1
```

The use of subsidiary predicates, such as *process_image* and *process*, allows the programmer to think at a higher conceptual level and to defer deciding exactly what image processing is to be performed until later.

23.1.4 Sample Programs

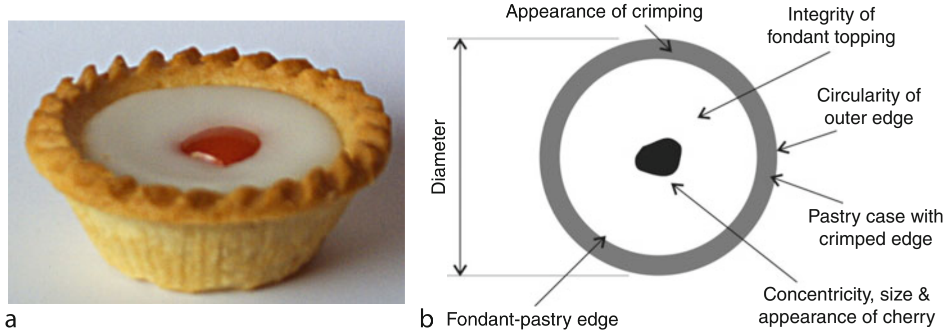
Now that we have illustrated the basic principles of Prolog+, we are able to consider more advanced programs to illustrate its main features. It is important to realise that we must always use Prolog+ to describe the *image* generated by the camera, not the object/scene being inspected. The importance of this point cannot be over-emphasised. Additional points of general interest will be discussed as they arise.

23.1.4.1 Recognising Bakewell Tarts

Figure 23.4 which shows a small cake, called a Bakewell tart. We shall explain how Prolog+ might be used to inspect it from an overhead view.

The top level of the program consists of four separate tests, incorporated into the predicate *bakewell_tart/0:*

```
     bakewell_tart :-
          segment_image,          % Convert image as in Fig. 23.4
          outer_edge,             % Check the outer edge
          cherry,                 % Check the cherry
          icing.                  % Check the icing
```



a
b
Appearance of crimping
Integrity of fondant topping
Circularity of outer edge
Diameter
Pastry case with crimped edge
Concentricity, size & appearance of cherry
Fondant-pastry edge

Fig. 23.4
Bakewell tart. (a) Photograph (Credit: B. R Wheatley, *copyright free*) and (b) critical features

Programs written in PQT are almost invariably written from the top level downwards. In this instance, *bakewell_tart/0* was the first predicate to be defined. Notice that there are four obvious stages in verifying that the tart is a good one:

(a) Simplify the image (possibly with 2–4 intensity levels), using *segment_image/0.*
(b) Check the integrity of the outer edge, using *outer_edge/0.*
(c) Check the presence, size and placing of the cherry, using *cherry/0.*
(d) Check the icing, using *icing/0.*

Clearly, *bakewell_tart/0* is only satisfied if all four of the subsidiary tests succeed. Although the secondary predicates are not defined yet, this is not necessary for us to understand the broad concepts involved in recognising a Bakewell tart. Three of these are defined below. (*segment_image/0* is not given here, because it is problem specific and would distract us from the main point.)

```
outer_edge :-
        thr(1),                 % Select outer edge
        circular.               % Test for circularity. Defined below

cherry :-
        thr(1),                 % Select outer edge
        cgr(X1,Y1),             % Centroid of outer edge
        swi,                    % Switch images
        thr(200),               % Select cherry
        swi,                    % Switch images
        cgr(X2,Y2),             % Centroid of the cherry
        distance([X1,Y1,],[X2,Y2],D),
                                % D is distance [X1,Y1] to [X2,Y2],
        D < 20.                 % Are cherry & outer edge concentric?

icing :-
        thr(128),               % Select icing
        rei(mask),              % Read annular mask image from disc
        exr,                    % Differences between these images
        cwp(A),                 % Calculate area of white region
        A > 50.                 % Allow few small defects in icing

circular :-
        cwp(A),                     % Calculate area
        perimeter(P),               % Calculate perimeter.
        S is A/(P* P),              % Shape factor
        S < 0.08.                   % S >= 1/(4* π) (min. for circle)
```

Notice the highly modular approach to Prolog+ programming and the fact that it is possible to define what is an “acceptable” Bakewell tart, in a simple and natural way. Apart from the predicate *segment_image/0*, whose definition depends upon the lighting and camera, the program *bakewell_tart/0* is complete and provides a simple yet effective means of inspecting Bakewell tarts.

23.1.4.2 Recognising Printed Letters

This application is included to illustrate Prolog+, rather than explain how a practical optical character recognition system might work. The top two layers of a Prolog+ program for recognising printed letters are given below:

```
% Top level predicate for recognising printed
% letters, which may be either upper or lower case
% and in any one of three fonts.
letter(X) :- upper_case(X).                 % May be upper case ...
letter(X) :- lower_case(X).                 % ... or lower case

upper_case(X) :-
        font(Y),                            % Find what font we are using
        member(Y,[times,courier,helvetica]),
                                            % Is font Y known to us?
        recognise_upper_case(X,Y).          % X is upper case in font Y

lower_case(X) :-
        font(Y),                            % Find what font we are using
        member(Y,[times,courier,helvetica]),
                                            % Is font Y known to us? to us
        recognise_lower_case(X,Y).          % X is lower case in font Y
```

The complex task of recognising an upper- or lower-case letter in any of the three known fonts has been reduced to a total of 156 (=3*2*26) much simpler sub-problems. (A simple declarative definition of the *sans serif* upper-case letter A is presented later.) Now, let us consider what changes have to be made if a new font (e.g., *Palatino*) is to be introduced. Two changes have to be made:

(i) the second line in the body of *upper_case/1* and *lower_case/1* is changed to
member(Y,[times,courier,helvetica,palatino])
(ii) two new clauses are added for each letter X, one for
recognise_upper_case(X,palatino)
and another for
recognise_lower_case(X,palatino).

If we wanted to add recognition rules for the numeric characters, then 10 new clauses would be added, as in (ii). In other words, extending the scope of a Prolog+ program is conceptually simple, if rather tedious to accomplish. Here, as promised, is a naive but quite effective declarative definition of the *sans serif* upper-case letter A:

```
recognise_upper_case(a,sans_serif) :-
        apex(A),                    % There is an apex called A.
        tee(B),                     % There is a T-joint called B
        tee(C),                     % There is a T-joint called C
        line_end(D),                % There is a line_end called D
```

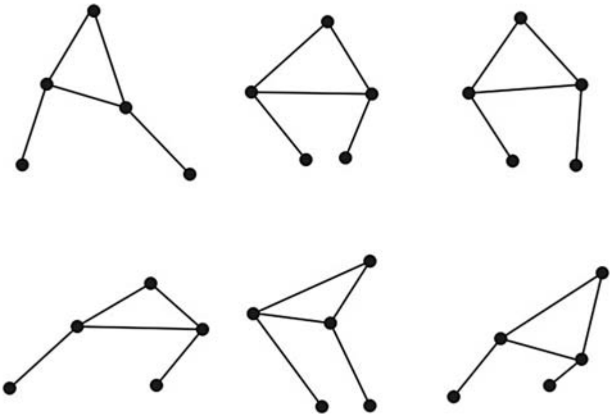


Fig. 23.5
Objects that are inappropriately recognised as the sans serif upper-case letter A by the goal *recognise_upper_case(a,san_serif)*

```
line_end(E),                    % There is a line_end called E
above(A,B),                     % A is above B.
above(A,C),
about_same_vertical(B,C),
about_same_vertical(D,E),
above(B,D),
above(C,E),
connected(A,B),
connected(A,C),
connected(B,D),
connected(C,E),
connected(B,C),
left(B,C),
left(D,E).
```

The reader should be able to understand the above program without detailed knowledge about how the predicates *apex/1, tee/1, line_end/1, above/1, about_same_vertical/2, above/2, connected/2, left/2* and *right/2* are defined. *Figure 23.5* shows some of the objects which are recognised by this program. Obviously, *recognise_upper_case/2* can be refined by adding further conditions, to eliminate some of the more bizarre objects that are recognised by the present definition and which are shown in *Fig. 23.5*.

23.1.4.3 Identifying Table Cutlery

The following Prolog+ program identifies items of table cutlery that are viewed in silhouette. (It is assumed, for the sake of brevity, that the input image can be segmented using simple thresholding.) The top-level predicate is *camera_sees(Z)* and is a general purpose utility that can find any object, given an appropriate definition for the subsidiary predicate *object_is/1*. In its present somewhat limited form, the program recognises only forks and knives; additional clauses for *object_is/1* are needed to identify other utensils, such as spoons, plates, mats, etc. When the query *camera_sees(Z)* is specified, Z is instantiated to the type of object seen by the camera. In practice, there may be many objects visible to the camera and the program will progressively analyse each one in turn. Any objects visible to the camera that are not recognised are indicated by instantiating Z to the value *unknown_type*.

```
% Top level predicate for recognising individual items of table cutlery
camera_sees(Z) :-
        grb,                    % Digitise the camera image
        segment_image,          % Example: [enc, thr(128)]
        ndo,                    % Shade resulting binary image; each
                                % blob has different intensity
        wri(temp),              % Save image in disc file
        repeat,                 % Begin loop - analyse blobs in turn
        next_blob,              % Select 1 blob from image in "temp"
        object_is(Z),           % Blob is object of type Z
        finished.               % Succeeds when no more blobs
% Select one blob from the image stored in disc file “temp”.
% Remove this blob from the stored image, so that it will not be considered next time.
next_blob :-
        rei(temp),              % Read image from disc file “temp”
        gli(_,A),               % Identify next blob - i.e., brightest
        hil(A,A,0),             % Remove it from stored image
        wri(temp),              % Save remaining blobs
        swi,                    % Revert to previous stored image
        thr(A,A).               % Select one blob
% Recognises individual non-overlapping objects in a binary image. See➔ Fig. 23.6
object_is(fork) :-
        mma(X,Y),               % Lengths of major & minor axes. mma is not defined here
        X >= 150,               % Length must be >= 150 pixels
        X =< 450,               % Length must be =< 450 pixels
        Y >= 25,                % Width must be >= 25 pixels
        X =< 100,               % Width must be =< 100 pixels
        Z is X/Y,               % Calculate aspect ratio - whatever
                                % orientation
        Z =< 10,                % Aspect ratio must =< 10
        Z >= 4,                 % Aspect ratio must be >= 4
        count_limb_ends(N),
                                % N is number of limb ends
        N >= 3,                 % Skeleton of fork has >= 3 limb ends
        N =< 5.                 % Skeleton of fork has =< 5 limb ends
% Add extra clauses to recognise each possible type of object. See➔ Fig. 23.4
object_is(knife) :-
        mma(X,Y),               % Lengths of major & minor axes
        X >= 150,               % Length must be >= 150 pixels
        X =< 450,               % Length must be =< 450 pixels
```

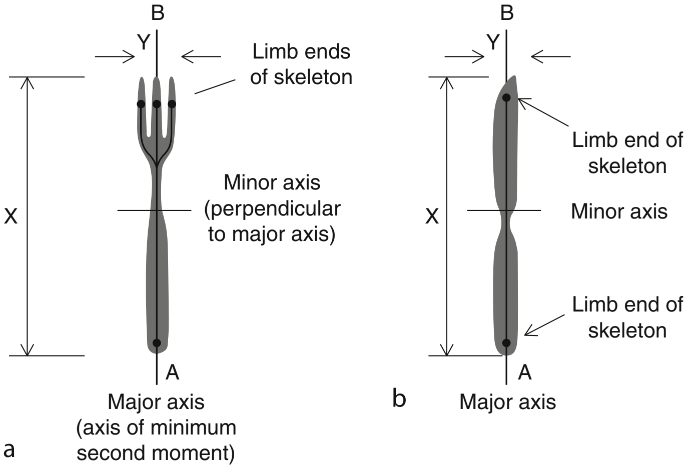

Fig. 23.6

Explaining the operation of two object recognition programs (a) *object_is(fork)*. AB is the axis of minimum second moment. Criteria to be satisfied, before this object can be accepted as a fork: 150 =< X =< 450; 25 =< Y =< 100; 4 =< X/Y =< 10; skeleton here has 3–5 limb ends. (b) *object_is(knife)*. AB is the axis of minimum second moment. Criteria to be satisfied, before this object can be accepted as a fork: 150 =< X =< 450; 25 =< Y =< 100; 6 =< X/Y =< 12; skeleton must have exactly two limb ends

```
        Y >= 25,            % Width must be >= 25 pixels
        X =< 100,           % Width must be =< 100 pixels
        Z is Y/X,           % Calculate aspect ratio - whatever
                            % orientation
        Z =< 12,            % Aspect ratio must be =< 12
        Z >= 6,             % Aspect ratio must be >= 6
count_limb_ends(2).
                            % Skeleton of knife has 2 limb ends
object_is(unknown_type).
                            % Catch-all clause. Not recognised
% Search is finished. Image is black everywhere.
finished :-
        rei(temp),          % Read image from disc
        thr(1),             % Threshold stored image
        cwp(0).             % Succeeds if no. of white points = 0
% Count the limb ends on a skeleton ("match-stick") figure.
count_limb_ends(N) :-
        mdl,                % Generate skeleton of the blob
        cnw,                % Count white neighbours, 3*3 window
        min,                % Ignore back-ground points
        thr(2,2),           % Select limb ends
        eul(N).             % Instantiate N to no. of limb ends
```

23.1.4.4 Analysing All Visible Objects

The list of all objects that are visible to the camera can be found using the predicate *list_all_objects/1* defined below. This will be useful in the next section.

```
list_all_objects(A) :-
        grb,                    % Same pre-processing . . .
        segment_image,          % . . . as is used in . . .
        ndo,                    % . . . the predicate . . .
        wri(temp),              % . . . "camera_sees"
        find_object_list        % Generate list of objects seen
        ([],A).
% Terminating recursion. Succeeds when there are no more blobs left to analyse.
find_object_list(A,A) :- finished.
% Analyse all blobs in the image
find_object_list(A,B) :-
        next_blob,              % Select blob from image in file "temp"
        object_is(C),           % Blob is object of type C
        !,                      % Cut (!) makes recursion more efficient as it freezes
                                variable C
        find_object_list        % Recursion - analyse all blobs
        ([C|A],B).
```

This makes use of the fact that *object_is/1* is able to recognise an object in the presence of other objects, provided that they do not touch or overlap. We will now make good use of *list_all_objects/1* in performing a more challenging task, namely that of recognising a well-laid table place setting.

23.1.4.5 Recognising a Table Place Setting

The following Prolog+ program can recognise a table place setting with the cutlery laid out as shown in ➋ *Fig. 23.7a*. For this program to work properly, we must first define additional clauses for the predicate *object_is*, so that appropriate types of object, such as *small_knife/1, tea_spoon/1, dinner_fork/1, plate/1, mat/1*, etc., can be recognised. Notice that *table_place_setting/0* is defined in standard Prolog, without any further use of the image processing built-in predicates.

```
table_place_setting :-
        list_all_objects(A),
        equal_sets(A, [mat, plate, dinner_knife, small_knife,
        dinner_fork, small_fork, soup_spoon, desert_spoon]),
        left(dinner_fork, mat),                 % Defined below
        left(mat, dinner_knife),
        left(dinner_knife, small_knife),
        left(small_knife, soup_spoon),
        below(mat, small_fork),                 % Defined below
        below(small_fork, desert_spoon).
```

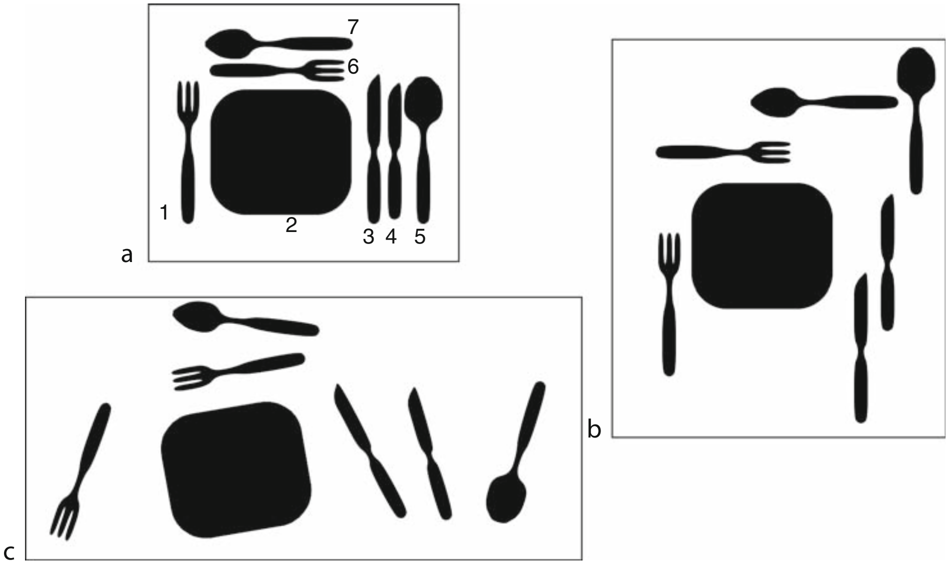

Fig. 23.7
Table place settings: (a) Ideal arrangement. Key: 1, dinner_fork; 2, mat; 3, dinner_knife; 4, small_knife; 5, soup_spoon; 6, small_fork; 7, desert_spoon. (b) Scene that is misrecognised by *table_place_setting/0* with the original definitions of *left/2* and *below/2* but which is correctly rejected by the revised version. (c) A scene that is incorrectly recognised by the revised version of the program

For completeness, we now define the *predicates left/2, below/2* and *equal_sets/2.* These and many other useful "general purpose" predicates like them form part of a PQT Library, which augments the basic language.

```
left(A,B) :-
        location(A,Xa,_),          % Horizontal position of A
        location(B,Xb,_),          % Horizontal position of B
        !,                         % Inhibit backtracking
        Xa < Xb.                   % Compare horizontal positions
below(A,B) :-
        location(A,_,Ya),          % Vertical position of A is Ya
        location(B,_,Yb),          % Vertical position of B is Yb
        !,                         % Inhibit backtracking
        Ya < Yb.                   % Compare vertical positions
equal_sets([],[]).                 % Terminate recursion
% Checking two non-empty lists are equal
equal_sets([A|B],C) :-
        member(A,C),               % A is a member of C
        cull(A,C,D),               % Delete A from C. Result D
        !,                         % Improve efficiency
        equal_sets(B,D).           % Are sets B & D equal?
cull(_,[],[]).                     % Empty list, Do nothing
```

```
% Delete A from list if A is at its head
cull(A,[A|B],C) :-
        !,                              % Don't back-track - improves efficiency
        cull(A,B,C).                    % Repeat until A & B are empty
% A is not head of "input" list [B|C] so work on its tail
cull(A,[B|C],[B|D]) :-
        !,                              % Improves efficiency
        cull(A,C,D).                    % Repeat until A & B are empty
```

Using these simple definitions, a range of unusual configurations of cutlery and china objects is accepted (see Fig. 23.7b). To improve matters, we should refine our definitions of *left/2* and *below/2*. When redefining *left(A,B)*, we simply add extra conditions, for example that *A* and *B* must be at about the same vertical position:

```
left(A,B) :-
        location(A,Xa,Ya),
        location(B,Xb,Yb),
        !,
        Xa < Xb,                            % Compare horizontal positions
        about_same(Ya,Yb, 25).              % Tolerance level = 25
about_same(A,B,C) :- A =< B + C.
about_same(A,B,C) :- A >= B − C.
```

The predicate *below/2* is redefined in a similar way:

```
below(A,B) :-
        location(A,Xa,Ya),
        location(B,Xb,Yb),
        !,
        Ya < Yb.                              % Compare vertical positions
        about_same(Xa,Xb, 25).                % Tolerance level = 25
```

In a practical application, it would probably be better for the tolerance parameter required by *about_same/3* (third argument) to be related to the size of the objects to be recognised. This would make a program such as *table_place_setting/0* more robust, by making it size-independent. This modification to our program improves matters, but it still recognises certain cutlery arrangements as being valid place settings, even though we would probably want to exclude them in practice (Fig. 23.7c). Clearly, we can go on adding further conditions to our program, in order to reduce the number of cutlery arrangements accepted by it.

In Part 2, we discuss the task of recognising a well-laid place setting, using a natural language (English) description of the ideal layout.

23.1.5 Justifying the Design

We have repeatedly emphasised that Prolog is able to handle abstract concepts, expressed in symbolic form. In this section, we shall try to justify this claim and explain why our latest implementation of Prolog+ was based on QT, rather than the unadorned MATLAB Image

Processing Tool-box. In doing so, we shall explain how to recognise items of fruit in PQT and then pack a lunch box that provides a well-balanced diet. This is achieved using the same language that we might use for other very different tasks such as inspecting piece parts, identifying flaws in a woven fabric, operating a robot or controlling a lighting array.

23.1.5.1 Additional Spatial Relationships (➲ *Fig. 23.8*)

The predicate *table_place_setting/0* relies upon *abstract* concepts about spatial relationships between pairs of objects in an image. The relationships in question (i.e., *left/2* and *below/2*) were defined earlier. Another predicate based on the spatial relationship between two objects is *encloses/2* and is clearly related to its reciprocal relationship, *inside/2*:

```
% A encloses B if B is inside A
encloses(A,B) :- inside(B,A).
inside(A,B) :-
        wri(image),            % Save the original image
        isolate(A),            % Isolate object A
        wri(A),                % Save image until later
        rei(image),            % Recover the original image
        isolate(B),            % Isolate object B
        rei(A),                % Recover saved image during "wri"
        sub,                   % Subtract images
        thr(0,0),              % Find all black pixels
        cwp(0).                % There are zero black pixels
```

Notice that *inside(A,B)* creates two binary images, containing objects *A* and *B*. These images are then compared. If all white pixels in one image (i.e., the one containing object *B*) are also white in the other (containing object A), then we can conclude that *A* is inside *B* and the goal *inside(A,B)* succeeds.

There are, of course, many other abstract relationships of this kind. Here are the definitions of a few of them:

```
% Are objects A and B concentric?
concentric(A,B) :-
        location(A,Xa,Ya),            % Definition may be based on centroid
        location(B,Xb,Yb),
        near([Xa,Ya],[Xb,Yb],10).     % Distance [Xa,Ya] to [Xb,Yb] =< 10?

% Are objects A and B in about the same vertical position?
about_same_vertical(A,B) :-
        location(A,Xa,Ya),            % Definition may be based on centroid
        location(B,Xb,Yb),
        about_same(Ya,Yb,10).         % Is |Ya−Yb|=< 10?

% Test whether object A is in the upper part of
% object B (i.e., the bottom-most point in A is
```

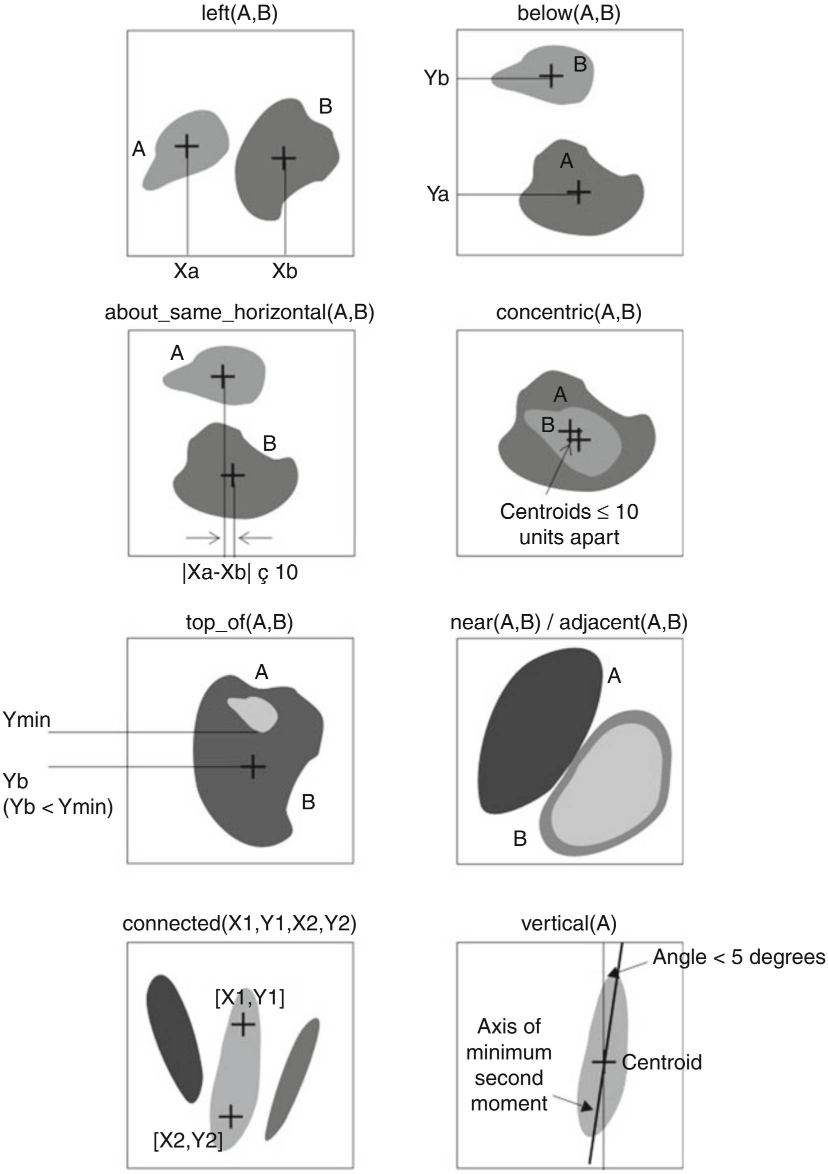

Fig. 23.8
Spatial relationships in Prolog+

```
% above B's centroid). A must be entirely contained inside B.
top_of(A,B) :-
        isolate(A),                 % Isolate object A
        dim(_,Ya,_,_),              % Bottom of object A
        isolate(B),                 % Isolate object B
        cgr(B,_,Yb),                % Centroid of B
        Ya =< Yb,                       % Is bottom point in A above the centre of B?
        inside(A,B).

% Are the points [X1,Y1] and [X2,Y2] connected by a continuous set of white pixels?
connected(X1,Y1,X2,Y2) :-
        ndo,                            % Shade blobs.
        pgt(X1,Y1,Z),                   % Z is intensity at [X1,Y1]
        pgt(X2,Y2,Z),                   % Z is intensity at [X2,Y2]
        Z = 255.                        % Both pixels are white

% Are regions A and B adjacent?
adjacent(A,B) :-
        isolate(A),                     % Isolate region A
        exw,                            % Expand region by 1 pixel
        wri,                            % Save image for use later
        isolate(B),                     % Isolate region A
        rei,                            % Read image A expanded
        mni,                            % Logical AND of the 2 images
        cwp(N),                         % Count white points
        N > 0.                          % Are there some?
```

The reader may like to consider how a predicate can be defined that can test whether an object in a binary image is nearly vertical (➔ *Fig. 23.8h*). (The pivotal QT function is *lmi.*) This predicate could be used to prevent *table_place_setting/0* from detecting scenes like that shown in ➔ *Fig. 23.7c*.

23.1.5.2 High-Level Concepts

Suppose that we want to devise a Machine Vision system to identifying highly variable objects that conform to a set of rules, expressed either formally, or in a natural language, such as English, Dutch or German. We might, for example, want to recognise objects in an image that are

yellow
sausage-like in shape
curved, with a bend of 5–30°
15–50 mm wide
70–200 mm long.

There are no prizes for guessing what class of objects we are trying to recognise! We can express the recognition rule in Prolog+, in the following way:

```
object(banana) :-
        isolate(yellow),        % Keep “yellow” objects
        big,                    % Ignore small objects
        sausage,                % Shape recognition rule based on “length” and “width”
        curved,                 % Another test for shape
```

```
width(W),              % Measure the width
W >= 15, W =< 50,      % Arithmetic tests
length(L),             % Measure the length
L >= 70, L =< 200.     % Arithmetic tests
```

Look around the room where you are reading this. Is there anything in it that could possibly match this specification? It is most unlikely that there is, unless of course, you happen to have a banana nearby! However, a few other things do look like bananas (e.g., plastic replica bananas, sweet-corn (maize) cobs, rolls of yellow paper, etc.) In addition, some perfectly good bananas may be too large, too small, or be so deformed that this rule fails. Indeed rule-based recognition criteria will almost always make some mistakes. However, if we have been diligent in seeking the most appropriate discriminating criteria, the error probability should be quite low. This approach frequently results in heuristic, rather than algorithmic, rule-based recognition procedures (see ➜ Chap. 17). There are no formal, universally acceptable rules for recognising a "sausage", or a "curved" object. Human beings do not always agree about what is/is not "yellow". (The author and his wife often disagree about what is blue/green! See ➜ Chaps. 4 and ➜ 16) Despite this, our test for "banana-ness" is quite precise; very few objects exist that pass such a test. The reason is that we have juxtaposed several highly specific factors, relating to colour, shape and size. We might also add descriptions of texture, by including a test for "spottiness", based upon the density of small dark features within a yellow blob. The reader may like to contemplate how such an idea can be expressed in PQT.

The recognition rule for "banana-ness" relies on elementary concepts that can each be specified in QT. Clearly, "raw" MATLAB, NeatVision (➜ Chap. 22) and similar systems might be used instead. Each of these is, on its own, able to perform all of the necessary image processing, arithmetic and logical operations needed to implement the object(banana) recognition rule. We shall explain later why Prolog+ has been implemented using QT. For the moment we shall concentrate on justifying the use of Prolog. To do this, consider the following extensions of our program.

First of all, bananas can be green, yellow and green, yellow, or yellow with brown spots. Our program can easily be modified to recognise under-ripe, ready to eat and over-ripe bananas:

```
fruit(banana) :- object(under_ripe_banana).
fruit(banana) :- object(ripe_banana).
fruit(banana) :- object(over_ripe_banana).
```

Each of these three clauses then requires the description of a banana in a different state of ripeness. While this adds to the total quantity of program code that we must create, each of the new subsidiary predicates (i.e., *object(under_ripe_banana), object(ripe_banana)* and *object (over_ripe_banana))* is easy to write. We have divided the problem into simpler rules that each deals with a separate state of affairs.

Moreover, we can recognise the more general predicate *fruit*, by combining several rules like the one already listed:

```
fruit(apple) :- object(apple).
fruit(banana) :- object(banana).
fruit(grapefruit) :- object(grapefruit).
fruit(kiwi) :- object(kiwi).
fruit(orange) :- object(orange).
fruit(pear) :- object(pear).
```

Of course, each class, such as *apple,* can be sub-divided, which may will probably make the program easier to write:

```
object(apple) :- object(cox_orange_pippin_apple).
object(apple) :- object(golden_delicious_apple).
object(apple) :- object(macintosh_apple).
object(apple) :- object(pink_lady_apple).
```

In addition, we can plan a lunch box thus:

```
lunch_box(A,B,C,D,E) :-
        savoury(A),          % Savoury item (e.g., ham sandwich))
        desert(B),           % Choose a desert (e.g., cake)
        fruit(C),            % Choose one item of fruit
        fruit(D),            % Choose another item of fruit
        not(C = D),          % Items of fruit must be different
        drink(E).            % Choose a drink
```

It is a straightforward matter to add extra criteria for checking dietary balance; we simply add a database of important nutritional factors for each food type and add simple tests to make sure that the lunch-box contains a healthy meal.

We are able to plan the contents of the lunch box in the very same language that we use to perform a wide variety of image processing operators. We have moved quickly and effortlessly from image-based recognition criteria of specific types of fruit (e.g., ripe bananas), through the more general concept of *banana*, then to the bigger class *fruit*. After a short step further, we are able to discuss the planning of a healthy meal. We can do all this in PQT, which is also well suited to tasks such as controlling a robot and multi-function lighting rig.

PQT is an extension to Prolog, giving it the ability to sense the world visually. This does not limit Prolog's powers in any way. So, all of the arguments that support the use of Prolog in applications requiring abstract reasoning are all still valid.

Notice that the Prolog inference engine is not used to handle images directly; QT does that. This is an important point as Prolog does not handle large volumes of numeric data comfortably.

23.1.5.3 Why Base Prolog+ on QT?

Thus far, we have explained why we have used Prolog but have not yet justified the reliance on QT. There are several points in answer to this question.

1. QT is built on the solid ground of experience and is the latest in a series of interactive image processing systems whose development began over 30 years ago [9]. During this time, the command repertoire has been developed specifically for analysing industrial inspection and visual control applications. Some of the commands available in MATLAB, for example, do not have any obvious use in industrial Machine Vision systems.

2. QT's functional command structure fits in well with Prolog's syntax. Although the two are not directly compatible it is a straightforward matter to translate from one form into the other. On the other hand, MATLAB's basic command structure is not so easily matched to Prolog.
3. QT has a standardised image format and a simple operating paradigm, based on the current-alternate image model. While it may seem to be restrictive, QT's heavy reliance on monochrome images reflects current usage in many industrial Machine Vision systems and has never been observed to cause even minor difficulties. Recall that QT can also perform a wide variety of operations on colour images, despite this constraint. (If the 8-bit model ever proved to be unduly restrictive, it is reassuring to note that a 16-bit version of QT could be produced with reasonable ease.) On the other hand, "raw" MATLAB allows the use of certain image formats, most noticeably sparse and indexed arrays, that are unlikely to be used in dedicated, high-speed systems. In short, MATLAB's great versatility makes it more difficult to use, compared to QT.
4. PQT must be capable of being operated interactively, as well as in programmed mode. It is important therefore that the same commands be used in both modes of operation.

QT is simple to operate because it does not require the user to think about the identity of the image being processed nor where the result will go. Consider a simple image processing function, such as negation (*neg*). In QT, the input image is implicitly taken to be the *current* image (see Chap. 21). The result is placed in the *current* image and the original (i.e., the contents of the current image just before *neg* was performed) is stored in the *alternate* image. Almost all QT functions behave in this way. Dyadic operators (e.g., *adi*, *sub*, *mxi*) require two inputs. Again, these are the current and alternate images. In neither case, is there any need to specify the source and destination images. Here is the equivalent operation to neg expressed in "raw" MATLAB format:

```
global current
global alternate
alternate = current;
current = imcomplement(current);
subplot(1,2,1)
imshow(current)
subplot(1,2,2)
imshow(alternate)
```

(For the sake of fairness, we should shorten the image names to minimal size.) It requires a lot of typing to perform even a simple task, such as negate (*neg* in QT) and is certainly not conducive to maintaining effective user interaction. In addition, the user has to keep a mental note of all the images that have been created. QT allows additional images to be created but normally discards those that will not be needed again.

23.1.5.4 Using Prolog+

Using PQT for interactive image processing is almost as easy as using QT. In response to each system prompt, the user types a simple query. The processed image is displayed almost immediately. The syntax is, of course, slightly different for PQT and QT; the latter sometimes requires a few more characters to be typed. As a result, the computational speed and effectiveness of the user interaction are hardly diminished. It is just as easy to write a new PQT predicate, as it is to define a MATLAB script to execute a sequence of QT functions.

In normal practice, when using PQT, it is best to group together any long sequences of image processing commands before beginning to program in conventional "Prolog mode". There is no point in carrying a burden of perhaps 20, or more, separate image processing operations when writing programs that involve backtracking and recursion. As far as possible, "wrap up" standard image processing sequences first. Thereafter, try, as far as possible, to write Prolog code from the top down, bearing in mind what image features can be detected, located and measured, easily. In many cases, morphology can be used to good effect to do this (see ➲ Chap. 19). It is a straightforward matter then to express any relationships that exist between them, image features by declarative programming.

We have already seen that the spatial relationships between the apex, T-joints and limb-ends of upper-case letter A are simple to define in terms of *left_of/2*, *above/2*, etc. Higher level spatial relationships have been defined (➲ *Fig. 23.8*). In addition, region properties can be expressed in PQT predicates, including *spotty/1*, (*spotty(X)* tests whether region/feature *X* is spotty*)*, *smooth/1*, *striped/1*, *darker/2 (darker(X,Y)* tests whether region *X* is darker than region *Y)*, *brighter/2*, etc. Do not be afraid to use very simple definitions of relationships and qualities like these. In general terms, do not be tempted to be very precise when programming in PQT. Such a blatant lack of precision presents some people with a fundamental difficulty. However, the maxim when programming in PQT is to accet that it is concerned with "sloppy programming". (The word *fuzzy* would be better but this invokes ideas of Fuzzy Sets, which is not intended.) This approach is justified in ➲ Chaps. 2 and ➲ 17.

23.2 Part 2: Using Prolog to Understand Natural Language

23.2.1 Prolog and Natural Language

It has long been the ambition of computer scientists to use natural language for programming. While the structure of a language, such as English, Welsh or German, is very complex, it is possible to represent a *small subset* using Prolog. For example, the sentences that might be needed to describe the movements of pieces on a chess board use both a restricted vocabulary and have a well-defined structure that can be represented using Prolog. Of course, a human being can always find ways to confuse a machine, by perversely using complex phraselogy and abstruse references. For the purposes of the present discussion, it is expected that human beings will behave reasonably when holding conversations with a machine.

23.2.1.1 Definite Clause Grammars

One popular approach to linguistic analysis relies upon *Definite Clause Grammars* (DCGs), which form an integral part of Prolog. DCGs closely resemble the familiar Backus-Naur Form (BNF), which is frequently used to define computer language syntax. A definite clause grammar consists of a set of *production rules* of the form

```
head –> body.                    % To recognise “head” recognise “body”.
body –> part1, ..., partn.       % Concatenation of part1, ..., partn.
```

Production rules may also contain the connective operator ‘;’ (sometimes ‘|’ is used instead), which allows elements to be ORed together. For example,

```
head –> test1 ; test2 ; test3 ; . . .. . . ; testn.
```

states that in order to recognise *head*, it is sufficient to recognise *any one* (or more) of the subsidiary tests: *test1*, *test2, test3,* . . .. . ., *testn.* An alternative is to use several separate rules. Thus:

```
head –> test1.
head –> test2.
head –> test3.
etc
```

has the same meaning as:

```
head –> test1 ; test2 ; test3.
```

or

```
head –> test1.
head –> test2 ; test3.
etc
```

The operator ‘,’ (comma) is used to signify that two or more tests must *all* be satisfied. Thus:

```
head –> test1,test2,test3.
```

states that, in order to satisfy *head*, all three of the subsidiary tests (*test1, test2, test3*) must be satisfied. Syntactically, production rules closely resemble Prolog rules. However, it should be understood that they are treated in a different way.

The body of a DCG is composed of terminal symbols and conditions, separated by commas or semi-colons. Here is a very simple DCG which describes traditional British personal names

```
name –> forename, surname.                          % Forenames & surname
forename –> forename3 ; forename 4.                 % Multiple forenames
forename3 –> forename1 ; forename3, forename1.      % Male names
forename4 –> forename2 ; forename4, forename2.      % Female names
% Items in square brackets [...] are terminal symbols, which Prolog does not try to analyse
forename1 –> [philip] ; [edward] ; [andrew] ; [jonathan] ; [godfrey].
forename2 –> [elizabeth] ; [elaine], [susanna] ; [louisa] ; [victoria] ; [catherine], [grace].
surname –> [smith] ; [higgins] ; [cook] ; [martin] ; [jones].          % Terminal symbols
```

Here are a few of the possible names that satisfy these grammar rules.

```
[philip,andrew,cook]
[elizabeth, susanna,martin]
```

[jonathan,philip,higgins]
[godfrey, jonathan, godfrey, philip, godfrey, edward, godfrey, andrew, godfrey, jones]

The first three are quite acceptable. However, the last one is silly and is permitted since we have chosen to use an over-simplified set of grammar rules.

23.2.1.2 Example: Moving Chess Pieces

The grammar rules listed below define a language for controlling a robot that moves pieces around a chess board. (They do not yet explain how "meaning" is extracted from the commands to operate a real robot.)

```
move –> order, man, [to], position.
move –> order, man, [from], position, [to], position.
order –> movement ; [please], movement.
movement –> [move] ; [shift] ; [translate] ; [transfer] ; [take].
man –> article, color, piece.
article –> [] ; [my] ; [your] ; [a] ; [the].
color –> [] ; [white] ; [black].
piece –> [pawn] ; [rook] ; [castle] ; [knight] ; [bishop] ; [queen] ; [king].
position –> [column], number, [row], number ; [row], number, [column], number.
position –> number, number.
number –> [1] ; [2] ; [3] ; [4] ; [5] ; [6] ; [7] ; [8].
number –> [one] ; [two] ; [three] ; [four] ; [five] ; [six] ; [seven] ; [eight].
```

The following sentences are accepted by this grammar:

[please, move, my, white, pawn, to, column, 5, row, 6]
[shift, a, black, pawn, to, row, 4,column, 6]
[please, move, the, white, queen, from, column, 3, row, 6, to, column, 5, row, 6]
[transfer, my, bishop, from, 5, 6, to, 7, 3]
[take, the, black, rook, to, 7, 3]
[please, transfer, my, knight, from, row, 3, column, 2, to, 6, 8]

23.2.1.3 Parsing

DCG rules are recognised by a parser, which is embodied in the Prolog predicate *phrase/3*. However, for our present purposes, the simpler form

parse(A,B) :- phrase(A,B,[]).

is preferred. The goal

parse(A,B)

tests to see whether the list B, which may contain both terminal symbols and variables, conforms to the grammar rules defined for A. Here is a simple example, showing how it is used in practice:

parse(move, [please, move, the, white, queen, from, column, 3, row, 6, to, column, 5, row, 6]).

Prolog will simply satisfy this goal. On the other hand, the following goal is not satisfied *parse(move, [please, do, not, move, the, white, queen, from, column, 3, row, 6, to, column, 5, row, 6]).*

An important feature of the parser is that it allows us to analyse sentences that are incompletely specified. (Notice that the variable Z is initially uninstantiated.) Consider the compound goal

parse(move, [take, the, Z, to, row, 3, column, 2]), write(Z), nl, fail.

This prints seven possible instantiations for Z:

pawn, rook, castle, knight, bishop, queen, king

This suggests a possible method for extracting "meaning" from a sentence:

(a) Use the parser to check that the sentence conforms to the given set of grammar rules.
(b) Use the unification process to search for specific symbols in certain places within the given sentence.

23.2.1.4 Another Example: Controlling a Set of Lamps

The following rules define a grammar for controlling a set of lamps. Comments indicate possible symbols that would be accepted by the parser. At this stage there is no attempt, to extract meaning or switch the lamps on/off.

```
% Simplify the problem by breaking it into simpler sub-problems.
```

Examples of each object type are given in the comments (i.e. following the % symbol)

```
light –> light1 ; light2 ; light3 ; light4 ; light5 ; light6 ; light7 ; light8.
light1 –>
        light_verb,                     % set
        type1,                          % every
        light_dev1,                     % lamp
        light_par1.                     % [to,level,5]

light2 –>
        light_verb,                     % set
        [all],                          % all
        light_dev2,                     % lamps
        light_par1.                     % half_on

light3 –>
        light_verb,                     % put
        light_dev1,                     % lamp
        numbers,                        % 5
        light_par2.                     % on

light4 –>
        light_verb,                     % [], empty string
        light_dev1,                     % lamp
        [number],                       % number, no option
        numbers,                        % 5
        light_par2.                     % half_on
```

```
light5 –>
        light_verb,                        % switch
        light_dev3,                        % front_light
        light_par2.                        % off

light6 –>
        light_verb,                        % switch
        light_dev1,                        % lamp
        numbers,                           % 3
        [to],                              % to, no option
        numbers.                           % 7

light7 –>
        light_verb,                        % put
        light_dev1,                        % lamp
        numbers,                           % 1
        [to],                              % to, no option
        lamp_intensity,   % [brightness, levl]
        numbers.                           % 8

light8 –>
        light_verb,                        % switch
        light_dev1,                        % lamp
        [number],                          % number, no option
        numbers,                           % 3
        [to],                              % to
        lamp_intensity,                    % level
        numbers.                           % 5

light_verb –> [] ; [set] ; [put] ; [switch].

type1 –> [each] ; [every].

light_dev1 –> [light] ; [lamp].
light_dev2 –> [lights] ; [lamps].
light_dev3 –> [laser] ; [projector] ; [back_light] ; [front_light].

light_par1 –> [on] ; [off] ; [half_on] ; [to], [level], numbers.
light_par2 –> [on] ; [off] ; [half_on].

lamp_intensity –> [] ; [level] ; [brightness] ; [brightness, level] ; [intensity] ; [intensity,
                  level].
```

➜ *Table 23.1* Lists a sample of the sentences that are accepted by this set of grammar rules.

Table 23.1
Some of the sentences that are accepted by the DCG rules defined in the text

Clause	Accepted string
light1	[switch, each, lamp, off]
	[switch, every, light, on]
	[set, each, lamp, off]
	[put, each, lamp, half_on]
	[every, lamp, off]
	[each, lamp, half_on]
light2	[put, all, lamps, off]
	[set, all, lights, on
	[all, lamps, half_on]
light3	[put,lamp, 6, off]
	[switch, light, 4, half_on]
light4	[put, lamp, number, 6, off]
	[light, number, 8, on]
light5	[switch,laser,off]
	[put, back_light, on]
	[projector, off]
light6	[set, lamp, 6, to, 7]
	[light, 5, to, 9]
light7	[put, lamp,6, to, level, 7]
	[light, 5, to, brightness,4]
light8	[put, lamp, number, 6, to, intensity, level, 7]
	[set, light, number, 6, to, level, 4]

23.2.1.5 Extracting Meaning

First Method: Discarding Non-relevant Terminal Symbols
Consider the goal sequence

```
X = [put, lamp, number, 6, to, intensity, level, 7],
parse(light8,X),                    % We are parsing according to "light8" rule not "light"
discard_non_numbers(X,[Y,Z]),  % Y is the lamp identifier. Z is the lamp brightness.
switch_lamp(X,Y)                   % Switch lamp X to state Y
```

This instantiates Y to 6 and Z to 7, so lamp 6 is switched to brightness level 7. Notice that the parser is being used simply to check that it is reasonable to apply *discard_non_numbers*/2, which is unintelligent and therefore could not be used safely on its own. Of course, a similar approach is adopted for *light1, light2, ..., light8.*

Second Method: Pattern Matching

Consider the predicate

```
meaning(light7,X,[A,B]) :- parse(light7,X), X =[_,_,A,_,_,B].
```

This tries to match X to a list containing six elements, of which only the third and sixth are retained. Matching is only allowed if X first satisfies DCG rule *light7*. Again, the parser is being used to check that it is reasonable to apply the pattern matching goal, (*X =[_,_,A,_,_,B]*).

However, the rule for *light_verb* permits both *empty* and *non-empty* strings, which causes some slight complications. (The list X can vary in length.) To accommodate all of the cases where rule *light7* holds, we require *four* separate conditions:-

```
meaning(P,X,Y) :-
        parse(light7,P),
        (P = [_,_,X,_,_,Y] ; P = [_,X,_,_,Y]),        % Semi-colon (;) denotes OR
        number(X).                                     % Check that X is a number

meaning(P,X,Y) :-
        parse(light7,P),
        (P = [_,_,X,_,_,_,Y] ; P = [_,X,_,_,_,Y]).     % Semi-colon (;) denotes OR
```

In this way, Prolog can "understand" the lighting control language. (➔ *Table 23.2*) The goal *meaning(A,B,C)* tries to parse the given sentence A. If the parsing succeeds, then A is analysed, so that the lamp(s) (B) and brightness level (C) can be found.

```
% Understanding sentences which are accepted by "light1"
meaning(P,all,Z) :-
        parse(light1,P),
        (P = [_,_,_,Z] ; P = [_,_,Z]).
% Understanding sentences which are accepted by "light2"
meaning(P,all,Z) :-
        parse(light2,P),
        (P = [_,_,_,Z] ; P = [_,_,Z]).
% Understanding sentences which are accepted by "light3"
meaning(P,X,Y) :-
        parse(light3,P),
        (P = [_,_,X,Y] ; P = [_,X,Y]).
```

Table 23.2
Sample queries for *meaning(A,B,C)*

A	B	C
[put,all,lamps,off]	all	off
[switch,each,lamp,half_on]	all	half_on
[set,laser,on]	laser	on
[lamp,3,to,level,2]	3	2
[switch,lamp,number,6,to,intensity,level, 5]	6	5
[switch,lamp,number,6,off]	6	off

```
% Understanding sentences which are accepted by "light4"
meaning(P,X,Y) :-
        parse(light4,P),
        (P = [_,_,_,X,Y] ; P = [_,_,X,Y]).
% Understanding sentences which are accepted by "light5"
meaning(P,X,Y) :-
        parse(light5,P),
        (P = [_,X,Y] ; P = [X,Y]).
% Understanding sentences which are accepted by "light6"
meaning(P,X,Y) :-
        parse(light6,P),
        (P = [_,_,X,_,Y] ; P = [_,X,_,Y]).
% Understanding sentences which are accepted by "light7"
meaning(P,X,Y) :-
        parse(light7,P),
        (P = [_,_,X,_,_,Y] ; P = [_,X,_,_,Y]),
        number(X).          % Resolve ambiguity with next clause
meaning(P,X,Y) :-
        parse(light7,P),
        (P = [_,_,X,_,_,_,Y] ; P = [_,X,_,_,_,Y]).
% Understanding sentences which are accepted by "light8"
meaning(P,X,Y) :-
        parse(light8,P),
        (P = [_,_,_,X,_,_,Y] ; P = [_,_,X,_,_,Y]),
        number(X).          % Resolve ambiguity with next clause
meaning(P,X,Y) :-
        parse(light8,P),
        (P = [_,_,_,X,_,_,_,Y] ; P = [_,_,X,_,_,_,Y]).
% Catch-all rule for use when the sentence is not recognised
meaning(_,unknown,unknown) :-
        message_to_user(['Sentence was not recognised']).
```

Third Method: Including Variables and Prolog Goals Within DCG Rules

Consider the following revised DCG rule:

```
light6 –>
        light_verb,                 % Unchanged
        light_dev1,                 % Unchanged
        Y,                          % Variable - lamp identifier
        {number(Y)},                % Prolog goal: check that Y is a number
        [to],                       % Unchanged
        Z,                          % Variable lamp brightness
        {number(Z)},                % Prolog goal: check that Z is a number
        {control_lights6(,[Y,Z])}.  % Prolog goal must be satisfied before parsing
                                      is accepted
```

This grammar rule includes three Prolog sub-goals, which must all be satisfied before the parser accepts the input list as valid. An example will illustrate this:

parse(light6,[switch, lamp, 3, to 7]).

While the parser is trying to prove that this is true, the following tests are carried out:

1. *switch* is verified as being a *light_verb.*
2. *lamp* is verified as being a *light_dev1.*
3. *Y* is instantiated to 3.
4. *Y* is checked to be a number (embedded Prolog goal).
5. *to* is found in the input list.
6. Z is instantiated to 7.
7. Z is checked to be a number (embedded Prolog goal).
8. *control_lights6(,[Y,Z])* switches lamp Y to brightness level Z (Prolog code).

Choosing Which Method to Use

A parser is able to check whether a vaild sentence has been presented. This can be envisaged as acting like a filter, eliminating sentences that are non-sensicle to the system. A machine can respond by indicating that it does not understand, leaving it to the user to think again about what he is saying. Shifting the responsibility for achieiving an effective dialogue is acceptable within limits; people learn quicker than machines and will tolerate some restrictions, if the overall benefits are large enough. This means that naive methods for extracting meaning, such as Method 1, are safer than we might imagine. Simply deleting words that have no obvious relevance to the discourse would be dangerous without such a filter. Individual grammar rules are usually very selective. That is, safe! DCGs can be made more general in a variety of ways. Each time we add a new rule, or generalise a rule, perhaps by including variables, the system becomes a bit less secure, simply because we allow more sentences to pass through the filter. However, most DCGs are safe because they are still highly selective compared to natural unconstrained human speech. As a result, Method 1 is well worth exploring first, because it is simple to program. Method 2 is conceptually straightforward but rather cumbersome, while the third method is concenptually the most elegant. Once mastered, Method 3 is probably the most attractive because actions, such as switching lights ON/OFF, are directly embedded in the DCG rules.

23.2.1.6 Remarks

The use of DCGs for understanding a limited sub-set of natural language has considerable potential that has, as yet, not been exploited to its full potential for vision systems. As stated earlier, it is assumed that people using such a system as the one described will act reasonably and will not deliberately look for ways to confuse the program. With this in mind, it is feasible now to build a system of moderate cost that accepts input from a speech recognition device and can perform tasks such as controlling

- Lights, within a fixed array
- Simple manipulator, including
    - (X,Y,θ)-table
    - Pick-and-place arm

  - Conveyor stop/start
  - Accept/reject mechanism
  - Filter wheel
- Pan, tilt, zoom and focus of a camera
- High-level image processing operations
- Navigation of help files, including the catalogue of lighting-viewing methods [10]
- Administration and analysis of the Machine Vision Questionnaire (MVQ)
- System initialisation, configuration and testing
- Recall of performance statistics

When designing such a speech-controlled natural language system, it is important to remember that homophones can cause confusion. For example: *rows* and *rose* sound the same and therefore must be treated as the same entity when defining a set of grammar rules. While the attractions of hands-free speech-controlled operation of industrial vision systems are obvious, there are great difficulties when trying to use DCGs to describe complex and highly variable images. Matters are made somewhat easier in the context of Automated Visual Inspection, where we know quite precisely what kind of objects and faults to expect. Nevertheless, with our present capabilities, it is impractical to employ low-level programming of vision systems (e.g., specifying individual QT commands).

23.3 Part 3: Implementation of Prolog+

23.3.1 Implementation of PQT

Using Prolog to control an image processing sub-system was conceived by David H. Mott in the mid-1980s [11]. (Also see [8, 12].) He linked Prolog and an image processing package, similar to QT, running on the same computer. Since then, several other approaches have been followed (➲ *Table 23.3*). PQT is one of the most recent implementations of Prolog+ and was constructed by interconnecting SWI-Prolog [1] and the QT image processing software described in ➲ Chap. 21. Communication between them is achieved using “glue” programs written in Java [13]. This allows Prolog and QT to run on the same or different computers, perhaps thousands of kilometres apart. While a Prolog program is able to control several QT “slave” modules, we shall concentrate on implementing Prolog+ using just one image processing engine. This does not limit the number of the cameras that can be used, nor their location. Another interface between MATLAB and SWI-Prolog is described in [14], although this was not designed specifically for image processing.

23.3.1.1 Structure of a PQT System

➲ *Figure 23.9* shows the overall structure of a system implementing PQT and which employs the following software components

(a) QT, implemented using MATLAB’s *Image Processing Tool-box* [15].
(b) *SWI-Prolog* [1]. This is available free of charge from the University of Amsterdam.
(c) Java interfacing (“glue”) software between QT and SWI-Prolog (boxes labelled J1, . . ., J4 in ➲ *Fig. 23.9*).

Table 23.3
Methods for implementing Prolog+

Prolog	Image processing	Interface	Remarks
Computer/ single-card processor	External hardware	Serial line (e.g., RS232)	Easy to build. Despite the low data rate across the Prolog-IP interface, this is surprisingly effective.
	Separate computer		
	Smart camera		Low cost. Simple to implement. IP command repertoire is fixed by the camera and may be somewhat limited compared to QT. Adequate for some of the less demanding shop-floor applications.
	External hardware (e.g., pipe-line or array processor), or plug-in card	Parallel bus	Fast enough for some shop-floor applications.
Same computer		Tight integration; direct connection between IP and Prolog programs	Can be difficult to maintain, as Prolog, the image processor and the operating system all evolve separately.
		Loose integration via operating system	Easy to build and maintain, as a standard interface is used.
Computer	Separate computer	Ethernet/Internet	Easy to build and maintain as a standard interface is used. Possible to implement multi-camera & multi-processor systems. Unpredictable delays are possible on public networks.

It is not necessary or appropriate to describe the minutiae of the Prolog-QT interface. Let it suffice to say that it involves several data-type conversions, involving MATLAB arrays and strings, Prolog strings (different delimiters), terms, atoms, lists and numbers.

The following general points should be noted:

(i) Prolog and QT can be run on the same, or different, computers.

(ii) Images from any web-enabled camera, or image file with a known URL, can be acquired, processed and analysed by the PQT system.

(iii) A range of electro-mechanical devices can be operated, via a suitable device-control hardware unit. One supervisor module that the author has used is web friendly and responds to HTTP commands. It can operate up to 16 slave boards containing power switches for such devices as stepper motors, DC motors, LEDs, solenoids, etc. (Also see Appendix J.) Since the supervisor module is connected to the network, these devices could be located anywhere in the world. Effective communication can be achieved using standard wired, or wireless, Internet paths and protocols.

(iv) Once the initialisation process has been completed, both SWI-Prolog and QT run continuously; there are no delays associated with re-starting either of them. This also means that we do not have to take any special measures to carry data from one query/command

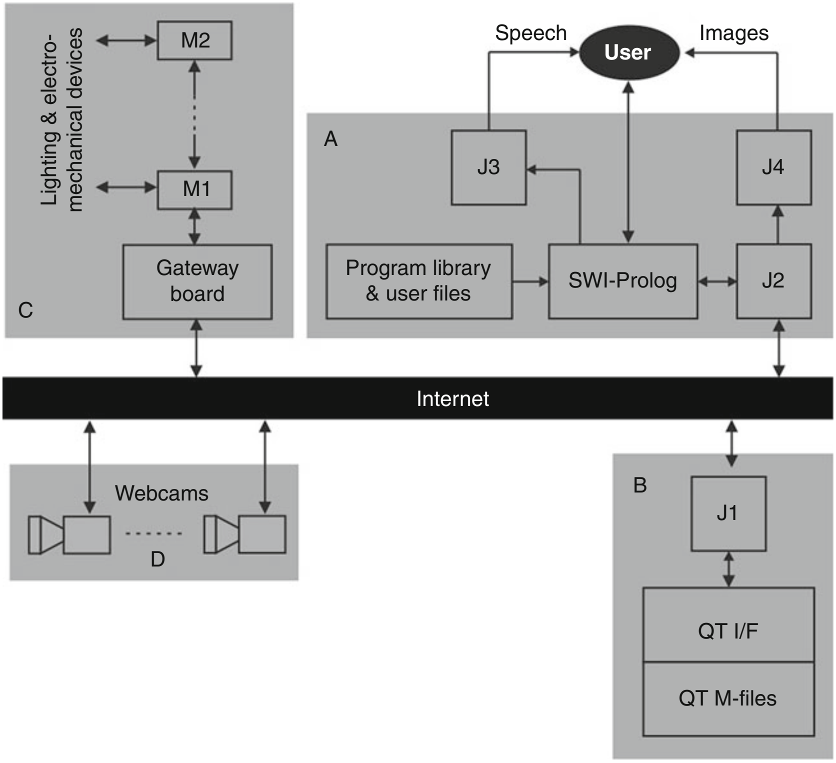

Fig. 23.9
Implementing PQT using Java "glue" software. Box C contains hardware control devices. J1 – J4 are small Java programs

over to the next. (Keeping both QT and Prolog "alive", particularly during error conditions, was one of the main factors that influenced the design of the "glue" software.)

(v) The user interface has been enhanced by using a speech synthesiser controlled from Prolog. Since Prolog can generate natural language sentences using DCGs, it is possible to construct quite sophisticated user feed-back sequences. An earlier implementation of Prolog+ also used speech recognition hardware to provide hands-free user interaction [8]. This showed quite very clearly that speech control is potentially very useful - and is great fun!

(vi) An infix Prolog operator (∼) has been programmed to perform repeated operations. This allows iterated processes, such as image filtering and morphology, to be performed very easily. (This operator is listed later.)

(vii) New functions can be written for PQT in either of two ways:
- Adding new Prolog code
- Adding MATLAB M-functions

23.3.1.2 Processing Prolog+ Goals

We shall now explain how Prolog goals incorporating image processing operations are processed

1. Prolog generates a command (C1) for QT. (The process of generating C1 from the original Prolog specified interactively by the user, or from a goal in a QT program, will be explained later.) C1 is expressed in the form of a Prolog string (S1) and sent via Java interface programs (J2 and J1 in ➲ *Fig. 23.7*) to MATLAB.
2. The command string S1 is received by a MATLAB interface M-function (*QT I/F*), which is responsible for all communication between QT and Prolog. Assuming that string S1 is correctly formatted, the appropriate command is executed by MATLAB and the results is passed back to *QT I/F.*
3. *QT I/F* standardises the data format for values that are to be returned to Prolog. First, a (MATLAB) array of size 7 × 1 elements is created, irrespective of how many values the QT M-function executed by S1 actually computes. Then, the array is converted to a string, S2. ➲ *Table 23.3* shows some examples which illustrate this. (This 7-element array allows for six values or fewer to be returned from QT, plus a variable indicating any error conditions that have occurred. Error 0 (zero) indicates no error. No current QT operator returns more than six values, although there is no fundamental reason why more values could not be calculated.)
4. String S2 is then despatched, via Java programs J1 and J2 to Prolog.
5. Program J2 reformats S2, to form a Prolog string (S3).
6. Prolog converts string S3 into a Prolog list, L1.
7. Prolog then analyses L1, to extract the values calculated by QT and ignoring the undefined ("padding") variables. Several layers of Prolog code are required to do this. For the convenience of the user, Prolog-style operators have been implemented and are explained below.

23.3.1.3 Prolog Programs Implementing Prolog+

Step 6 in the sequence described above results in a 7-element Prolog list. The head of this list indicates how many of the numbers in its tail are valid (i.e., how many outputs the QT command S1 actually generated.) As we indicated earlier, analysing this list is made easier by using Prolog-style operators.

The <- Operator represents the first step towards implementing Prolog+, although it does not provide a complete solution.

Syntax

Prefix operator	<- *command*
Infix operator	*[N,V1,V2,V3,V4,V5,V6]* <- *command*

Function Performs the QT function *command*, if it exists

Returned values N indicates how many of *V1,V2,V3,V4,V5,V6* are valid
Vi (i = 1,...,N) are the values calculated by the QT function *command*
If N is negative an error condition has been found. MATLAB does not quit.

Example 1

Goal	*[N,V1,V2,V3,V4,V5,V6]* <- *cgr*
Results	N = *2;* V1 and V2 are instantiated to the (X,Y)-coordinates of the centroid

Example 2

Goal *[N,V1,V2,V3,V4,V5,V6] <- eul(4)*

Results N = 1*;* V1is instantiated to the 4-neighbour Euler number

Example 3

Goal *<- neg*

Results [N,V1,V2,V3,V4,V5,V6] = [0,0,0,0,0,0,0]

Example 4

Goal *<- thr(123,234)*

Results [N,V1,V2,V3,V4,V5,V6] = [0,0,0,0,0,0,0]

Example 5

Goal [N|_] <- qwerty

Results N = −1 (Error: QT command *qwerty* does not exist)

The # Operator is easier to use than <- and takes us closer to Prolog+ see (*Table 23.4*). # is a prefix operator and conveniently masks some quite sophisticated processing. To understand how # works, consider the Prolog goal

# abc(1,2,3,X,Y,Z).

First, the variables are removed, leaving the Prolog term:

abc(1,2,3)

This is then converted into the following Prolog goal, which is then resolved in the manner described above:

[N,V1,V2,V3,V4,V5,V6] <- abc(1,2,3).

Table 23.4

Commands and data format used by MATLAB. The right-hand column shows the output *string* generated by the QT I/F program. This is then converted to a Prolog list that looks the same when printed. (Valid results is this list are shown in bold-face type; undefined padding variables are indicated by italics.)

Command (C1)	Operation	No. of output values calculated	String S2
neg	Negate	0	[0,0,0,0,0,0,0]
thr(123,234)	Threshold	0	[0,0,0,0,0,0,0]
avg	Average intensity	1	[1,**123**,0,0,0,0,0]
cgr	Centroid	2	[2,**111,222**,*0,0,0,0*]
mar	Min. area rectangle	4	[4,**111,222,333,444**,*0,0*]
eul(8)	Euler number	1	[1,**4**,0,0,0,0,0]
nonsense	Not a QT command	Error!	[−1,0,0,0,0,0,0]

Let us assume that the QT command *abc(1,2,3)* has been completed satisfactorily and has returned three values, instantiating the variables in this list as follows:

N = 3
V1 = 444
V2 = 555
V3 = 666

The "padding" variables V4, V5 and V6 remain uninstantiated. The final action of the # operator is to match these variables with those specified in the original goal (C1):

X = V1
Y = V2
Z = V3

Hence, the goal succeeds with the following instantiations:

```
# abc(1,2,3,444,555,666).
```

There are three other cases to consider:

1. The command *abc(1,2,3)* returns fewer than three values. In this case, some of the variables specified in the original goal remain uninstantiated. For example, if N = 1 (i.e., V2–V6 have undefined values), only X is instantiated. The goal then succeeds as
   ```
   # abc(1,2,3,123,_,_).
   ```
   Notice that the last two arguments remain uninstantiated.
2. The command *abc(1,2,3)* returns more than three values. In this case, only the results V1, V2 and V3 are retained; V4, V5 and V6 are discarded. The goal succeeds as before
   ```
   # abc(1,2,3,444,555,666).
   ```
3. If the command *abc(1,2,3)* generates a QT error, the Prolog goal C1 fails.

Completing the implementation of Prolog+ While the # operator takes us closer to implementing Prolog+, there is a still a small gap remaining. To avoid the need to precede each QT command by the # symbol, it is expedient to define a library of simple rules like those following, for each QT image processing function:

```
neg :- # neg.               % Predicate neg/0 can now be used in lieu of #neg
thr(A,B) :- # thr(A,B).     % Predicate thr/2 can now be used in lieu of thr(A,B)
thr(A) :- # thr(A,255).     % Predicate thr/1 can now be used in lieu of #thr(A)
thr :- # thr(128,255).      % Predicate thr/0. Default values can be redefined in Prolog
cgr(X,Y) :- # cgr(X,Y).     % Predicate cgr/2 can now be used in lieu of # cgr(X,Y)
cgr :- # cgr(A,Y), write(X), nl, write(Y),nl.
etc.
```

Writing rules like this for all QT commands is straightforward but rather tedious to do manually. To automate this task, the author devised a small Prolog program which builds a library of rules based on the total number of arguments (i.e., inputs plus outputs), needed for each QT function. (This "input" data was obtained from QT's *hlp*, HELP, command.) Here is a small sample of the database generated automatically by the program:

```
.....
dor(V1,V2,V3,V4) :- # dor(V1,V2,V3,V4).
```

Table 23.5
Command formats in QT, with the <- and # operators and in PQT

Abstract: Human beings are hard-wired to discover and categorize patterns as a way of understanding the world. Humans can easily read poorly handwritten text, parse and understand human speech, recognize faces in a crowd, classify people as old or young, etc. However, it is difficult for a machine to solve these kinds of perceptual problems. In this chapter, we explore some of the concepts and techniques of machine-based pattern recognition, including statistical-based approaches and neural network-based approaches. We illustrate the concepts with case studies taken from image and video processing.

24.1 Introduction

24.1.1 What Is Pattern Recognition?

Human beings are hard-wired to discover and categorize patterns as a way of understanding the world. We find patterns everywhere: in the structures of nature [2], language and music [7, 8], human behavior [9] and human history [3]. Human beings are prone to seeing patterns even when none exist! [12].

In terms of processing perceptual data, human beings are amazingly adept. They can easily read poorly handwritten text, parse and understand human speech, recognize faces in a crowd, classify people as old or young, etc. However, it is difficult for a machine to solve these kinds of perceptual problems. One difficulty stems from having to process the enormous amount of data inherent in these perceptual problems. With the advent of modern computers, significant advances have been made for machine understanding and processing of patterns.

Automated pattern recognition has been successfully applied in a variety of fields, including engineering, science, medicine, and business. Applications include character and string recognition, speech understanding, image understanding, mobile robots, and security systems. Successful commercial applications include address recognition in mail, isolated word recognition, recognition of bank checks, automated processing of tax forms, finger print matching, detection of abnormalities in manufactured parts, face recognition, signature verification, speaker verification, and detection of forgery in financial documents.

Pattern recognition involves mapping input perceptual data into some other (often simpler) form so that meaningful action can be taken. A schematic diagram of a pattern recognition system is shown in ➲ *Fig. 24.1*. There are four stages: preprocessing, feature extraction, recognition, and decision. In the preprocessing stage, the raw data is put in a form suitable for further processing. For example, if the raw data consists of MPEG video, a preprocessing step might be to uncompress the video. In an image processing application, typical preprocessing involves cropping the area of interest, size normalization, and performing color correction, such as histogram equalization.

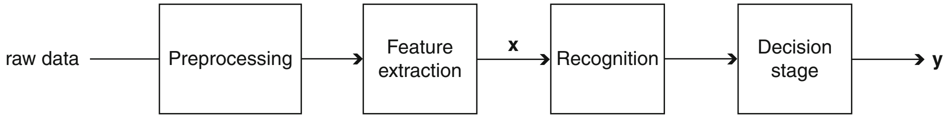

Fig. 24.1
Main computational stages of a pattern recognition system

The second stage involves extracting useful features from the input perceptual data. For our purposes, a feature vector **x** is simply a set of numbers which accurately represents the input perceptual data. A main goal here is to come up with an efficient representation; that is, reduce the dimensionality of the input as much as possible, but not to the point where it adversely affects recognition and classification performance. As an example, speech is typically processed at about 10 kHz. Thus a 1 min segment of speech will have 600,000 samples. However, through an in-depth understanding of the process of speech generation, it is possible to extract ten features for each 250 ms segment of sampled speech, giving a total of only 2,400 features. Similarly, a word such as “*hundred*” written on a piece of paper has a size of about 2″ × 0.25″. When scanned at 200 dpi and 8 bits/pixel, the resulting image is 400 × 50 pixels. These 20,000 pixels can be reduced to features that are essentially eight 64-dimensional vectors.

An illustration of feature extraction for a character recognition problem is shown in *Fig. 24.2*. Here, the feature of interest is the contour of the character. A quantitative measure of the contour can be obtained by examining the behavior of local pixel changes in four directions of interest: 0°, 45°, 90°, 135°, as shown in *Fig. 24.2a*. Starting with the binary image shown in *Fig. 24.2b*, we first extract the edges, as shown in *Fig. 24.2c*. A feature vector can be constructed consisting of the histograms of the chain codes of the contour elements. The rectangular frame enclosing character contours is divided into 4 × 4 rectangular regions. In each region, a local histogram of the chain codes is calculated. The feature vector is composed of these local histograms. Thus the feature vector has 64 components when all the 16 regions are included. *Figure 24.2* illustrates the procedure. Thus if we consider written digit recognition, we will have ten such patterns for each digit from 0 to 9.

The third stage in the pattern recognition system is the actual recognition or classification algorithm employed. Here, the task is to partition the feature space (that is, the set of all possible feature vectors) into a set of disjoint regions, as shown in *Fig. 24.3*. It is hoped that feature vectors from the same class are as close together as possible, while feature vectors from different classes are as distinct as possible. *Figure 24.3a* shows an example where a simple linear separation is possible between the two classes. In *Fig. 24.3b*, perfect separation is not possible; however, it is desired that the separating surface be positioned to minimize the resulting misclassification. The patterns in *Fig. 24.3c* require something more sophisticated than a linear separating surface; for example, a quadratic surface. In a multi-class problem shown in *Fig. 24.3d*, sometimes it is possible to achieve a piecewise linear separation between classes.

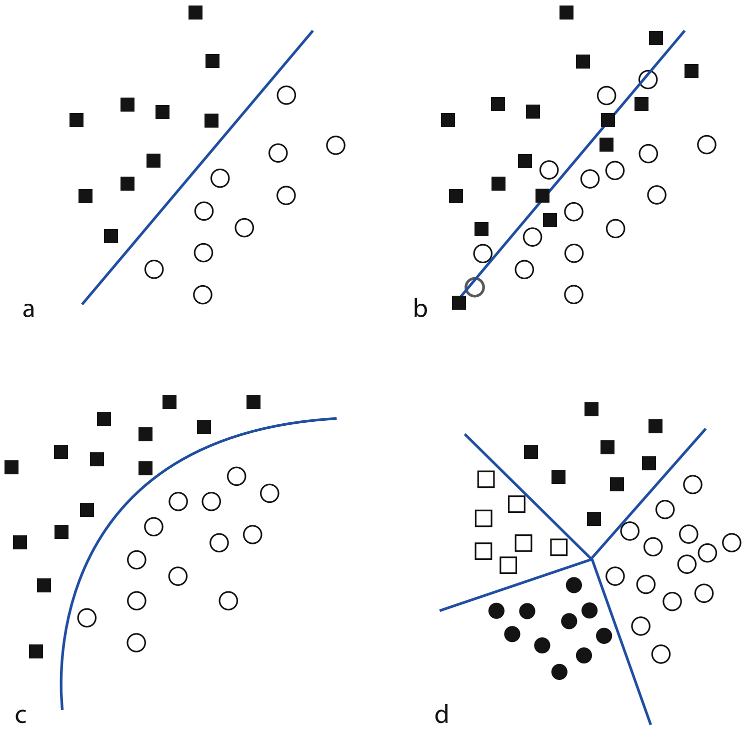

Fig. 24.3
Separation of patterns in feature space. (a) Good linear separation. (b) Linear separation, but statistical variation. (c) Quadratic separation. (d) Multiclass problem with piecewise linear separating regions

The primary objective in any pattern recognition application is the assignment of a specific class (from a finite list of known classes) to data acquired from a specific application. It is also highly desirable to provide a *confidence* value to this assignment. Thus in digit recognition, each input pattern has to be assigned one of ten classes with associated confidence value. In some cases, the test character may not be a digit. In this case, one expects the associated confidence to be very low and the input to be rejected.

In the decision stage, one examines the confidence values of all classes and makes a determination as to what action to take. For example, if the confidence is high enough, the pattern might be recognized and assigned to the best matching class. A different objective arises when it is required to determine whether a given pattern belongs to a specific class or not. Such applications are termed *verification tasks*.

For any given pattern recognition application, the system designer has to address the following questions:

- What are the stored features and how are they derived?
- What is the process of comparison?
- How does one determine the confidence value associated with a specific class?
- What does a confidence value really mean? In most pattern recognition applications, one utilizes a distance metric that generates a numeric value whose magnitude is

a measure of how similar the test pattern features are compared to the reference pattern features. It is often a challenge to convert these numbers to a confidence value in the range 0–100. Scale normalization is frequently required when combining classifiers. As an example one could look at results generated by a statistical classifier using one set of features and combining this with results generated by a neural network using a different set of features. Such issues are often dealt with in an ad hoc manner depending on specific applications.

In this chapter, these questions will be further discussed and several strategies presented to deal with a large variety of applications.

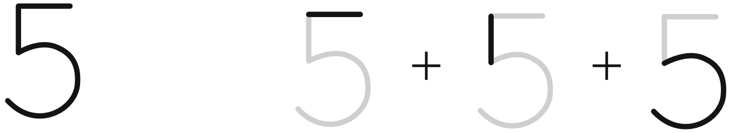
24.1.2 Pattern Recognition Strategies

Pattern recognition strategies can be classified into two broad categories: *statistical* or *structural*. Statistical methods generally require quantitative features extracted from perceptual data, while structural methods rely on primitives (such as edges in an image) and the inherent relationship among the primitives. Primitives are often symbolic (such as horizontal line) and do not have a numerical value. This is illustrated for the character recognition problem shown in ➜ *Fig. 24.4*. Structural recognition uses a grammar that describes the relationship among the primitives. Statistical recognition, on the other hand, utilizes statistical parameters like mean and variance of features to characterize a given class.

In certain applications, it is possible to use both quantitative (statistical) and structural techniques to improve the accuracy of recognition. This hybrid approach has been used very effectively to achieve high accuracies in recognition of handwritten characters [1]. In subsequent sections, only statistical methods will be discussed. Illustrative examples from character recognition and machine vision will be presented to highlight specific strategies. Typical recognition problems involving machine vision are shown in ➜ *Fig. 24.5*. In ➜ *Fig. 24.5a*, the application is the recognition of the stamped text on a gas bottle. Here it is required to design a classification system that can read all stamped text, irrespective of their orientation. In ➜ *Fig. 24.5b*, the problem is verification of the texture of rattan weaving and the detection of any anomalies [22, 23].

24.2 Statistical Methods

Statistical pattern recognition is typically grounded on Bayesian decision theory. In this approach, it is assumed that the underlying probabilistic structure of the features associated with the pattern is known or can be computed. The Bayesian approach is best illustrated with



■ **Fig. 24.4**
Structural features for the character 5, consisting of horizontal line, vertical line, and semicircle

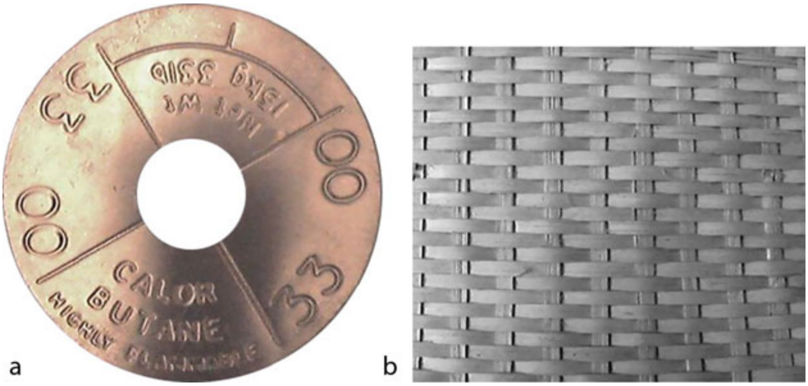


Fig. 24.5
(a) Recognition of stamped text on a gas bottle. (b) Verification of rattan texture

the following example. Suppose we have only two classes, denoted ω_1 andω_2. Here, for a given input feature vector **x**, the task is to decide if **x** belongs to class ω_1 or class ω_2.

Let $P(\omega_1)$ and $P(\omega_2)$ be the prior probabilities of ω_1 and ω_2. If only this information is available, then one assigns **x** to ω_1 if $P(\omega_1) > P(\omega_2)$. On the other hand, if $P(\omega_2) > P(\omega_1)$, then **x** is assigned to ω_2. In the case that $P(\omega_2) = P(\omega_1) = 0.5$, either class can be chosen. Note that here, the classifier always outputs the same class!

Now, suppose we have additional probabilistic information about the classes: the *conditional probability densities* $P(\mathbf{x}|\omega_1)$ and $P(\mathbf{x}|\omega_2)$. Baye's Theorem allows us to write the following expressions:

$$P(\omega_1|\mathbf{x}) = \frac{P(\mathbf{x}|\omega_1)P(\omega_1)}{P(\mathbf{x})} \tag{24.1}$$

$$P(\omega_2|\mathbf{x}) = \frac{P(\mathbf{x}|\omega_2)P(\omega_2)}{P(\mathbf{x})}$$

where

$$P(\mathbf{x}) = \sum_{i=1}^{2} P(\mathbf{x}|\omega_i)P(\omega_i)$$

Hence, the Bayesian decision rule takes the following form: Given a test pattern **x**, assign the pattern as follows:

$$\text{class}(\mathbf{x}) = \begin{cases} \omega_1 \text{ if } P(\omega_1|\mathbf{x}) > P(\omega_2|\mathbf{x}) \\ \omega_2 \text{ if } P(\omega_2|\mathbf{x}) > P(\omega_1|\mathbf{x}) \end{cases} \tag{24.2}$$

It is easily seen that $P(\omega_1|\mathbf{x}) > P(\omega_2|\mathbf{x})$ if

$$\frac{P(\mathbf{x}|\omega_1)P(\omega_1)}{P(\mathbf{x})} > \frac{P(\mathbf{x}|\omega_2)P(\omega_2)}{P(\mathbf{x})}$$

Since the denominator is the same on both sides of the inequality, the decision strategy is simply

$$\text{class}(\mathbf{x}) = \begin{cases} \omega_1 \text{ if } P(\mathbf{x}|\omega_1)P(\omega_1) > P(\mathbf{x}|\omega_2)P(\omega_2) \\ \omega_2 \text{ if } P(\mathbf{x}|\omega_2)P(\omega_2) > P(\mathbf{x}|\omega_1)P(\omega_1) \end{cases} \tag{24.3}$$

In the equally likely case $P(\omega_1) = P(\omega_2)$, we get a simpler decision strategy:

$$\text{class}(\mathbf{x}) = \begin{cases} \omega_1 \text{ if } P(\mathbf{x}|\omega_1) > P(\mathbf{x}|\omega_2) \\ \omega_2 \text{ if } P(\mathbf{x}|\omega_2) > P(\mathbf{x}|\omega_1) \end{cases} \tag{24.4}$$

If accurate estimates of $P(\mathbf{x}|\omega_i)$ can be derived and prior probabilities $P(\omega_1)$ are known, one has an efficient strategy for classifying test pattern **x** as belonging to class ω_1 or ω_2 using (➲ 24.3) or (➲ 24.4). It is straightforward to extend this strategy to recognizing patterns that may come from more than two classes. Assuming that there are p distinct classes ω_i, $i = 1, 2, \ldots, p$ then one assigns a test pattern **x** to ω_k, if

$$P(\mathbf{x}|\omega_k) > P(\mathbf{x}|\omega_i), \quad i = 1, 2, \ldots, p \quad \text{and} \quad i \neq k \tag{24.5}$$

In summary, Bayesian decision theory uses the conditional densities $P(\mathbf{x}|\omega_i)$ as well as the prior probabilities$P(\omega_i)$. This is also one of the challenges of Bayesian decision theory, as in many practical applications, the conditional densities are not readily available. Another factor affecting the Bayesian approach is the nature of the feature vector **x**. **x** could be a scalar in simple applications, or a vector in more complex applications. Also **x** could be continuous or discrete depending on specific recognition applications. A common density function that lends itself to analytic approaches is the normal (Gaussian) density function. The *multivariate normal density* in n dimensions is written as

$$P(\mathbf{x}) = \frac{1}{(2\pi)^{n/2}|\Sigma|^{1/2}} \exp\left[-\frac{(\mathbf{x}-\mu)^T\Sigma^{-1}(\mathbf{x}-\mu)}{2}\right] \tag{24.6}$$

Here, Σ is the covariance matrix of the feature vector **x, $\boldsymbol{\mu}$** is the mean vector and n is the dimension of **x**.

The unique feature of the Gaussian density is due to its dependence on just two parameters: $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. All relevant measures including higher order moments can be derived in terms of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. In the context of pattern recognition, the density function is evaluated over each class ω_k $k = 1, 2, \ldots, p$. Thus we define

$$p(\mathbf{x}|\omega_k) = \frac{1}{(2\pi)^{n/2}|\Sigma_k|^{1/2}} \exp\left[-\frac{(\mathbf{x}-\mu_k)^T\Sigma_k^{-1}(\mathbf{x}-\mu_k)}{2}\right] \tag{24.7}$$

Here μ_k and Σ_k are the mean vector and covariance matrix for class ω_k. Assuming that the density function of the feature vectors are Gaussian, pattern class assignment described in (➲ 24.5) can be restated using a discriminant function $g_i(\mathbf{x})$. Thus one assigns a test pattern **x** to ω_k when

$$g_k(\mathbf{x}) > g_i(\mathbf{x}), \quad i = 1, 2, \ldots, p \text{ and } i \neq k \tag{24.8}$$

In the case where **x** is described by a Gaussian density function, a suitable form for $g_k(\mathbf{x})$ is the logarithm of the density function:

$$g_k(\mathbf{x}) = -\frac{1}{2}(\mathbf{x}-\mu_k)^T\Sigma_k^{-1}(\mathbf{x}-\mu_k) - \frac{1}{2}\ln(\Sigma_k) - \ln P(\omega_k) \tag{24.9}$$

If all classes are equally likely, then the last term in (➲ 24.9) may be omitted.

The principal difficulties with using Bayesian classification are the underlying assumptions that prior probabilities $P(\omega_k)$and conditional densities $P(\mathbf{x}|\omega_\mathrm{k})$ are known or can be estimated. In most real world applications, one will have knowledge of design samples for each class and some general knowledge about the classification issues. When $\mathbf{x}$ is a high-dimensional feature vector, the covariance matrix Σ is often ill-conditioned, due to the high correlation among the components of the feature vector. This results in serious numerical errors when computing $\boldsymbol{\Sigma}^{-1}$. Alternative approaches have been proposed to alleviate these errors. For example in (Kimura et al. 1989), the authors recommend the use of a *modified quadratic discriminant function* (MQDF).

It is also worth noting that the discriminant function $g_k(\mathbf{x})$ defined in (24.9) is frequently employed, even if the underlying statistics are not Gaussian, due to the ease with which the mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$ can be computed.

While statistical methods have found many practical applications, the need for large amounts of training data has often been the primary difficulty in machine vision applications. Neural networks present some advantages in this regard. This will be discussed in the next section.

24.3 Statistical Recognition Case Study: License Plate Recognition

In this section the recognition of license plates used in the Netherlands will be presented. Typical images of license plates are shown in *Fig. 24.6*. A false image that was captured by the camera is also shown in this collection, as well as the license plate of a foreign car. The objective here is to recognize the string of characters that constitute the license plate. In the Netherlands, license plate characters have some predefined structure (Shridhar 1997). The sequence is typically XY-23-CD or XY-PQ-43. There is always one pair of numerals in the license plate string and they usually occur in the second or third set. All license plate strings have six characters in them. For historical reasons, the combinations of SS and SA are not used. Since 1978, the vowels AOEIU and the letters C, Q and W are not used. The principal advantage is that a more robust and accurate license plate recognition system can be developed.

Figure 24.7 shows the actual picture taken by an overhead camera of a vehicle as it moves along on the road.

The recognition of character strings has been the subject of extensive study in the last decade (Fujisawa et al. 2002). Recognition systems based on Maximum Likelihood (ML) or Hidden Markov Model (HMM) remain the most popular techniques for string recognition

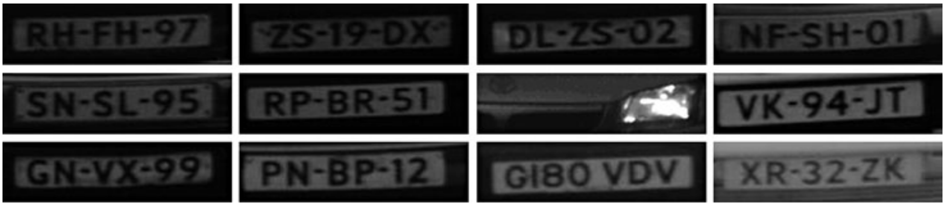

Fig. 24.6
Images of license plates from the Netherlands

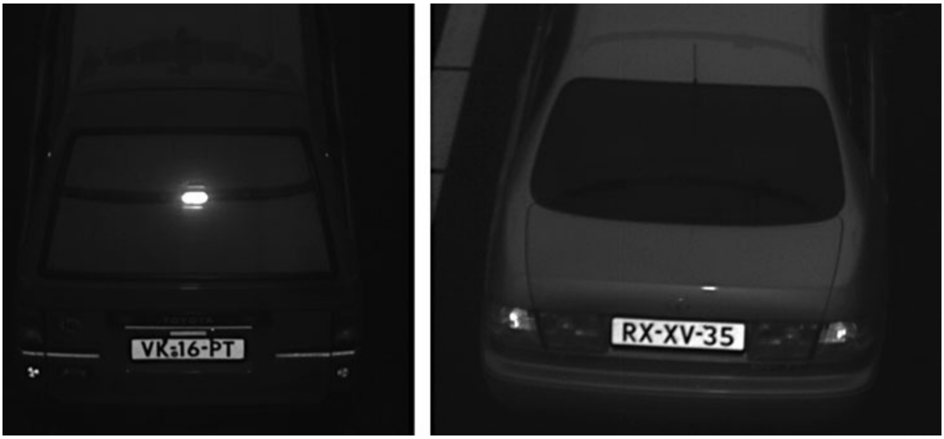

Fig. 24.7
Input images for the license plate recognition problem

[19, 20]. However, these techniques were developed to meet the challenges of handwriting analysis and recognition.

In the case of license plates one observes that characters are for the most part well separated. The authors also observed that at most only two characters were touching or connected. Also, only upper case alphas and numerals are present in the string. The additional character is used: the hyphen. These characteristics suggested that a simplified maximum likelihood technique would be adequate for recognition of the string. Maximum Likelihood (ML) technique was used to achieve the recognition [21]. A 64-dimensional digit classifier and a 64-dimensional alpha classifier, designed with NIST samples were used to derive likelihood measures. Contextual information was used to penalize strings that were not inherent to the data set; for example, the hyphen was not allowed to be located in the second or fourth position in the string. Also, strings whose length exceeded known limits were penalized. ➲ *Figures 24.8* and ➲ *24.9* shows the recognition process used for this study.

The processing involves the following steps:

- Illuminate acquired image through log transformation
- Perform grayscale morphological closing operation on log transformed image
- Subtract closed image from the original image
- Eliminate all non-character blobs in image
- Apply grayscale morphological closing to image that contains only character size blobs. This will cause the character string in the license plate to form a rectangular blob with appropriate aspect ratio
- Extract this region of image containing the license plate and its characters
- Apply string recognition to extract the license plate string.

A limited study with 700 images of license plates captured at 72 dpi and 256 gray levels indicated that an acceptance rate of 80% or higher and an error rate less than 1% is achievable. Some problems remain to be resolved. These problems include ambiguities between similarly shaped characters such as (B – 8), (O – o – 0), (I – 1), (A – 4) and confusion errors from the character pairs like (C – G), (D – O), and (K – X). Some typical results are shown in the table

	Y	**Y – 69**	4– 52

Total likelihood = 463; average likelihood = 77

[a]Correct recognition is shown in bold type; + Hyphen gets removed as noise, depending on its size. The letter "O" is automatically converted to the numeral "0," since "O" is not used in Dutch license plates. Similarly the letter "I" is replaced by the numeral "1"

Optimum string+ 	Optimum recognition[a]	Recognition from alpha classifier[a] with confidence	Recognition from numeral classifier[a] with confidence
	4	A – 57 (not used)	**4–69**
	0	**O – 93** (replace with 0)	0–85
	P	**P – 83**	8–56
	T	**T – 88**	8– 61
	F	**F – 79**	5–43
	N	**N – 91**	4–55

Total likelihood = 503; average likelihood = 83

[a] Correct recognition is shown in bold type; + Hyphen gets removed as noise, depending on its size. The letter "O" is automatically converted to the numeral "0," since "O" is not used in Dutch license plates. Similarly the letter "I" is replaced by the numeral "1"

Fig. 24.10
An example frame from the driver video

The characters extracted from the image of the license plate are sent to an alpha classifier as well as a numeric classifier, each yielding a confidence value for the top choice. Using contextual information described previously, the errors due to ambiguities can be resolved

The rule based decision strategy shown in *Fig. 24.10* utilizes the results from the alpha and numeral classifiers and uses the license plate structure to derive three potential strings along with their confidences as shown below:

RR – ZF – 14 with total confidence of 433
RR – 25 – IA with total confidence of 286 (I and A are not used – Reject)
28 – ZF – IA with total confidence of 236 (I and A are not used – Reject)

The total likelihood (confidence) is obtained by adding the confidences associated with each character in the string. This is illustrated by considering the first string RR – ZF – 14. Each of the characters in this string have the confidence values R – 78, R – 81, Z – 73, F – 61, 1 – 79, 4 – 61, which when added together will yield a total confidence of 433 and an average likelihood value of 72.

The three strings above represent the best letter and number pairs with the letter pairs and the number pair in various permissible positions. It is to be noted that strings such as 4B – XY – 8Z are not permitted. In the example above, the string RR – ZF – 14 is chosen as the final recognition.

24.4 Non-parametric Approaches to Pattern Recognition

24.4.1 Eigenfaces

The eigenface algorithm employed here is based on the formulation given in [11, 15].

Briefly, we start with a *database* or *training set* containing sample images of each of the classes of interest. In this problem, there are seven classes of interest. Let m_i represent the number of samples of class i, $i = 1, 2, \ldots, 7$, and let M denote the total number of training samples: $M = m_1 + m_2 + \ldots + m_7$. The training images will be denoted $\mathbf{I}_1, \mathbf{I}_2, \ldots, \mathbf{I}_M$ and each training image is assumed to be an N-dimensional vector of grayscale pixel data. In addition, let t_j represent the facial pose for each training image $\mathbf{I}_j$ so the training set has the following form: $(\mathbf{I}_1, t_1), (\mathbf{I}_2, t_2), \ldots, (\mathbf{I}_M, t_M)$.

An $N \times M$dimensional matrix of zero mean images $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_M]$ can be constructed with column entries $\mathbf{x}_j = \mathbf{I}_j - \mathbf{I}_{ave}$, where $\mathbf{I}_{ave}$ is the average of all the images: $\mathbf{I}_{ave} = \frac{1}{M}\sum_{j=1}^{M} \mathbf{I}_j$.

The covariance matrix of $\mathbf{X}$ is then given by $\mathbf{C} = \mathbf{X}\mathbf{X}^T$. In general, $M << N$ and so rather than compute the eigenvectors of the $N \times N$ matrix $\mathbf{C}$, we compute the eigenvectors of the $M \times M$ matrix $\mathbf{X}^T\mathbf{X}$. The eigenvectors $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_M$ (or eigenfaces) of the covariance matrix $\mathbf{C}$ are then computed as $\mathbf{X} \bullet \mathbf{eig}(\mathbf{X}^{\mathrm{T}}\mathbf{X})$. For each training image, an eigen representation $w_{ij} = \mathbf{e}_j{}^T\mathbf{x}_i$, $j = 1, 2, \ldots, M$ is obtained by projecting the corresponding $\mathbf{x}_i$ onto each of the eigenfaces $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_M$. So each database image is now represented by a M-dimensional vector of eigen coefficients $\mathbf{w}_i$. For $M << N$, this amounts to a significant dimensionality reduction. In addition, the dimension can be further reduced by only considering the eigenvectors which have sufficiently large eigenvalues. We will denote the number of eigenvectors used by M'.

24.4.2 Fisherfaces

While the eigen approach allows for a low-dimensional representation of the training images, it implicitly reduces the discrimination between training images. While this is a useful property for compactly coding images, it may have some undesirable consequences when it comes to classification. The Fisher representation on the other hand, provides better discrimination between classes while preserving the reduced discrimination property of the eigen representation within each class [4].

In the Fisherfaces algorithm [14], we compute the average image within each of the seven classes. That is, for each $i = 1, 2, \dots, 7$

$$\mu_i = \frac{1}{m_i} \sum_{x_j inclassi} \mathbf{x}_j$$

is the average of all the memory set images which are in class i.

The within-class scatter matrix $\mathbf{S}_W$ is an $N \times N$ matrix which provides a measure of the amount of variation among the memory set images within each class and is given by

$$\mathbf{S}_W = \sum_{i=1}^{7} \sum_{xinclassi} (\mathbf{x} - \mu_i)(\mathbf{x} - \mu_i)^T$$

The between-class scatter matrix $\mathbf{S}_B$ is also $N \times N$ and measures the amount of variance between the means of each class, and is computed by:

$$\mathbf{S}_B = \sum_{i=1}^{7} m_i(\mu_i - \mathbf{I}_{ave})(\mu_i - \mathbf{I}_{ave})$$

The Fisher criterion is to choose a linear projection such that the distance between the projected class means is maximized, but the selection is normalized by the within-class scatter. This amounts to computing the eigenvectors of the matrix $\mathbf{S}_W^{-1}\mathbf{S}_B$. Again, since this is an $N \times N$ matrix, the computation of the eigenvalues of $\mathbf{S}_W^{-1}\mathbf{S}_B$ is computationally inefficient. Hence rather than directly computing the eigenvectors, we first project the memory set data onto a lower dimensional space using eigenfaces.

If we let $\bar{\mu}_i = \mu_i - \mathbf{I}_{ave}$, $\mathbf{A} = [\mu_1, \mu_2, \dots, \mu_7]$, $\mathbf{B} = [m_1\mu_1, m_2\mu_2, \dots, m_7\mu_7]$, and $\mathbf{S}_B = \mathbf{BA}^T$, then we can give an effective measure of $\mathbf{S}_W$ and $\mathbf{S}_B$ in the eigenspace coordinates:

$$\bar{\mathbf{S}}_W = \sum_{i=1}^{7} \mathbf{W}_{pca}^T \mathbf{A}_i \mathbf{A}_i^T \mathbf{W}_{pca}$$

and

$$\bar{\mathbf{S}}_B = \mathbf{W}_{pca}^T \mathbf{B} \mathbf{A}^T \mathbf{W}_{pca}$$

where $\mathbf{W}_{pca}$ is the eigenfaces linear projection operator. Finally, the Fisher projection is computed as the eigenvectors of $\bar{\mathbf{S}}_W^{-1}\bar{\mathbf{S}}_B$.

$$\mathbf{W}_{fld} = eig(\bar{\mathbf{S}}_W^{-1}\bar{\mathbf{S}}_B)$$

Once the projection matrix is computed, and just like in the eigenfaces method, the Fisher projection matrix is used to project each of the database images $\mathbf{I}_i$ onto an M'-dimensional vector $\mathbf{w}_i$ of Fisher coefficients.

24.4.3 Nearest Neighbor Classifier

To classify an input image $\mathbf{I}$, we first compute the corresponding zero mean image $\mathbf{x} = \mathbf{I} - \mathbf{I}_{avg}$ and then project the image onto the eigen space: $\mathbf{w} = \mathbf{W}_{pca}\mathbf{x}$ or the Fisher space: $\mathbf{w} = \mathbf{W}_{fld}\mathbf{x}$.

Various classifier designs can be used to map **w** to one of the seven poses (for example, a nearest neighbor classifier or radial basis function classifier, etc.).

In the nearest neighbor classifier, we compute the distance between **w** and the eigen or Fisher representation vectors for each of the database images:

$$\begin{aligned} d_1 &= \|\mathbf{w} - \mathbf{w}_1\| \\ d_2 &= \|\mathbf{w} - \mathbf{w}_2\| \\ &\ldots \\ d_{M'} &= \|\mathbf{w} - \mathbf{w}_{M'}\| \end{aligned}$$

The coefficient vector $\mathbf{w}_i^*$ which gives the smallest such distance is then determined, and **x** is classified to the pose associated with database pattern $\mathbf{w}_i^*$.

24.5 Case Study: Driver Pose Estimation

The problem addressed in this section is stated as follows: Given a video sequence consisting of a driver as he or she drives a vehicle, determine the pose of the driver for each frame in the sequence. An example of a single video frame is shown in ➲ *Fig. 24.10*, and shows the driver looking straight at the road ahead.

Determining the pose of a driver means determining where the driver is looking. And although there are an endless number of possibilities, the National Highway Traffic Safety Administration has formulated seven standard driver pose classes, which are of importance to the ITS community:

Pose 1: Looking over left shoulder
Pose 2: Looking in left rear view mirror
Pose 3: Looking at road ahead
Pose 4: Looking down at radio/instrument panel
Pose 5: Looking at center rear view mirror
Pose 6: Looking at right rear view mirror
Pose 7: Looking over right shoulder

Hence given a video sequence, the problem here is to assign the appropriate class label (1–7) to each frame of the video.

The main reason why the intelligent transportation systems (ITS) community is interested in the pose estimation problem is that the way a driver behaves behind the wheel can give an indication as to the driver's attentiveness and/or fatigue [13, 14, 16]. For example, one study has shown that drivers who are falling asleep at the wheel tend to blink at a faster rate than drivers who are fully awake.

Of course, one way to determine driver pose is by hand, and have a human operator look at the video and mark those frames where the driver changes pose and then, by visual inspection, classify the resulting pose sequences. This process, however, is very tedious and prone to errors. For example, to partition and classify one 20-min video took a student assistant 6 h! Even so, the resulting ground truth contained a number of missed pose transitions and sequences that were misclassified. Clearly, an automatic and computer-based classification method is needed.

In this section, we compare the performance of two non-parametric techniques to determine driver pose from video data: eigenfaces and Fisherfaces. The pose of an input facial image can be determined by first computing the appropriate representation (using a linear projection to project the image onto a smaller dimensional space) and then comparing it to the representation of each standard pose.

24.5.1 Post Classification Filtering

Experimental results [17] indicated that, when presented with temporally correlated data, the nearest neighbor classifier suffers from isolated errors. Meaning, in a sea of correct classifications, there may be a few sporadic misclassifications. To eliminate such misclassifications, we post-process the temporal record of the classifier results. A simple majority rule filter – choosing the pose that appears a majority of the time in a symmetric sliding window of fixed width – eliminates many of these misclassifications without introducing too many new ones. In some cases, the improvements in classification rates are significant.

24.5.2 Experimental Results

MPEG videos of two test subjects were obtained from Transportation Research Center in East Liberty, Ohio: Subject 11 (11092002.mpg) and Subject 46: (46107002.mpg). Images obtained from the MPEG video were cropped to extract the upper left-hand quadrant containing the facial image – the image size was 150(W) × 115(H). Sample poses from the Subject 11 database are shown in *Fig. 24.11*.

The ground truth for each database was obtained by hand-classifying each frame of the video (the same person truthed both videos). For the Subject 11 video, the total number of frames available for testing and training the classifier was 31,000, and for the Subject 46 video, there were 25,000 frames available.

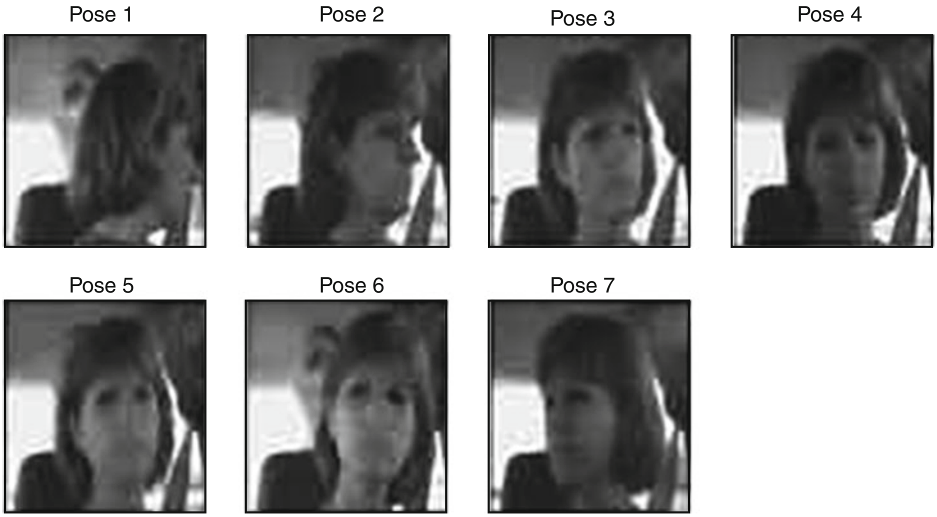

Fig. 24.11
The 7 driver poses

For all of the results given below, the memory set consisted of 50 images per pose – except for pose 3 (the straight pose) which had 150 samples. The reason that more memory set samples were taken for pose 3 is that there were many more samples of pose 3 in the database than any of the other poses. It is to be expected (and hoped for!) that the driver will primarily be looking straight while driving.

For the post-processing majority rule filter, the filter width was fixed at 10 frames.

➲ *Table 24.1* shows the percent correct classification for the Subject 11 database using the eigenface approach and ➲ *Table 24.2* shows the results for the Fisherface approach. ➲ *Tables 24.3* and ➲ *24.4* shows the corresponding results for Subject 46. For these sample experiments, the Fisherface algorithm clearly outperforms the eigenface algorithm in terms of overall percent correct classification. In fact for many other experiments that we conducted (and due to space limitations we cannot report them here), the Fisherface algorithm outperformed the eigenface algorithm. And hence we conclude that the Fisher representation is more suitable for this pose estimation problem.

24.6 Neural Networks

Artificial neural networks are modeled (loosely) after the neural structure of the brain. The brain learns from repeated exposure to specific events. New practical machine vision applications utilizing neural networks have begun to appear in the market; for example, consider the *Eyebot* from Sightech Machine Vision, which can learn up to 20 million features a second (http://www.sightech.com/). Unlike the quadratic discriminant functions associated with statistical methods, neural networks can be trained to generate complex discriminating surfaces.

24.6.1 Artificial Neurons

The basic computational element of a neural network is a single neuron, often called a node. It receives input from external sources (or possibly from other neuron) and computes a single output. Let the n-dimensional input be denoted $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$. Associated with each input is a real-valued parameter w_i called a *weight*. The output of the neuron y is obtained by first computing a weighted sum of inputs:

$$net = w_1 x_1 + w_2 x_2 + \ldots + w_n x_n$$

And then applying an *activation function* f (typically a nonlinear function):

$$y = f(net)$$

A schematic diagram of a neuron is shown in ➲ *Fig. 24.12*.

A few commonly used activation functions are given below and shown in ➲ *Fig. 24.13*.

1. Logistic activation

$$f(net) = \frac{1}{1 + e^{-net}}$$

2. Hyperbolic tangent activation

$$f(net) = \tanh(net) = \frac{e^{net} - e^{-net}}{e^{net} + e^{-net}}$$

3. Linear activation function

$$f(net) = \beta net, \text{ where } \beta \text{ is the slope,}$$

4. Threshold activation

$$f(net) = \begin{cases} 1 \text{ if } net \geq 0 \\ -1 \text{ otherwise} \end{cases}$$

The choice of the activation function depends on the application and the nature of the required data processing. For example, if a real-valued output between 0 and 1 is required, then a logistic activation function is appropriate; if the output is required to be bipolar binary, then a threshold activation is appropriate. Note that for backprop learning, a smooth activation function is required. Oftentimes, the network will be trained with sigmoidal functions and then when training is done, the activation function of the output units will be replaced with threshold functions.

The computation performed by a single neuron is rather simple. However, by interconnecting these simple processors in a network structure can vastly increase the computational power. The most common network structure is the 2-layer model shown in

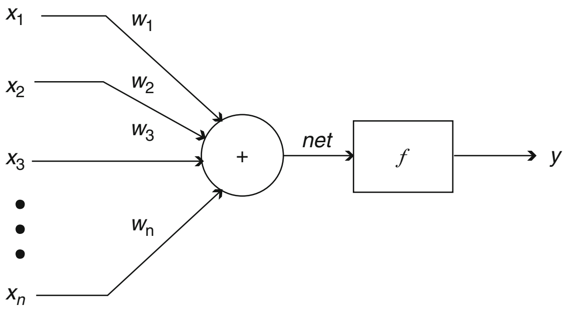

Fig. 24.12
Model of a neuron

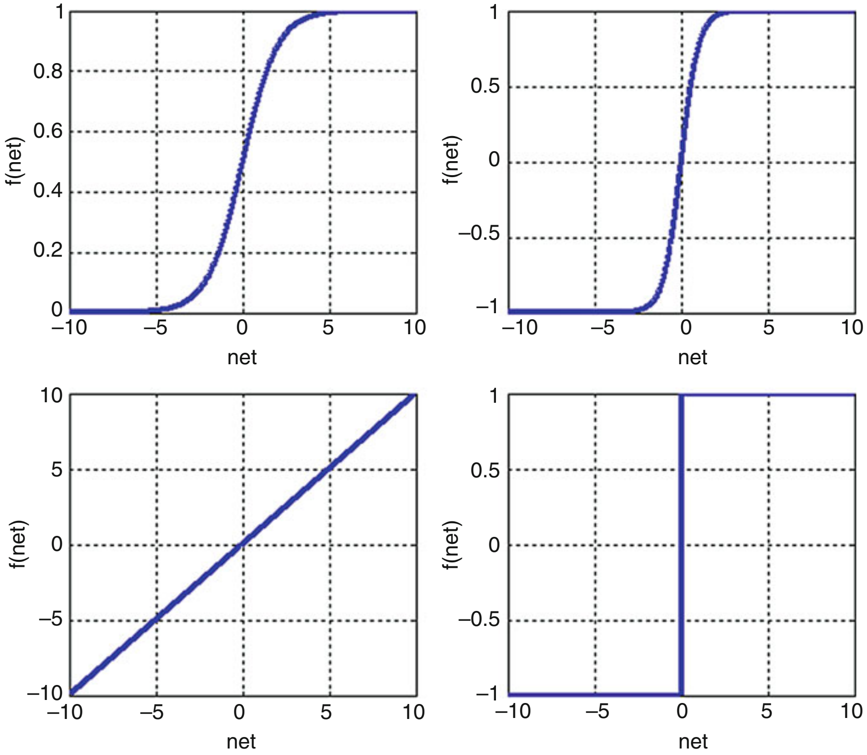

Fig. 24.13
Commonly used activation functions

Fig. 24.14. Here, the input **x** is connected to each neuron in the first layer, called the *hidden layer*. Each hidden unit computes a weighted sum, applies an activation function f_h and produces an output. Let the hidden unit outputs be denoted $\mathbf{z} = [z_1, z_2, \ldots, z_J]^T$. An expression for **z** can be written as $\mathbf{z} = F_h(\mathbf{Vx})$, where $F : R^J \rightarrow R^J$ is a vector mapping of all the hidden unit activation functions: $F_h(\mathbf{net}) = [f_h(net_1), f_h(net_2), \ldots, f_h(net_J)]^T$. The hidden unit outputs are inputs to the output layer of neurons. The final network outputs $\mathbf{y} = [y_1, y_2, \ldots, y_K]^T$ are given by $\mathbf{y} = F_o(\mathbf{Wz})$.

The design of a neural network for pattern classification applications is a non-trivial task, and requires addressing the following issues:

- Selection of external inputs (features) to the neural network
- Construction of a training set of representative examples
- Choice of activation function
- Size of the hidden layer and the number of hidden layers to use
- Learning algorithm to determine the weights

Determination of the weights usually follows an iterative process, called the *learning phase*. A widely used algorithm for determining the weights is called the *backpropagation*.

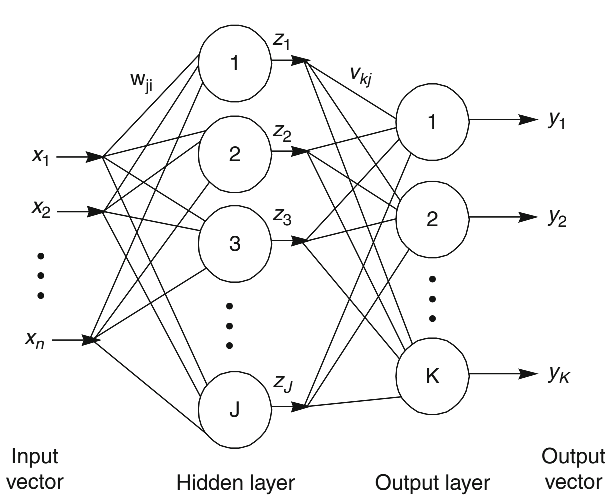

Fig. 24.14
A two layer artificial neural network

24.6.2 Backpropagation Algorithm

The backpropagation algorithm is a method for supervised training of multilayer neural networks. In this case, we assume we have a training set of inputs and associated desired or *target* outputs: $\{(\mathbf{x}_1, \mathbf{y}_1), (\mathbf{x}_2, \mathbf{y}_2), \ldots, (\mathbf{x}_m, \mathbf{y}_m)\}$. There are two phases of neural network operation: *training* and *testing*. The training phase consists of presenting a pattern to the input and passing the signals through the network in order to yield outputs from the output units. The weights are updated according to the chosen learning rule (by using the known target values). In the test phase, a different set of data is used to asses the performance of the system. In this case, test inputs are processed, but no weight adjustment is done (called feedforward operation).

Given a network topology (i.e., given the values of n, J, and L) and given the hidden layer weights $\mathrm{W} = [w_{ji}]$ and the output layer weights $V = [v_{kj}]$, the output of the network $\mathbf{y}$ can be computed for any input vector $\mathbf{x}$ using (24.3–24.6). The process of computing the output given an input vector is called a *forward pass* of the network because of its left-to-right chain of computations: starting at the left with the input $\mathbf{x}$, we compute the hidden unit weighted sums net_j, the hidden unit outputs, z_j, the output unit weighted sums net_k, and then finally the network outputs y_k.

A feedforward artificial neural network may be viewed as a multiple input-multiple output system which maps an n-dimensional input vector $\mathbf{x}$ to a K-dimensional output vector $\mathbf{y}$. The actual input-output mapping implemented by the neural net depends on its architecture (that is, the values of n, J, and K) and the setting of its internal parameters (that is, the value of the weights).

One of the most popular and extensively studied learning algorithms for such feedforward networks is called error backpropagation, or simply *backprop* [10], and is briefly explained below. In this case, we start with the *sum-squared error function* (SSE):

$$E = \frac{1}{2}\sum_{m=1}^{M} \| d^m - y^m \|$$

This SSE error function is taken as the objective function of an unconstrained optimization problem. In particular, the problem is to find network weights w_{ji}^* and v_{kj}^* such that E is minimized. This optimization problem can be solved using the gradient descent approach:

$$w_{ji}^{t+1} = w_{ji}^{t} - \rho \frac{\partial E}{\partial w_{ji}}$$

$$v_{kj}^{t+1} = v_{kj}^{t} - \rho \frac{\partial E}{\partial w_{kj}}$$

Here, the gradient descent step size $\rho > 0$ is called the *learning rate*. If ρ is set too small, then learning will take a long time. On the other hand, if ρ is too large, the gradient descent equations become unstable and learning reduces to random search. The learning rate is typically adjusted empirically to balance between these two extremes. In this learning scheme, given a training pair (**x, d**) randomly chosen from the training set, the output layer weights are modified by the following amount:

$$\Delta v_{kj} = \rho(d_k - y_k) f'(net_k) z_j \tag{24.10}$$

where ρ is a small positive constant called the learning rate, and $f'(net_k)$ is the derivative of the activation function $f(net)$ evaluated at net_k; that is, $f'(net)|_{net=net_k}$.

It is easy to verify that the derivative of the activation functions in ➲ *Fig. 24.1b* is given as follows:

1. $f'(net) = f(net)(1 - f(net))$ for the logistic activation,
2. $f'(net) = [1 - f^2(net)]$ for the hyperbolic tangent activation.
3. $f(net) = \beta$ for the linear activation, and
4. Since the threshold function is not differentiable (more precisely, not differentiable at the origin), it is not suitable for backprop learning.

The hidden layer weights are modified by the following amount:

$$\Delta w_{ji} = \rho \left(\sum_{k=1}^{K} (d_k - y_k) f'(net_k) w_{kj} \right) f'(net_j) x_i \tag{24.11}$$

Training proceeds by randomly choosing a training pattern from the training set, computing the required weight changes using (➲ 24.10) and (➲ 24.11), and then updating the hidden and output layer weights. There are various ways to check for convergence of the algorithm. The simplest way, though, is to choose a maximum number if iterations C and keep training until this number of training steps is achieved. The entire algorithm is summarized below.

Backprop algorithm

1. Choose the network structure, i.e., choose values for n, J, and K. Initialize all hidden and output layer weights to small random numbers, select a small learning rate $\rho > 0$, choose a desired number of learning iterations C, and initialize the iteration counter: $t = 0$.
2. Increment the count: $t \leftarrow t + 1$. Select an input pattern $\mathbf{x}^t$ from the training set and compute the following quantities:

$$net_j \text{ and } z_j \text{ for each } j = 1, 2, \ldots, J;$$
$$net_k \text{ and } y_k \text{ for each } k = 1, 2, \ldots, K.$$

3. Using the desired target $\mathbf{d}^t$ associated with $\mathbf{x}^t$ employ Equations (➲ 24.10) and (➲ 24.11) to compute the output layer weight changes Δv_{ij} and hidden layer weight changes Δw_{ji}.
4. Update all output layer weights: $v_{kj} \leftarrow v_{kj} + \Delta v_{kj}$ and hidden layer weights: $w_{ji} \leftarrow w_{ji} + \Delta w_{ji}$.
5. Test for convergence: $t \geq C$. If convergence criterion is met, then end; otherwise, go to step 2.

The above process of adaptively adjusting the weights of the network is called the *training phase*. Once the training phase is complete, the weights of the network are frozen at their final values and the network can be tested with patterns from the training set as well as additional patterns which were not used during training; this is called the testing or *testing phase*. The ability of the neural net to supply reasonable outputs for entirely new inputs (i.e., inputs not "seen by" or "presented to" the network during training) is called *generalization*.

25 Implementing Machine Vision Systems Using FPGAs

Donald Bailey
Massey University, Palmerston North, New Zealand

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_25,

Abstract: Field programmable gate arrays (FPGAs) offer a convenient and flexible platform on which real-time machine vision systems may be implemented. This chapter discusses how FPGA based design differs from conventional software design for implementing image processing algorithms. Simply porting from software to hardware can give disappointing results. The process of transforming an algorithm for mapping it onto an FPGA is described in some detail, illustrating how a range of low-level image processing operations may be efficiently implemented. Systems integration issues such as interfacing, debugging and tuning are also discussed.

25.1 Introduction

As outlined earlier in this book, machine vision is the integration of vision, or image processing, as part of the control system for a machine. This requires that the system capture images and automatically analyse them to obtain the necessary control data for directly controlling the machine to perform its required task [34]. Throughout this process, the timeliness of the whole process is critical. Machine vision generally focuses on real-time operation. Here, real-time is defined as the ability to provide the data extracted from the images in sufficient time for the processing task to be performed effectively.

This section considers the real-time requirements of machine vision systems, and how these can be overcome by exploiting the parallelism inherent within image processing algorithms. In ➲ Sect. 25.2, FPGAs are presented as a potential platform for the flexible implementation of parallel algorithms in hardware. ➲ Section 25.3 outlines the design process when using FPGAs for image processing. Particular attention is given to the differences between software and hardware based implementations of algorithms. Many of the transformations required in mapping an algorithm onto hardware are demonstrated in ➲ Sect. 25.4. The examples chosen illustrate some of the key techniques, with some of the tradeoffs for a range of low level and intermediate level image processing operations discussed in ➲ Sect. 25.5. ➲ Section 25.6 describes how external devices may be interfaced to the FPGA, with particular focus on image capture, display, and interacting with the user where necessary. In any complex system, debugging and algorithm tuning are of particular importance. The design issues associated with these are elaborated in ➲ Sect. 25.7. The final section brings everything together, and analyses some of the advantages and limitations of using FPGAs as the implementation platform for machine vision systems.

25.1.1 Real Time Processing

There are two aspects to real-time operation that are important to distinguish between. The first is the processing latency. This is defined as the time from when an image capture is triggered until the time that the processed output is available. The second is the throughput. This corresponds to the average rate at which images are processed and the required data is produced. Note that if there is a wide variation in the processing time for individual images then significant storage may be required. In this situation, the worst case processing rate may be a more relevant measure than the average. On a conventional computer the processing rate and latency are intimately related because the processor can only do one thing at a time. However, as will be seen shortly, in a parallel processing system the processing rate and latency can be decoupled. Different machine vision applications may place different constraints on the latency and throughput.

When using vision to provide direct feedback for a control task, the latency is usually a critical constraint. Delays within the feedback path complicate the design of a control system, and can directly lead to instability. However, in an inspection task, latency may not necessarily be the critical constraint. When grading, for example on a conveyor, the critical constraint is the time from when the image is captured to the first actuation point. This may be arranged at some distance (hence time) after the image capture, resulting in a very loose latency constraint. On the other hand, a system for 360° inspection may perform the image capture while the item is in freefall, and a decision must be reached to control a compressed air jet to deflect the item before it lands. In this case, there is a tight latency constraint.

In control tasks, the sample rate of the system governs the throughput. This is usually taken to mean that all of the processing must be completed within the time between samples [27] (usually the video frame rate). However, in a parallel system only each processing step needs to be completed at this rate if the data can be passed on to another processing stage. The sampling rate (or frame rate) must be sufficiently high to accurately capture any high speed phenomena. From the Nyquist sampling theorem, there must be at least two samples or frames within the highest frequency variation for it to be captured accurately. This applies a lower limit to the frame rate and hence throughput. For inspection applications, the throughput is governed by the rate at which items are presented for inspection.

Both the latency and throughput place severe constraints on the image processing system. Many vision applications require high performance computing to operate at the required rates. To achieve the required processing rates, it is often necessary to exploit the parallelism inherent in image processing algorithms [27]. Although this problem has to some extent been alleviated by the ever increasing processing power as a result of Moore's law, the complexity of the problems and expectations on the system have also increased, requiring some form of parallel solution.

25.1.2 Parallelism in Image Processing

When accelerating an algorithm by exploiting parallelism, it is important to consider how much of the algorithm is inherently sequential, and how much of the algorithm is parallelisable. The serial portions of the algorithm cannot be sped up. Therefore, if 20% (for example) of an algorithm is constrained to run serially, then the minimum latency is 1/5 of the original processing time, or a maximum of only five times speedup can ever be obtained. Such a speedup can only be achieved if the remaining 80% of the algorithm can be implemented in parallel with the serial 20% (on multiple processors if necessary). This is known as Amdahl's law of parallelism [6]. To achieve any significant speedup, the algorithm must have a high proportion of its operations that are parallelisable, and that implementing them in parallel does not introduce any significant additional overhead, from communication or intermediate storage. Note that the speedup here is in terms of the latency; it is always possible to increase the throughput, even if by using a separate processor for each image. Fortunately, there are several forms of parallelism inherent within the processing of images [18]. These will be described in turn.

At the highest level, an image processing algorithm consists of a sequence of image processing operations. These operations are independent in the sense that the processing performed by each operation is independent of the processing performed by each of the other operations. The only dependencies are the flow of data from one operation to the next through the processing chain. The captured image is input at the start of the pipeline and as it

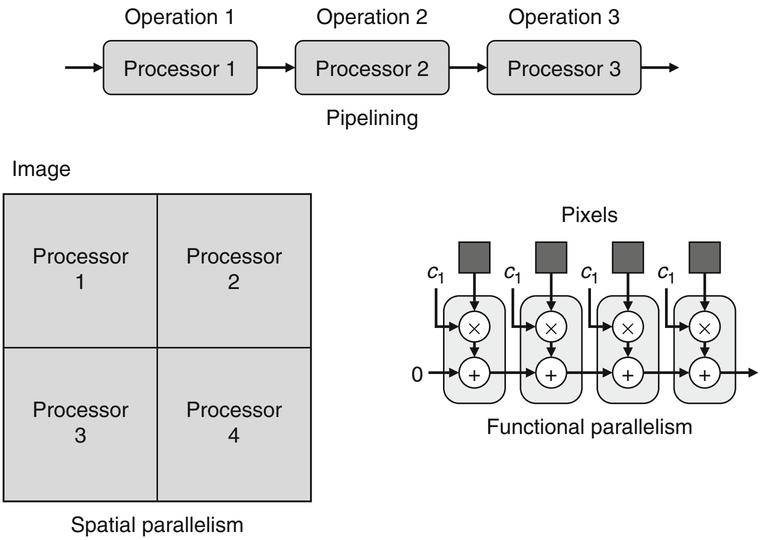

Fig. 25.1
Different types of parallelism within image processing

flows through the sequence of operations, the data is transformed until at the output the required data is produced. This temporal parallelism may be exploited by pipelining – a separate processor is used for performing each operation within the algorithm, as shown in *Fig. 25.1*. Such pipelines work like assembly lines. At a given stage, once the input is available, the operation may be performed on the image with the results passed on to the next stage in the chain. It may then begin processing the next input, without having to wait until the processing for the previous image is complete. The independence of the operations allows each processor to work independently of the others, subject to the flow of data between the operations. The latency is determined by how long it takes for an image to pass completely through the pipeline. The throughput, however, is governed by the one operation that takes the longest time to complete. Pipelining, therefore, decouples the throughput and latency because processing may begin on a new image before the processing is completed on a previous image.

At the next level, many image processing operations perform the same operation for each pixel within the image. In software, this is represented by the outermost loop iterating through the pixels in the image. This therefore corresponds to spatial parallelism, which may be exploited by partitioning the image among several independent processors, as illustrated in *Fig. 25.1*. The main factor in determining the best partitioning is to minimise the communication between processors, because any such communication is an overhead and reduces the effective speedup that can be achieved. Minimising communication usually corresponds to minimising the data required from other partitions. Such partitioning is therefore most effective when only local processing is required. This is one of the drivers for investigating separable algorithms, because separating row and column processing provides a partitioning that has inherently low communication overheads.

Stream processing is another way in which spatial parallelism may be exploited. Bandwidth constraints mean that images are usually passed sequentially from one operation to the next in a pipeline. Serialising the image data, using a raster scan, converts spatial parallelism into temporal parallelism. In a stream processing system, each stage of the processing pipeline operates one pixel at a time, rather than a whole image at a time. One simple example of such a system is the use of a lookup within an image capture card to provide contrast adjustment on an image as it is captured. Since each pixel is only provided once on the input, it is necessary for any operation that uses more than one pixel to buffer the input pixels until they are required. Stream processing therefore works best when only local information is required and the processing time for each pixel is constant. It is also the natural processing mode for data being streamed from a camera or to a display. Note that stream processing adds a throughput constraint, generally one pixel per clock cycle. However, the advantage is a significantly reduced latency, because each operation in a pipeline can begin processing as soon as pixels start arriving, without having to wait until the complete image is available.

At the lowest level is logical or functional parallelism. This is where a single function block is reused many times within an operation. For example, a linear window filter implemented in software would consist of an inner loop which iterates through the pixels within a window, multiplying each pixel by the corresponding filter coefficient, and adding the result to an accumulator. The content of the inner loop – the multiply and accumulate – is repeated many times, but could readily be parallelised by building several multiply and accumulate blocks (see ➲ *Fig. 25.1*). Since these inner loops are where most of the processing time is spent, from Amdahl's law, parallelising these can give the largest processing speedup, and can be the most effective at minimising the latency.

In the past, to accelerate the image processing algorithms by exploiting parallelism, it was necessary to develop dedicated image processing hardware. While such systems were fast, they were both expensive and relatively inflexible. As long as the task did not change, it could be performed well, but it was difficult to reconfigure the system in the event of even relatively minor changes to the task. The introduction of field programmable gate arrays (FPGAs) in the 1980s allowed hardware to be more flexibly reprogrammed. While the early devices were too small for implementing image processing algorithms, modern FPGAs now have sufficient resources to enable complete systems to be implemented on a single chip.

25.2 FPGAs

In its most basic form, a field programmable gate array is essentially a sea of programmable logic gates, combined with programmable interconnect, as illustrated in ➲ *Fig. 25.2*. The logic is performs the required computation, while the interconnect is used to connect the data from one computation point to another. The two main vendors for FPGAs are Xilinx and Altera, although there are a number of other smaller players.

This section will explore the architecture of currently available FPGAs (the latest generations are the Spartan 6 [40] and Virtex 6 [42] from Xilinx, and Cyclone IV [4] and Stratix IV [5] from Altera) and how this can support the parallel implementation of image processing algorithms. This section concludes with a discussion of some of the different approaches to programming FPGAs.

25.2.1 FPGA Architecture

The basic logic cell in most FPGAs is a small, single bit wide, lookup table (LUT). This enables it to implement any arbitrary Boolean function of the inputs, with propagation delay

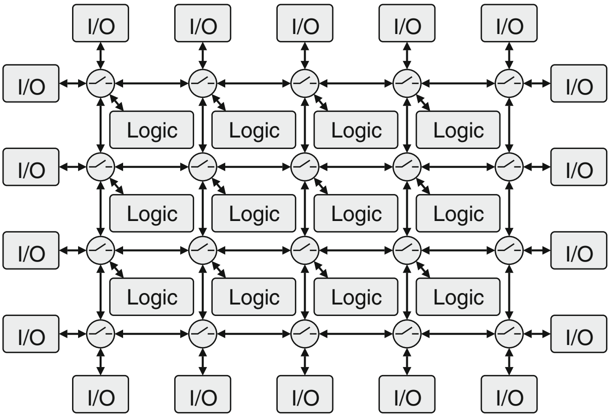

Fig. 25.2
Basic structure of an FPGA

independent of the actual function. More complex functions requiring more inputs can be created by having multiple levels of LUTs. In this way any arbitrarily complex logic function can be implemented.

Previous generations of FPGAs were based around 4-input LUTs, although this has increased with reducing fabrication technology scale. The basic logic element in the latest Xilinx FPGAs is a 6-input LUT, which can be split into two separate 5-input LUTs with the same inputs [42]. Altera have taken a slightly different approach. Their adaptive logic module [5, 25] combines up to 8 inputs with two adaptive LUTs that can vary between 3 and 6 inputs each. Each LUT also has a flip-flop on the output that may be optionally bypassed. These may be used as registers for holding intermediate results, or to demarcate the stages within a pipelined design. In addition to the LUTs, modern FPGAs also incorporate additional logic to simplify and reduce the propagation delay required to implement common operations. These include dedicated logic for carry propagation to speed addition, and support for wide multiplexers. The arrangement of logic cells within a Spartan 6 is illustrated in *Fig. 25.3*.

Each logic block is made up of a number of logic cells (8 in the case of Xilinx, 10 for Altera). Grouping logic cells in this way enables higher speed direct connections between cells within the same logic block. This reduces the propagation delay when implementing more complex logic functions. Otherwise, connections between blocks are via the programmable interconnect. The interconnect network is typically arranged in a grid structure, with switches at intersections enabling signals to be routed between the horizontal and vertical lines. Each interconnection segment and each switch introduces propagation delay. In a typical design, approximately half of the propagation delay comes from the logic, with the remaining delay from the interconnect.

For digital signal processing (DSP), a common operation is multiplication. It is expensive (both in terms of the logic required and the propagation delay) to build multipliers out of logic blocks. Therefore, in addition to the fine-grained logic blocks, most modern FPGAs also have dedicated multiply and accumulate or DSP blocks. DSP blocks can also include dedicated word-wide shift registers to simplify the implementation of finite impulse response filters.

In addition to the flip-flops associated with each logic cell, FPGAs also include on-chip memory blocks for storage of larger volumes of data. While the large, high-end FPGAs have sufficient storage for one or more images, this is usually poor value for money, and it

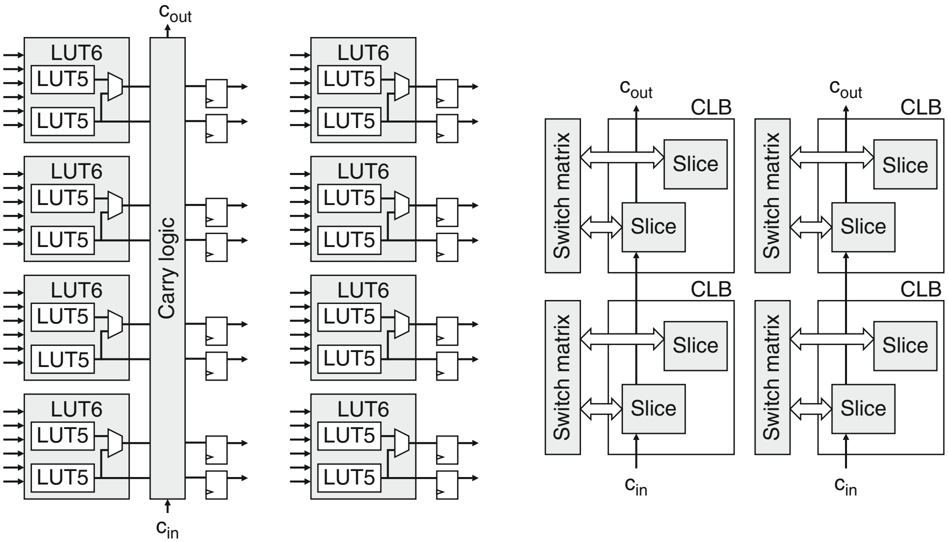

Fig. 25.3
Logic cells within a Spartan 6. *Left*: the arrangement of LUTs within slices. *Right*: the arrangement of slices as logic blocks, showing the linking of the carry chains. Simplified from [41]

is usually better to use off-chip memory for bulk storage. However the on-chip memories enable high bandwidth intermediate storage of data. The memory is implemented in two ways: either by adapting the logic blocks to use the LUTs as small memories, or as separate dedicated memory blocks.

Xilinx allow up to 50% of the logic elements to be used as separate 32-bit memories (giving up to 256 bits per logic block) for both the Spartan 6 and Virtex 6. These may be used as ROM, RAM (either single port or dual port), or programmable length shift registers. In their Stratix devices, Altera require that a whole logic block be used either for logic or as a memory, giving 640 bits per logic block. This memory is simple dual-port (one port is read/write, and the other is read only). These small memories are useful for short buffers for example for synchronising different parts of a design, or for storing coefficients.

In addition to the small blocks, FPGAs also have larger blocks of dual-port memory. In the Spartan-6, these memory blocks are 18 Kbits each (configurable in aspect ratios from 16 K × 1 up to 512 × 36). In the Virtex-6 they are larger at 36 Kbits each (32 K × 1 to 512 × 72), although they can also be configured as two independent 18 K memories. In the Cyclone IV, the blocks are 9 Kbits each (8 K × 1 to 256 × 36). The Stratix IV also has 9 Kbit blocks, but also adds larger 144 Kbit blocks (16 K × 8 to 2 K × 72). On the high end devices (the Virtex-6 and Stratix IV), the blocks may also be configured as FIFO buffers, with memory addressing provided by dedicated hardware. The 72-bit wide memories can also be configured to use 8 of the bits for hardware error detection and correction with 64 bit wide data. The block memories are reasonably plentiful, with each one accessed independently, allowing them to be used for row buffers and wide bandwidth caches.

The input and output blocks provide buffers and drivers to connect between internal logic and external devices. General purpose I/O pins can be configured to operate with a wide range of signalling standards, and include programmable termination for high speed signalling.

Other standards are also supported, including interfaces to double data rate (DDR) memories, and low voltage differential signalling (LVDS). High end devices also support multi-gigabit serial communication standards with built in serialisation and deserialisation logic to enable the FPGA core to run at a lower speed.

As synchronous devices, FPGAs require one or more clock signals to control their timing. Delay locked loops are used to synchronise clocks with external sources, and to minimise clock skew across the FPGA. Phase locked loops are used to synthesise new clock frequencies by multiplying a reference clock by an integer ratio. A series of dedicated clock lines and clock buffers distribute the clock signals across the FPGA and manage the high fanout while minimising skew between different parts of the chip.

A typical layout of the various logic components within the Xilinx FPGAs is shown in ➔ *Fig. 25.4*. The different elements are arranged in columns within the FPGA, with the I/O logic around the edges. The structure of the Altera devices is a little different, but follows the same principle of interspersing the DSP and RAM blocks throughout the logic.

All of the configurable components of the FPGA (LUTs, flip-flops, interconnect, DSP, RAM options) are controlled by static memory (SRAM) cells. Since these are volatile, the configuration must be reloaded after powering on before any processing can begin. This is achieved by loading a configuration file from an external ROM into the internal control memory (some devices contain an internal configuration ROM to reduce the component count). Some devices allow compression of the configuration file to reduce configuration time, and encryption of the configuration data to provide some protection against piracy or reverse engineering of the intellectual property. All of this uses dedicated logic on the FPGA to decompress, decrypt, and direct the configuration bits to their corresponding SRAM cells. An FPGA can be reconfigured at any time. This requires suspending the current execution, and loading a new configuration file. Since everything on the FPGA (including RAM contents) is changed by the new configuration, it is necessary to save any state information off the FPGA during this process. The Xilinx devices allow partial reconfiguration, which allows part of the device to be reconfigured without stopping execution on the remainder of the FPGA.

In summary, modern FPGAs consist of a homogenous mixture of fine grained logic and flip-flops, and coarser grained DSP blocks and memory, with a programmable interconnect that allows these to be configured to implement parallel hardware systems.

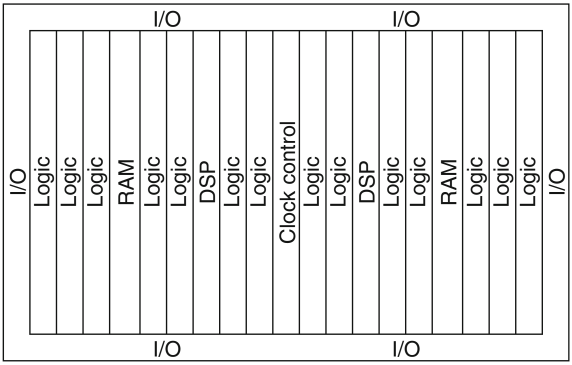

Fig. 25.4
Typical layout of Xilinx FPGAs

25.2.2 FPGAs for Image Processing

The parallel nature of FPGAs allows them to implement parallel algorithms and to exploit the parallelism inherent in images. Since each image processing operation is different, the very nature of hardware requires that separate operations be implemented by separate hardware, unless efforts are made to explicitly reuse various components. Implementation of an image processing algorithm on hardware therefore directly lends itself to coarse-grained pipelining.

In hardware, it is relatively simple to partition an image or other data structure over several parallel function blocks. This requires designing one function block, and replicating it. In the same way, functional parallelism can also be exploited – the only difference is the size and complexity of the function block. Additional logic is required to direct the appropriate pixels to their corresponding function blocks and managing any communication required between the blocks. If necessary, uneven processing rates may be smoothed through the use of FIFO buffers built from on-chip RAM.

Streaming can feed data serially through a series of function blocks. Again, streaming is natural for raster scanned image data. The complexity comes from ensuring that the data is processed at the pixel rate. This requires designing an appropriate architecture to ensure that all of the data is available when it is required. On-chip memory can be used to cache data until it is required. The abundance of registers facilitates the fine grained pipelining required to perform complex operations at the pixel clock rate. Operating a streamed pipeline is straight forward when in the middle of an image. However, pipelines require priming at the start of the image and at the start of each row. At the end of the row and image, it is necessary to keep the pipeline running until processing completes for the valid data remaining within the pipeline. The logic required for priming and flushing is often more complex than the normal processing logic.

Image processing, or at least the low-level pixel processing, is ideally suited to implementation on an FPGA. The operations are generally quite simple and inherently parallel. The reprogrammability of FPGAs allows the hardware implementing the algorithm to be redesigned and adapted if the nature of the machine vision task changes. FPGAs therefore give the best of both worlds: the flexibility and reprogrammability that normally comes with software, along with the speed and parallelism that comes from a hardware implementation.

25.2.3 Programming FPGAs

The configuration of an FPGA represents a hardware based logic circuit. Traditionally, electronic circuits are represented by schematic diagrams, although for large complex designs, these can quickly become unwieldy. In the 1980s, text based hardware description languages were developed to provide a standard representation of the specification and behaviour of a logic circuit. The two most commonly used languages are VHDL and Verilog, both of which are specified by IEEE standards. Since they must describe parallel systems, they are primarily concurrent languages. There are two main styles of programming with hardware description languages. The first is the structural style, which defines a design as a hierarchical series of functional blocks and their interconnections. This corresponds directly with the schematic type representation of a design. The alternative style is through a behavioural description of the operation of the circuit. This describes how the circuit or system should respond to changes on its inputs. This is therefore at a higher level of abstraction than a structural description, making it more appropriate for representing algorithms.

Programming FPGAs with VHDL or Verilog is a little like programming in assembler. The developer has full flexibility and control, enabling them to even explicitly use particular features of the target FPGA. The limitation however, is that the developer must also manage all of the fine detail and low-level control for implementing their algorithm. To overcome this, there has been significant research recently on synthesising hardware directly from higher level software based languages, mainly based on C. The goal of this is two-fold. First it makes the design more accessible to software engineers [3], enabling them to work in a familiar language. Second, the higher level of abstraction should make development more efficient by being closer to an algorithmic representation and removing much of the necessity of managing all of the low level details.

There are several problems with synthesising hardware directly from software languages [19]. First, software is primarily a sequential representation whereas hardware is naturally concurrent. It is often necessary to augment the language with new constructs for representing parallel execution. While some of this may be extracted automatically by the compiler through a dataflow dependency analysis, current compilers are limited in what they are able to extract. Modern compilers, usually in conjunction with operating system support, can implement concurrency with a threaded computation model, this is too coarse-grained for working with hardware. Strongly related to concurrent execution is the need for communication and synchronisation between different threads or different parts of the hardware. Semaphores, mutexes, channels, mailboxes, or other synchronisation mechanisms require a direct representation to simplify the design of the concurrent systems. A second aspect is that hardware implementation usually requires an explicit representation of time. This is particularly so for stream based processing where actions are synchronised with a data clock. In software, timing is only implicit in the order of operations. Third, in software, native data types are 8, 16, 32 and 64 bits wide. In hardware, efficient implementation requires tailoring the data width to the particular task. This requires the language to be able to explicitly specify the width of each variable and data path. Finally, software assumes a monolithic memory architecture, with single large memory used to store all data. In C, memory is commonly accessed via pointers, with a single address structure allowing pointer arithmetic to be used for efficient software implementation. In contrast to this, FPGAs have many small independent memory blocks which can be exploited to increase the bandwidth. Even external to the FPGA, the memory may consist of several independent parallel memory banks. Pointer arithmetic is not applicable to FPGAs.

One language we have found particularly useful for programming FPGAs is Handel-C. Originally developed in the Hardware Compilation Research Group at Oxford University [31], it was commercialised by Celoxica, and is now provided by Mentor Graphics [30]. Handel-C extends ANSI C with constructs that address the issues identified in the previous paragraph. The basic data type is an integer (floating point is not directly supported), with directly specified bit-width. A range of bit manipulation operations (extraction, concatenation) allow low-level data manipulation. In hardware, many operations are implemented simply by wiring the bits to the appropriate places. The normal sequential execution is augmented by a par{} construct, with all of the statements within the par block executed concurrently. Explicit timing is provided by each assignment statement taking exactly one clock cycle to execute. The complexity of the right hand side of an assignment determines the propagation delay, hence the maximum clock rate achievable. Concurrent constructs such as semaphores and channels are implemented as native constructs within the language.

While closely resembling standard C, it is important to remember that Handel-C is actually a hardware description language with each statement compiling to separate hardware. The compiler also builds an implicit finite state machine which controls the execution of each statement, and manages the sequential flow, including the appropriate control paths for looping and branching constructs. Structural design is supported through function calls, although because each function call connects to hardware, recursion is not supported (there is no programme counter, and no stack). While the language looks like C, it is still important for the developer to design the appropriate hardware and represent it using Handel-C. Simply writing C and expecting an efficient hardware implementation does not work! However provided that the FPGA architecture is kept in mind, the higher, algorithmic, level of representation does speed the development of efficient hardware.

Having chosen a hardware description language, and represented the design in the chosen language, there are several steps required to translate this into a form for operating the FPGA. The first step is synthesis, which translates the structural or behavioural description into a device or gate level net-list representing the hardware to be constructed on the FPGA. From a structural representation, this is a one-to-one mapping, although for a behavioural description the synthesis tools must determine the logic required to implement the specified behaviour. In VHDL or Verilog, this requires that the behavioural description conform to a register transfer level coding style. Synthesis tools can optimise a design for speed or area by selecting appropriate circuits for each task. The next step is mapping, which determines how the logic is implemented by the specific components and resources available on the FPGA. In particular, the logic is mapped onto the LUTs, merging related logic to fit within a single LUT, or partitioning complex logic over multiple LUTs. Once mapped, place and route tools place each component within specific logic blocks, and determine the particular routing resources required to connect between the components, and to external pins. Place and route is usually an iterative process, with components repositioned and rerouted to minimise connection lengths and meet timing constraints. The final stage is the generation of the configuration file that is loaded into the FPGA to implement the design.

25.3 Design Using FPGAs

So far, we have looked at FPGAs and how they can potentially accelerate machine vision algorithms by exploiting the parallelism inherent in processing images. In this section, the design process for an FPGA implementation will be compared with that for conventional software based design. A good software design does not necessarily correspond to a good hardware design for the following reasons [21]:

- The optimal processing mode in hardware is usually different from software [23]. Random memory access is efficient in software, especially with memory caching used by modern processors. On an FPGA, random access to image memory can be inefficient because it is usually stored off the FPGA. Software is often memory bound with intermediate variables stored within memory. On an FPGA, intermediate variables and data can be stored in dedicated registers or on-chip memory buffers, giving a much higher bandwidth. Stream based processing is better suited for manipulating images where possible.
- FPGA clock speeds are typically an order of magnitude slower than high performance serial processors. This is because the general purpose nature of FPGA logic, combined with the overhead of routing delays cannot compete with custom designed logic circuits. It is necessary to gain an order of magnitude acceleration through exploiting parallelism just to break even with serial processors. A parallel design is therefore essential rather than relying on a high clock speed.

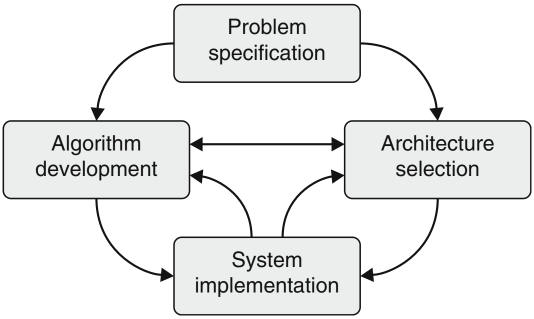

Fig. 25.5
Stages of FPGA based image processing design

- The concurrent nature of hardware complicates arbitration for resources. On a serial processor, this is significantly reduced because the processor can only do one thing at a time.
- The lack of an operating system on an FPGA system means that memory and other system resources must be managed or scheduled manually rather than via an operating system. It is also necessary to develop hardware drivers for any peripherals used by the application.

The design process needs to take these factors into account. There are four key stages of developing an FPGA based image processing system [21], as illustrated in *Fig. 25.5*.

25.3.1 Problem Specification

The problem specification stage is the same as for conventional software engineering. It is necessary to clearly define the image processing problem, identify assumptions that may be made about the images to be processed, and specify the set of functional and engineering constraints that must be met for a solution to be considered successful. For image processing, this requires clarifying and formalising the often vague description of the task to be performed by the image processing module. The resulting engineering specification must be sufficiently concise to enable any potential solution to be evaluated for correctness and completeness.

Some of the key issues to consider here are: the timing constraints; how knowledge of the task performed can be used to simplify the processing; the selection of representative sets of images for developing and testing the algorithms; the selection of appropriate features for performing any classifications; the specification of minimum success rates in terms of classifications; the robustness of the complete system to errors or misclassifications; and whether or not an FPGA based system is actually required. It is important to remember that image processing is only one module within the overall machine vision system [9] and success requires that it be integrated with the rest of the system.

25.3.2 Algorithm Development

Algorithm development requires determining the sequence of image processing operations that perform the task and meet the performance specifications. Algorithm development typically involves two phases. The first is to find an algorithm that meets the specifications.

This typically the same process as for a software based solution, and requires an interactive image processing algorithm development environment. This must be performed in a standard software based environment because an FPGA does not have the interactivity and a large range of image processing commands available for the development to take place directly on the FPGA system.

The second phase, once a suitable algorithm has been found, is to adapt it for parallel implementation. This often requires significant changes to the algorithm to exploit parallelism and to make best use of the resources available on the FPGA. It is at this stage that the design process diverges from the design for a conventional processor. The algorithm optimisation goals are different for software and hardware processors, although in both cases the design is usually iterative, with the algorithm adapted and refined until the processing goals and constraints are met.

25.3.3 Architecture Selection

On a software based system, the computational architecture is fixed. For an FPGA based machine vision system, very little is predefined. It is necessary to develop both the architecture as well as the algorithm. The concurrency of hardware opens a wide range of possibilities to tailor the architecture to the application.

The architecture needs to be designed at multiple levels. At the highest level is the system architecture. While low-level image to image operations are well suited to a hardware implementation, the higher level operations, such as recognition tasks, are harder to implement efficiently in custom hardware. Tasks which only run occasionally, or have complex data dependent flow, if implemented in hardware tend to require large amounts of hardware to account for the different situations, and leave much of the hardware idle for long periods of time. Such tasks also tend to have significantly lower data volumes, making them better suited to a conventional serial processor.

In many machine vision applications, such as inspection and grading, the low-level operations tend to dominate, and the high-level vision tasks are relatively simple. Such applications can be implemented solely on an FPGA, operating in standalone mode. In this architecture, everything is implemented on the FPGA, although it may be connected to a host computer during the initial development and for debugging. In the standalone configuration, the FPGA is responsible for everything, including image capture, display, and any interaction with the user.

Applications with more complex high-level processing may require partitioning the computation between hardware and software processors. Two possibilities for implementing the composite hardware/software system are to have a separate computer subsystem, or to implement the serial processor from the logic of the FPGA. In the latter case, both Xilinx and Altera provide processor cores (MicroBlaze and NIOS II respectively) and associated development environments.

The system architecture also includes how peripheral devices are connected to the system. The goal of machine vision is to autonomously control some activity, so the controllers must also be integrated into the system.

It is also necessary to design the computational architecture. The computational architecture for a serial processor consists of an arithmetic logic unit (ALU) and a set of general purpose registers. A series of machine instructions fetch data from registers or memory, determine the operation performed by the ALU, and store the results back into registers or memory. Many of the components are reused from one instruction to the next, and the data is passed through the ALU many times in the course of the processing.

In contrast with this, in a hardware system the computational architecture is designed to accelerate the processing by exploiting parallelism. Consequently, the processing tends to be more distributed, with the data passing through each processing block only once in the course of the algorithm. Each of the parallel processing modes described earlier can be used as the basis for designing a computational architecture.

Stream processing processes an image as a sequential stream of pixels. It is well suited to processing image data on the fly as it comes from a camera or is output to a display. It works with a fixed clock rate, usually one pixel per clock cycle, which constrains memory bandwidth. Stream processing is well suited to low-level image processing operations where only local information is required for each output pixel. Other operations may require significant algorithm redesign to fit within a stream processing framework. Algorithm acceleration is gained through pipelining, with low-level pipelining used to meet timing constraints. Stream processing may be extended through the use of systolic arrays, where a one or two-dimensional array of processors operates on data as it is streamed through. Systolic arrays effectively unroll a recursive processing loop over a set of parallel concurrent processors and use simple communication between the processors to maintain state as the data is passed through with each clock cycle.

Random access processing allows pixels to be accessed anywhere from a frame buffer as needed by an operation. The lack of explicit data access requirements make it much closer to the software approach to processing, although simply porting a software algorithm to hardware will usually be memory bound, with memory bandwidth limiting the performance. While random access processing relaxes the hard timing constraint of stream processing, acceleration can be gained by maximising the clock rate by reducing the combinatorial delay through low level pipelining. It is also necessary to identify parallel branches to distribute the processing effectively. Image partitioning can be used here where the algorithm allows. Memory bandwidth limitations are then overcome by associating local memory with each branch and reducing the number of accesses required to the global frame buffer. In the extreme case, a massively parallel architecture uses a simple processor for each pixel in the image. While fine in theory, such massively parallel architectures are resource hungry, and require large expensive FPGAs to be effective.

It is important to obtain a good match between the algorithm and the computational architecture. A poor match limits the acceleration available, and makes inefficient use of available resources. Therefore several iterations between algorithm development and architecture selection are often required before a good match is found.

25.3.4 System Implementation

The final stage is system implementation. This is where the algorithm is mapped onto the architecture. This task differs significantly from software based design. While the initial algorithm is developed as software, the mapping process does not simply port the software algorithm to hardware unless it was initially developed with a hardware implementation in mind. The function of the software is mapped, rather than the specific algorithm.

Image processing operations are often expressed in parallel, for example a filter applies an operation on the pixel values within a local neighbourhood or window in an image. This is implicitly parallel, since the operation is applied for every possible position of the window.

A software implementation represents this as a serial algorithm optimised for such a serial computational architecture. It is not always an easy task to convert or map such serial algorithms back onto parallel architectures. Therefore, it is necessary to remap the operation rather than simply translate the algorithm. Consequently, not all software algorithms map well to hardware. Implementation often requires significant changes to the actual algorithm, and sometimes to the computational architecture to make full use of parallelism and obtain an efficient implementation.

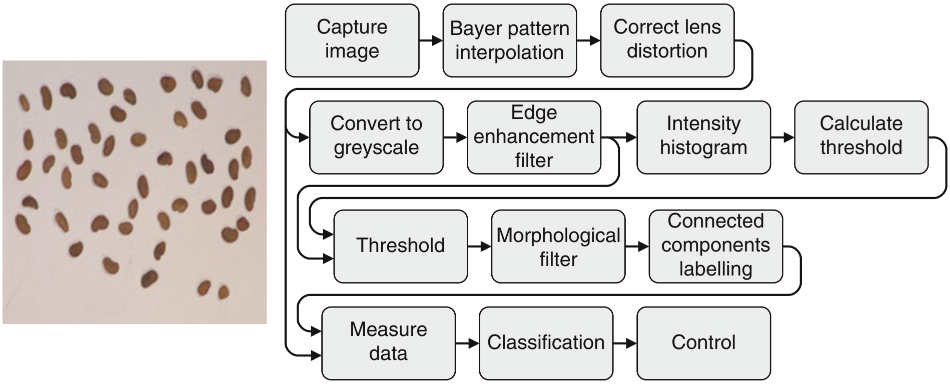
Another implementation task is to develop device drivers and interfaces for any peripherals. These are usually provided by an operating system in software based systems, but are not generally available in hardware. They therefore must be developed by the system designer.

It is important to remember that an FPGA based implementation requires hardware design. Even though the implementation language may look like software, an efficient design requires a hardware mindset.

25.4 Transforming an Algorithm for Hardware Implementation

The design process outlined in the previous section will be illustrated with an example application (see ➲ *Fig. 25.6*). This example is somewhat contrived to show how a range of different image processing operations are mapped onto an FPGA, and to demonstrate the mapping process from software to hardware. The application consists of grading seeds on the basis of colour and size. It will also be assumed that the latency of the algorithm must be minimised, hence the need to use an FPGA implementation.

A colour image is captured using a single-chip CMOS colour sensor using a Bayer colour filter array. From the camera, each pixel will either be red, green or blue depending on the filter associated with that pixel. To obtain a full colour image, it is necessary to interpolate between the pixels available to obtain the missing components. Since the control output needs to be able to precisely locate each seed, it is necessary to calibrate and correct for any geometric distortion introduced by the lens. Segmenting the seeds from the background does not require full colour, so the processing can be simplified and reduced by converting the colour image to greyscale. The edge enhancement filter sharpens edges between the seeds and the background to enable



◘ Fig. 25.6
Example machine vision algorithm, with a sample input image

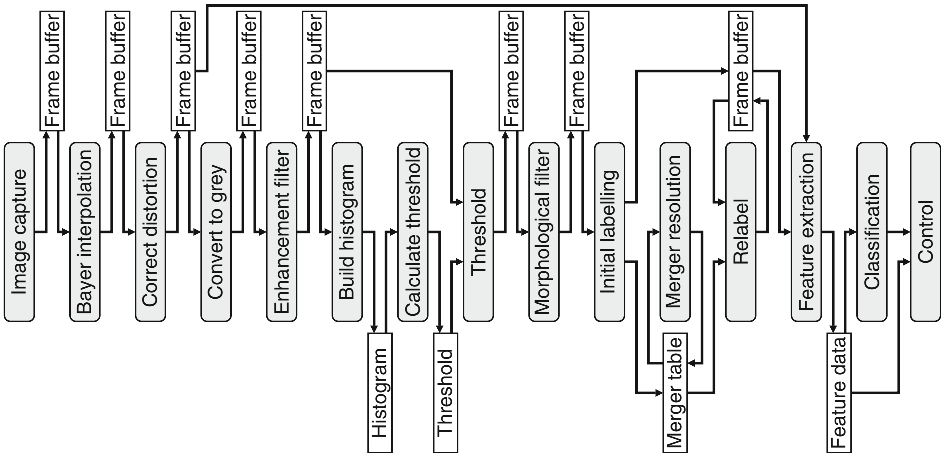


Fig. 25.7
Dataflow of software algorithm

more accurate segmentation. A simple global threshold is used to convert the image to binary. The threshold level is determined by analysing the intensity histogram of the image. After thresholding, a binary morphological filter is used to remove isolated misclassified pixels. Connected components labelling is then used to assign each binary blob (corresponding to a seed) a unique label. Then for each seed the centre of gravity, the area, and the average colour are measured. The area and colour are used to assign each seed into one of several classes, with the class and seed position passed to the control system to control an actuator that sorts the seeds on the basis of class.

The data flow through the algorithm is shown in ➲ *Fig. 25.7*. In this the connected components labelling operation is expanded out, using a standard two-pass labelling algorithm [33]. In the first pass, as the image is scanned, the previously processed neighbourhood of a pixel is examined. If none of the neighbouring pixels are labelled, a new label is assigned, otherwise the existing label is propagated. At the bottom of "U" shaped objects, two differently labelled regions merge, so the equivalence of those labels is stored in a merger table. At the end of the frame, the sets of equivalent labels are resolved, creating a mapping table from the initial label to the unique final labels. A second pass through the image uses the mapping as a lookup table to produce the output image. In software, this second pass reuses the same frame buffer for input and output.

The data flow clearly shows that a simple port of the software algorithm to hardware would not be effective. Eight separate frame buffers (or image arrays) are used, as are several other memory based data structures. In a software system, all of these data structures (along with other control variables) are maintained within a single global memory. The fact that every block is accessing memory means that the memory bandwidth will limit the extent to which the algorithm can be parallelised. Through the memory accesses, it is constrained to be a serial algorithm. To overcome the memory bandwidth problem, one simple (but not particularly practical) solution would be to use a separate memory block for each major data structure. An efficient parallel implementation requires that the algorithm be transformed, rather than simply ported [12].

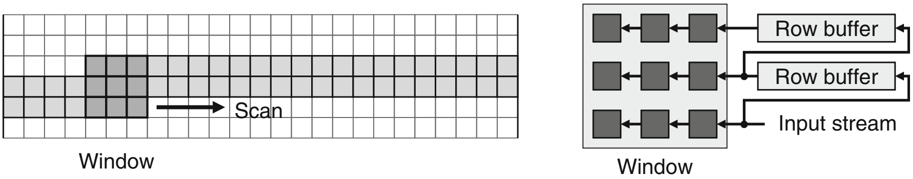
25.4.1 Pipelined Stream Processing

The main problem with the software approach is that it is memory bound. Each operation reads its input from memory, processes it, and writes the results back to memory. Stream processing can overcome this bottleneck by pipelining the operations. Rather than write the results to memory, they are passed directly on to the next operation in the pipeline, eliminating at least two memory accesses per pipeline stage. Stream processing requires that a downstream operation consumes data at the same rate and in the same order that data is produced by the operation immediately upstream. Since the outer loop of many image processing operations performs a raster scan through the image, this will be the case for those operations. Pipelined stream processing is effectively merging the outer loops of the pipelined operations, replacing a series of separate raster scans with a single raster scan but pipelining several operations within that single loop.

Point operations, where the output depends only on the corresponding input pixel, can easily be pipelined. This includes the conversion from colour to greyscale, thresholding, and the relabeling pass of connected components analysis.

Filters, which use only local information, can also be streamed since both the input and output follow the same raster scanned access pattern. However since each output pixel requires more than one pixel on the input, an operation specific cache is required to hold the input data until it is needed. Consider a 3 × 3 window filter – each output pixel value is a function of the nine pixel values within the window. In software, the input pixel values are accessed though a pair of nested loops. These loops can be unrolled and the required pixels accessed in parallel though the use of an appropriate cache. Without caching, each pixel must be read nine times as the window is scanned through the image. Pixels adjacent horizontally are required in successive clock cycles, so may simply be buffered and delayed in registers. This reduces the number of reads to three pixels every clock cycle. A row buffer caches the pixel values of previous rows to avoid having to read these pixel values from external memory again (see ➔ *Fig. 25.8*). A 3 × 3 filter spans three rows: the current row and two previous rows; a new pixel is read in on the current row, so two row buffers are required to cache the pixel values of the previous two rows. The row buffers are typically implemented using either FIFOs or circular memory buffers made from the dual-port RAM resources on the FPGA. This principle can be readily extended to larger window sizes or to other operations that require data from the previous rows of either the input or the output.

In the seed sorting algorithm, the edge enhancement and morphological filters can readily be placed in a streamed pipeline. The Bayer pattern interpolation is also a filter, although the actual filter function depends on location (which colour channels are missing); it may also be streamed. The initial labelling pass of connected components labelling propagates the output labels from the previous row. These may be cached using a row buffer, enabling this operation to be streamed as well.



■ **Fig. 25.8**
Row buffering caches the previous rows so they only need to be read once

Geometric transformations (such as that required for lens distortion correction) are a little more complex to pipeline. There are two approaches to implementing a geometric transform. In software, the usual approach is to use a reverse mapping. This determines for each output pixel where the input comes from in the image. It is therefore able to produce a streamed output, but the input requires random access, so cannot readily be streamed. The alternative is to use a forward mapping, which specifies where each input pixel maps to in the output image. This is able to operate with a streamed input, but the output does not generally follow a raster pattern. Therefore a geometric transformation will require a frame buffer on either the input or the output depending on the transformation approach used. In this application, since the output must be accessed later to measure the average colour, first analysis suggests that the forward mapping approach with a frame buffer on the output is the most appropriate.

Accumulating the histogram can be streamed, although the threshold level cannot be derived from the histogram until the complete frame has been accumulated. In many applications the histogram, and the threshold level calculated from it, will not change significantly from one frame to the next [29]. In this case, the threshold level determined from the previous frame can be used for the current image. This will reduce the latency of the algorithm by one frame, and enable the thresholding to be streamed directly from the output of the edge enhancement filter.

The input from the camera is naturally streamed, so can feed directly into the Bayer pattern interpolation without needing a frame buffer. The algorithm structure after transforming to a streamed architecture is shown in ➲ *Fig. 25.9*. It significantly reduces the number of frame buffers needed by eliminating buffers between pipelined stages. The buffer within the connected components analysis is required because the merger resolution step requires data from the complete frame. Pipelining also requires that a separate output buffer be used for relabeling the mergers. This is because the image cannot be relabelled in place because the first frame buffer is required for storing the initial labelling of the next image. Data from the lens distortion correction may actually require multiple buffers to prevent the colour pixel data from being overwritten before it is used by the feature extraction block.

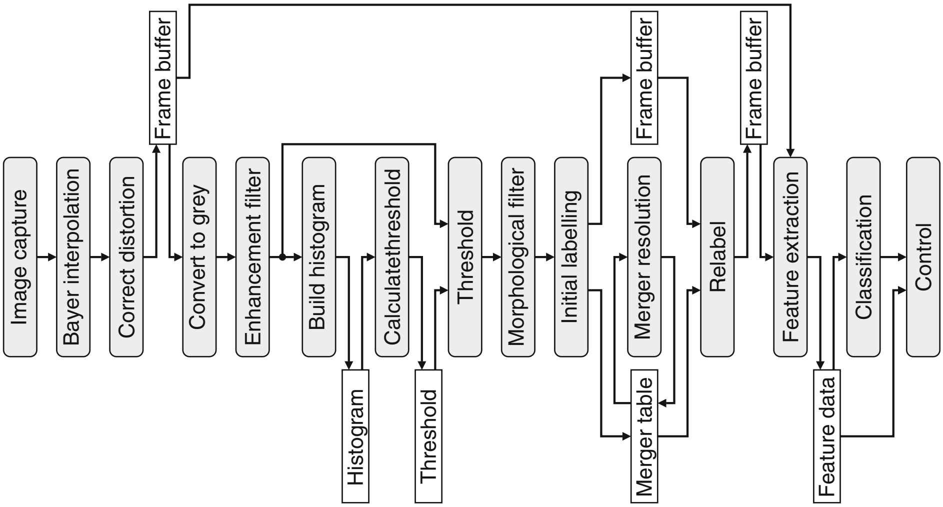


Fig. 25.9
After transformation to use a pipelined streamed architecture

The other effect of converting to a streamed pipeline is that everything becomes synchronised with the pixel clock rather than simply running as fast as possible. The reduction in clock frequency is made possible by eliminating the many unnecessary memory accesses, and exploiting parallelism through pipelining. It also has the potential to reduce the latency, although in this case it is not necessarily realised because of the remaining frame buffers. While every image is processed at the pixel clock rate, the latency is approximately three frame periods.

25.4.2 Strip Mining and Strip Rolling

The feature extraction step typically iterates through the labelled image extracting data for each label in turn. This iteration is a bottleneck within the connected components dataflow and would require an unrealistic clock rate to process all of the labels within a single frame period. However, since each iteration is processing a separate label, this step is readily parallelisable by having multiple feature extraction units. Unrolling and parallelising such loops is called strip mining. In this case, though, it creates another problem: all of the feature extraction processors would be competing for access to the single shared frame buffer. Using a streamed access would allow the frame buffer to be shared among all of the feature extraction processors. Many (but not all) useful object features can be accumulated using a raster scan through the image. This includes the centre of gravity, area, and average colour required in this application.

In this instance, however, strip-mining only partially solves the problem. Potentially there can be a large number of components within the image, requiring a large number of parallel processors to handle all of them in parallel. Images with only a few labels would leave most of the hardware sitting idle, resulting in inefficient hardware utilisation. Conversely, if only a few processors are constructed, then images with a large number of labels would require multiple passes to process all of the objects. This would require either a higher clock rate for the feature extractors, or a lower (and possibly variable) frame rate.

A second look at this problem results in the observation that each pixel can only have a single label. This implies that if stream processing is used, a single feature extraction processor may be shared for all of the iterations (strip rolling). Separate data registers must be maintained for each component with the particular registers used for processing each pixel multiplexed by the component label. Thus for each pixel, the label is used to select the data associated with the corresponding object. This data is then updated according to the pixel added, and saved again in the corresponding register. In this way, a single feature extraction processor is able to measure the features of an arbitrary number of objects in a single pass through the image.

The data register multiplexing may be readily implemented using a memory-based data table. The multiplexing hardware then comes for free, being implemented through the built in memory addressing logic. This transformation also makes the frame buffer between the relabelling and feature extraction modules redundant. Since both use stream processing, the final labels may be streamed directly into the feature extraction module, reducing both the memory requirements and latency.

25.4.3 Algorithm Optimisation

A number of other optimisations are possible. For example, the data volume and processing may be reduced by using appropriate data coding. In this application, run-length encoding may be used with connected components labelling [7] to reduce the size of the associated frame buffer. The second relabeling pass can then process whole runs of pixels as a unit, significantly reducing the latency. In this application, since the colour associated with each object pixel must be accessed, the object pixels must be processed one at a time. However, each run of background pixels can be can be processed as a unit, allowing the background to be quickly skipped. This can result in a significant reduction in the latency of the second pass as the image is typically 80–85% background for this task.

Another optimisation is to rearrange the order of the operations to simplify the processing complexity, or even eliminate some steps. A classic example of this is greyscale morphological filtering followed by thresholding. This sequence of operations is equivalent to thresholding first, followed by binary morphological filtering which uses considerably less logic.

With connected components analysis, the feature extraction step can be applied to the data during the initial labelling pass [13]. This has two significant effects on the algorithm. First, relabeling the pixel data is no longer required and the frame buffer storing the initial labelling can be eliminated. Second, the feature data table may now contain multiple entries for each connected component, corresponding to the multiple labels that are assigned during the initial labelling. The algorithm for merger resolution must now be modified to merge the corresponding separate entries within the feature data table.

A further algorithm rearrangement is to merge the feature data when the mergers are first identified. The reason merger resolution was deferred in the original algorithm was because a merger could result in relabeling a large number of pixels. However, now that the algorithm is working with regions rather than pixels, it is practical to reintegrate the merger resolution step with the initial labelling pass. Whenever two regions merge, the corresponding entries in the data table can also be merged [10].

Elimination of the frame buffers associated with connected components labelling implies that the image after distortion correction does not necessarily need to be buffered. The frame buffer may be replaced by a synchronising buffer to account for the latency between the distortion correction and feature extraction modules. Since all of the intervening operations are streamed, the delay through the operations is a constant number of clock cycles. A FIFO buffer may be used to delay the colour pixel value so that the corresponding colour value is available for the feature extraction step.

Revisiting the distortion correction step, the simpler reverse mapping may be used to give a streamed output. With lens distortion, the input will follow approximately a raster scan, implying that only a few rows rather than the whole image needs to be buffered on the input [2]. Alternatively, rather than apply distortion correction to each pixel, the distorted image can be processed, with the correction applied to the features extracted. The centre of gravity will need to be adjusted to correct for the distortion, and the area scaled to account for the fact that the magnification is not uniform throughout the image.

The result of these optimisations is shown in ➋ *Fig. 25.10*. The algorithm has been transformed so that all of the steps share a common processing mode, and are architecturally compatible. All of the frame buffers have been eliminated, reducing the latency to approximately one frame period.

25.5 Mapping of the Image Processing Operations

The previous section developed the system architecture for an example application. This section will explore the computational architecture of each operation in the resultant

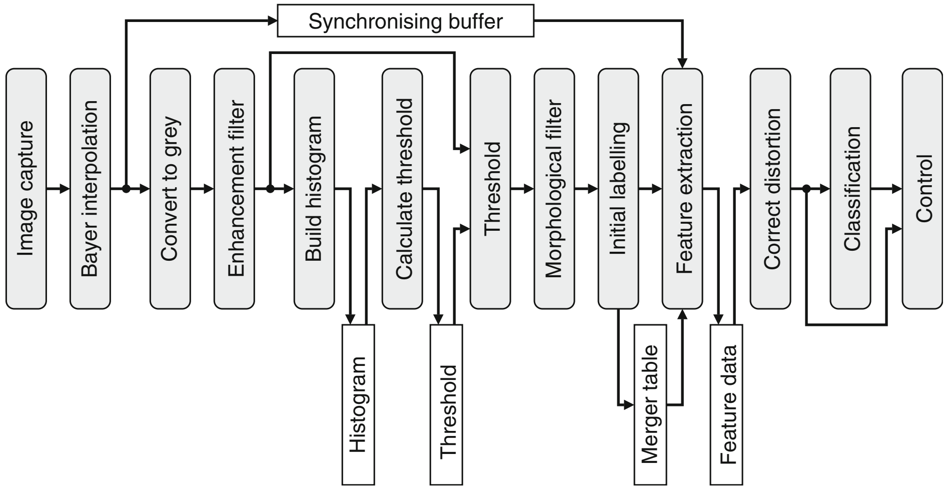

Fig. 25.10
Final stream based algorithm architecture

algorithm. The original algorithm was chosen so that the operations used are representative of the range of operations typically used in machine vision applications. Many of the points discussed here generalise to other similar operations.

25.5.1 Point Operations

Point operations are the simplest of image processing operations to implement, since the output value depends only on the corresponding input pixel value. Simple operations may be implemented directly, while for more complex operations, the mapping from input pixel value to output pixel value may be represented using a lookup table. For 8 bit images, such a lookup table requires only 256 entries and may be implemented using a single memory block within the FPGA.

The thresholding operation in the seed grading algorithm is dynamic, in the sense that the threshold level may vary from frame to frame. The simplest implementation is to subtract the threshold level from the input pixel values as they are streamed through. The sign bit of the result indicates whether the input is greater than or equal to the threshold (sign bit equals 0) or less than the threshold (sign bit equals 1). Since the background is lighter than the seeds, the sign of the difference may be used directly to indicate the presence of absence of a seed.

There are many ways to convert from a colour image to greyscale. In this application, the particular colour space is not important, so the simplest conversion is to use weights which are powers of two, since the multiplications may be implemented by bit shifting which is free in hardware:

$$\text{Greyscale} = \frac{1}{4}\ \text{Red} + \frac{1}{2}\ \text{Green} + \frac{1}{4}\ \text{Blue} \qquad (25.1)$$

Higher weight is given to green because with the Bayer pattern input, there are twice as many green pixels as red or blue.

25.5.2 Local Filters

Implementing a filter requires row buffers to cache the input stream for later use when calculating the output on subsequent rows. *Figure 25.11* shows the linear edge enhancement filter. The filter weights can be chosen to be powers of two to avoid the need for multiplications. In a direct implementation of a 3 × 3 linear filter, eight operations are required to add the nine pixel values within the window together. However, symmetries within the window allow the computation to be factorised, reducing it to five operations, as shown in *Fig. 25.11*. If the filter is separable, this generally provides the greatest opportunities for factorising the calculation.

The morphological filters can be implemented in a similar manner to linear filters, except using a logical AND of pixel values within the window for erosion, and a logical OR for dilation. Again, gains can be made if the window can be decomposed or is separable. Even if the window is not separable in the conventional sense, it can be made separable using the SKIPSM paradigm [36, 37]. Another alternative for small windows is to use a lookup table to evaluate the function. The bits within the window are simply concatenated and looked up to produce the corresponding output bit.

In this application, scattered noise pixels may be removed by using a 3 × 3 opening to remove false object pixels, followed by a 3 × 3 closing to remove small holes. The opening is performed first, to reduce the chance of objects becoming linked by noise in the background. The concatenation requires a series of three filters: a 3 × 3 erosion, followed by a 5 × 5 dilation, followed by a 3 × 3 erosion. All three filters are directly separable, simplifying their calculation.

The third filter in this application is to interpolate the missing colour components from the Bayer colour filter array. Each incoming pixel will either be red, green, or blue depending on the particular colour filter associated with that pixel (see *Fig. 25.12*). There is a wide range of algorithms for interpolating the missing colour values. Nearest neighbour and bilinear interpolation, while relatively simple and low cost, are prone to artefacts particularly around edges and in regions of fine detail. Many of the more complex algorithms are designed to reduce these artefacts, although this comes at the cost of significantly increased computational complexity, and the number of row buffers required can be quite large. One compromise described in [24] uses a 5 × 3 window requiring only two row buffers. The improvement in quality is obtained by detecting edge directionality and interpolating along, rather than across, an edge. A local gain term is also introduced to enhance fine details. The computational requirements are modest, requiring only 3 subtractions, 10 additions, 2 divisions, and 3 multiplications.

The difference between the interpolation filter and conventional filters is that the filter function varies from pixel to pixel, depending on the colour and context of the incoming pixel. This may be managed by a simple state machine.

Fig. 25.12
Arrangement of pixels with a Bayer colour filter array

One factor that has not been discussed is how to handle the edges of the image where the window extends past the edges. Additional logic is required to extend the image and correctly manage these situations. Further implementation details on managing the edge effects and related pipeline priming and flushing implications are beyond the scope of this brief overview, but are discussed in some detail in [8].

25.5.3 Histograms

Accumulating a histogram requires maintaining a series of counters, one for each possible pixel value, and incrementing the appropriate counter as the pixels are streamed in. With a set of parallel counters, the decoding logic can be quite resource intensive. Since only one counter is incremented in any clock cycle, the parallel counters may be strip-rolled into a memory structure. Each clock cycle, the memory entry corresponding to the incoming pixel value is read and incremented. On the following clock cycle, the new count is written back to memory. A dual-port on-chip memory allows the two simultaneous accesses. A problem arises when two successive incoming pixels have the same value. For the second pixel, the count read from memory will be the old count because it has not yet been updated. Therefore it is necessary to test for this condition, and use the previous count rather than that read from memory. This process is illustrated in *Fig. 25.13*.

The next step is to calculate the threshold level from the histogram. While there are many possible approaches that could be taken, in this case since the contrast is good, the simplest approach is to use the mean of means [32]. This method refines an existing threshold as the midpoint between the mean of the dark pixels (less than the threshold) and the mean of the light pixels (greater than or equal to the threshold):

$$\text{Threshold}_{n+1} = \frac{\mu_{I<\text{Threshold}_n} + \mu_{I\geq\text{Threshold}_n}}{2} \tag{25.2}$$

This calculation requires a counter to step through the histogram, and circuitry to accumulate the count and weighted count from which the two means are calculated. Equation 25.2 is normally iterated until it converges (typically three or four iterations). However, in this application, there should only be a small change (if any) from one image to the next. Therefore, a single iteration suffices. During the iteration to calculate the threshold level, the write port may be used to reset the histogram to zero in preparation for the next image.

Since only a single pass through the histogram is required, it is actually simpler to directly accumulate the pixel values and count above and below the current threshold level. The threshold block from the processing algorithm is reused to determine which set of accumulators is used, and the intermediate histogram is not actually required.

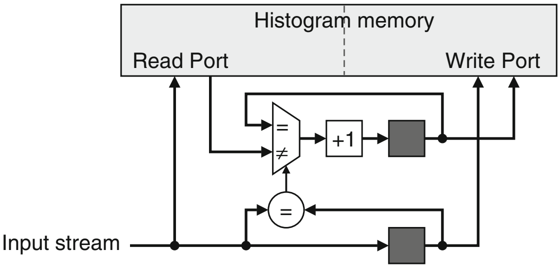

Fig. 25.13
Using dual-port memory for accumulating the histogram

25.5.4 Geometric Transformation

There are two main approaches to performing a geometric transformation. The forward mapping determines where each input pixel goes to in the output image, whereas the reverse mapping determines where each output pixel comes from in the input.

A common problem with the forward mapping is holes in the output, which result from output pixels that have no corresponding input pixels mapping to them [38]. This may be overcome by separating the transformation into two passes [16]. The first pass operates on each row, and warps the pixels to get them into the correct column. The second pass then operates on each column to get the pixels into the correct row. The advantage of the separable transformation is that the resulting one-dimensional transformations are much simpler than directly performing a two-dimensional transformation. Example hardware for performing each one dimensional transform is described in [39]. Rather than performing the two passes through the image separately, they can be pipelined [11]. In the second pass, all of the columns can be processed in parallel, with a memory based data buffer to hold the data for all of the columns. Then, when a pixel is output from the first pass, it is passed to the appropriate column in the second pass. Since the first pass scans along a row, the outputs will be for successive columns. However, as a result of the warping, the outputs from the column processing may not necessarily be successive memory locations, requiring a random access frame buffer on the output.

The alternative is to use a reverse mapping. This produces pixels in streamed order, but requires random access on the input. As a result of the mapping, the input may not fall exactly on an input pixel location, so interpolation may be used to give more accurate results. With interpolation, the integer part of the pixel location selects the nearest pixels, which are then weighted based on the fractional part of the location. This is much the same as image filtering, with the added complication that the path through the input image is curved. Since only one pixel can be read from the input frame buffer in each clock cycle, caching pixels that are likely to be reused becomes more complex (see for example [20]) because the path through the image does not, in general, follow a raster scan. If the input pixel values are stored in on-chip memory, this bandwidth limitation may be alleviated by using separate blocks of memory for both the odd and even row and column addresses. This allows four pixels to be read simultaneously for bilinear interpolation.

One optimisation that may be used with either streamed input or output is to perform incremental calculations. Rather than calculate the mapping independently for each pixel, in many cases it is possible to reuse the part of the result from the previous pixel with an incremental adjustment. In the application considered here, one model for lens distortion correction is [22]

$$r_u = r_d\left(1 + \kappa r_d^2\right) \tag{25.3}$$

where r_u and r_d are the radius from the centre of distortion in the undistorted and distorted images respectively, and κ is the distortion parameter. ➋ Equation 25.3 may be used directly with a forward mapping, or the corresponding equation for the reverse mapping is

$$r_d = r_u M\left(\kappa r_u^2\right) \tag{25.4}$$

where $M()$ is a magnification function determined through a lookup table. In either case, calculation of $r^2 = x^2 + y^2$ may be simplified through incremental calculation [22]. Along any row, y^2 is constant, and x^2 may be calculated from

$$(x+1)^2 = x^2 + 2x + 1 \tag{25.5}$$

A similar calculation may be used to update y^2 when moving from one row to the next. Another optimisation is that the size of the lookup table for determining $M()$ may be significantly reduced through using interpolation [22] (requiring a single multiplication), or bipartite tables [35] (requiring only an addition).

In the implementation of the algorithm shown in ➋ *Fig. 25.10*, the distortion correction is deferred until after the features have been measured. Correction at this stage requires calculating the both the position and area magnification functions for each object using the forward mapping. This position magnification $\left(1 + \kappa r_d^2\right)$ is used to scale the position, whereas the area magnification $\left(1 + \kappa r_d^2\right)\left(1 + 3\kappa r_d^2\right)$ is used to scale the area.

25.5.5 Connected Components Analysis

The architecture of the single-pass connected components algorithm is shown in ➋ *Fig. 25.14* [13, 26]. The label selection block determines the label for the current pixel based on the labels of its neighbours, with the labels on the previous row cached using a row buffer. Label selection follows the same approach as the classic two-pass algorithm for propagating the label. When two regions merge, the smaller of the labels is propagated. The merger control block records the equivalence by updating the merger table so that the larger label points to the smaller. Whenever a new label is created, the merger table is initialised by adding a new entry that points to itself. The role of the merger table is to ensure that only the current label for a component is used.

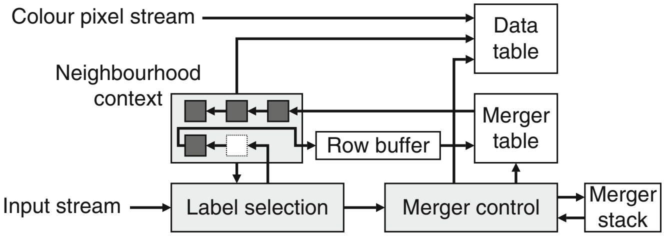

Fig. 25.14
Single pass connected components analysis computational architecture

Any old merged labels cached in the row buffer are translated to their equivalent label before reloading into the neighbourhood context.

When there is a series of mergers with the smaller label on the right, each merger requires updating several equivalent labels. This cannot be completed in the single clock cycle required. These chains may be resolved with a reverse scan of the row during the horizontal blanking period between rows. To accomplish this, pairs of equivalent labels where the smaller label is on the right are pushed onto the merger stack and at the end of the row they are popped off in reverse order for updating the merger table [13].

As the image is scanned, the data table accumulates the raw data for calculating the features of each connected component. The data table is indexed by the label of the current pixel, with the entry updated to include the current pixel within the region. Whenever two regions merge, the corresponding entries in the data table are also merged.

In the seed grading algorithm, six accumulators are maintained for each region: pixel count (for the area), sum of x and sum of y (for the centre of gravity), and the sum of each of the red, green and blue components (for the average colour). When two regions merge, the sums for each of the regions are added together to give the sum for the new composite region.

The size of both the merger and data tables depend on the number of labels that are allowed. To handle the worst case (one that will correctly process every possible image), the number of labels is one quarter of the number of pixels within the image [14]. (In this application, the use of the morphological filter reduces the worst case to 1/36 of the number of pixels in the image, but this is still proportional to the area of the image.) For typical images, such as those that will be encountered in this application, the number of labels needed is much smaller. A pragmatist would argue that as long as it handles the number required then that is sufficient, whereas the purist would require that it handle anything that could be given to it.

An observation is that at any time, the maximum number of labels in use depends only on the width of the image. This means that it should be possible to reuse the labels of completed objects. The next optimisation is to recycle labels from one row to the next [14, 28]. Since a labelled image is not required, the labels on each row can be allocated almost independently of the labels on previous rows as long as the labels are consistent with the connectivity as determined to that point. Therefore, assuming that the labelling is consistent for the previous row, it is only necessary to process the objects sufficiently to obtain a consistent labelling at the end of the current row. As each pixel is only visited once, it is necessary to have data structures to record merging of regions on the current row. The simplest label allocation scheme is to allocate labels sequentially on each new row. This requires that labels assigned on the previous row be translated to those used on the current row. The resulting optimised architecture is shown in ➲ *Fig. 25.15*. Its operation will be outlined here, with more details available in [28].

The label equivalence table is now split into two tables, with the merger table reflecting equivalences between labels on the previous row, and a translation table to update labels from the previous row to the current row. Two merger tables are required: one to look up mergers that have taken place in the previous row, and one to record new equivalences in the current row. At the end of each row, the table for the current row becomes the lookup table for the previous row, and the old table is reset for the new row. The translation table is built as the row is scanned, and is discarded at the end of the row.

Label selection logic and merger control are now slightly more complex than before. A new label must now be assigned each time a region is first encountered on a row. Old row labels on the previous row in the neighbourhood are updated with the new label, and the translation recorded in the translation table. If there happen to be two different previous row labels, then

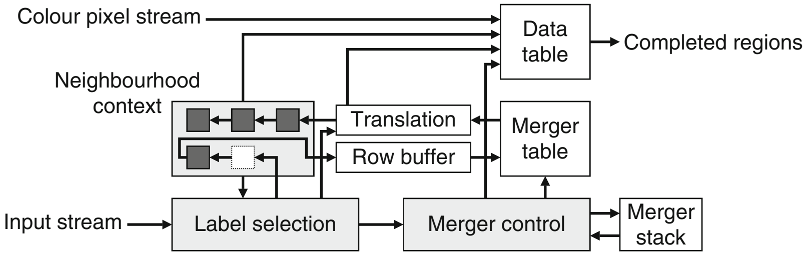

Fig. 25.15
Optimised computational architecture for connected components analysis

this merger is reflected in the state of the translation table. A merger is only recorded in the merger table when two current row labels in the neighbourhood merge. Otherwise the merger control block operates in much the same way as before.

Since the labels are changed with each new row, the data table must be replaced as each row is processed. Two data tables are required: one indexed by the current row labels, and one indexed by the previous row labels. Whenever a new translation is entered into the translation table, the feature data is copied to the current table and deleted from the previous table. Mergers entered into the merger table merge the data in the current table as before. At the end of the row, any entries remaining in the previous feature data table correspond to completed regions. The region feature data may be passed out at this stage rather than waiting until the end of the image.

Although two merger tables and two data tables are now required, these are both much smaller than before, being proportional to the width of the image rather than the area. This can significantly reduce the size of the memory required, even for a system that handles only the typical rather than worst case [14]. Another advantage is that the region data is available one row after the region is completed, rather than having to wait until the complete frame has been processed. This can significantly reduce the latency, especially for objects near the top of the image.

25.6 Interfacing

In any machine vision system, it is necessary to have input from a camera or other sensor. Since the primary purpose of a machine vision system is to autonomously perform an activity, it is usually necessary to control some form of actuator. It is often also necessary to have some form of display output, even if only to demonstrate to an operator that the system is working. In many applications, a user friendly display is important. Depending on the context, it may also be necessary to accept control input from a user, and to interface with a software processor. This section will briefly outline some of the possibilities and issues with interfacing between a vision algorithm on an FPGA and external devices.

Connecting to an analogue video camera requires appropriate decoding of a composite video signal, and high speed A/D converters for each colour channel. While this is simpler for a monochrome camera, the easiest and tidiest solution is to use an appropriate codec chip. This performs all the necessary filtering and conversion of the analogue signal to digital, and directly provides a pixel clock and the end of line and end of frame timing signals. Configuration of such codec chips is typically through some form of low speed serial interface. The communication protocol of such interfaces is usually sufficiently simple that a small control block can be built with FPGA logic to set up and control the device.

More modern commodity cameras have a USB or Firewire interface. Although they are digital, they are actually harder to interface to because they are based on a more complex communication protocol. The USB protocol requires a central controller which makes USB cameras quite difficult to interface to FPGAs. Firewire is a peer-to-peer protocol, reducing the complexity of the interface. Rather than interface directly, it is advantageous to use an external physical layer controller to manage the physical communication, timing, and arbitration logic. Similarly, using an external link layer controller simplifies the interface by correctly forming the packets and providing a higher level interface, including an integrated FIFO buffer. Integrated physical layer and link layer devices are also available that can be connected through a PCI express endpoint on high-end FPGAs.

An alternative is to interface directly with the CMOS imaging sensor if integrating the FPGA into the camera itself. Such cameras typically provide the pixel data using a parallel digital output which can be easily interfaced directly to the FPGA. If using an external camera, an industrial camera with a CameraLink interface is another way of connecting the digital video signal to the FPGA. The CameraLink standard [1] uses 28 bits to represent 24 bits of pixel data and 4 bits for synchronisation signals. The data is serialised over five LVDS pairs, four of which are used for data, and one for the clock. The signals may be interfaced directly with the LVDS I/Os available on FPGAs, and the communications protocol is sufficiently straightforward to require minimal control and decoding logic.

While most machine vision systems do not need a display for normal operation, having a video display is essential for algorithm debugging and tuning, and setting up the system. A driver for a VGA type display requires two counters: one for the counting the pixels across the row, and one for counting the rows in a frame. From these, the synchronisation pulses and blanking signals may be generated at the appropriate times. Producing an analogue signal for display may be achieved simply with a resistor divider network for low resolution displays. Higher resolution displays would either require high speed D/A converters (available as codecs integrating the blanking and synchronisation signals) or use of the digital visual interface standard [17]. This encodes each of the red, green and blue channels using a 10-bit transition minimised code, with the signals sent serially over four differential pairs (one for each colour and one for the clock). Signals for lower resolution displays may be produced using the general purpose I/O pins of the FPGA, although high resolution modes may require the built in serialisation of high end FPGAs to achieve the required bit rates.

For simple displays, it is possible to synchronise the display with the processing data stream, allowing images to be displayed on the fly without the need for a frame buffer. More complex display layouts, for example showing several images, will require an external memory to buffer the display contents. Using a frame buffer has the advantage that the display contents can be frozen to enable debugging. Additional logic is also required to direct the appropriate image data to the corresponding location in the frame buffer. Arbitration logic and FIFO buffers may be required to manage conflicts between writing to the frame buffer and reading data from the buffer for display. Any text written to the display will require character generation logic either when writing to the frame buffer, or as an overlay when producing signals for the display.

The logic required to control an actuator obviously depends on the type of actuator controlled. This may vary from sending high-level data to an external controller (for example using a serial port) through to implementing the controller logic on the FPGA, and providing low-level actuation signals directly to the actuator. In systems with an associated software processor or microcontroller (either separate or embedded within the FPGA) this may be used for implementing more complex control algorithms.

For debugging and tuning, some form of control input from a user is usually required. Interfacing with a PS/2 keyboard or mouse is straight forward because the associated serial protocol is relatively simple and low speed. The logic required to act on the commands received may however be more complex. In simple cases, this may be built using a relatively simple finite state machine in the logic of the FPGA. More complex logic would require considerable resources on the FPGA which would be underutilised. In this case, using a software based processor can more efficiently manage the associated operations.

Similarly, more complex high-level vision processing operations may be more efficiently performed in software than in hardware on the FPGA. Interface between a serial processor and the FPGA may take place in a number of ways. At one extreme, the FPGA may be mapped into the memory address space of the serial processor. This may be implemented using one or more dual-port memory blocks as shared memory, with one port accessible from the logic implemented on the FPGA, and the second port reserved for use by the serial processor. Shared memory is well suited for transferring large volumes of data between the systems. Alternatively, the FPGA can provide one or more control and status registers to the serial processor, with these mapped into either the I/O or memory address space. Providing such an interface to an external processor requires relatively little decoding logic unless a large number of registers are required. For looser coupling between the FPGA and external processor, a standard serial communication link could be used. Such a link is best suited when only low data volumes must be transferred between systems.

25.7 Algorithm Tuning and Debugging

Many algorithms have threshold levels and other parameters that must be tuned to give the best results. Where possible, the algorithm should be developed so that it is self-tuning as much as possible, because this reduces the opportunities for an inexperienced operator to mistune the algorithm. However, this makes the algorithm more complex and is not always practical.

One solution is to tune the algorithm once when it is initially developed, and hard wire the corresponding parameter values into the algorithm. Changing any parameter then requires recompiling and remapping the complete design. A more practical alternative is to store the parameters in registers where they may be modified either from a separate software process or through user interaction implemented in hardware. In the latter case, additional logic will also be required to load the initial parameter values from an external flash memory or other non-volatile storage.

When running with a host computer system, many of the tuning functions can be performed and controlled by the host computer. When running in a standalone configuration, it is necessary to build all of the required user interface logic into the FPGA [15]. Sometimes the additional logic required may be more extensive than the actual application. This may be managed by building multiple configurations: one for running the application, and one or more for tuning. The tuning configuration may not necessarily require all of the application logic, for example the actuator control logic can often be omitted. During tuning, it may be necessary to display additional information, such as images that show the effects of changing each control parameter. Once tuned, it is necessary to save the parameters in non-volatile storage before loading the configuration file with the actual application. This is because reconfiguration will replace everything within the FPGA, including the state of latches and the contents of any memories.

The requirements for system and algorithm debugging are similar to those for tuning. It is often important to view the results at various stages throughout the algorithm to check that it is operating correctly. Debugging an algorithm in hardware is much more difficult than in software because it is very difficult to stop a hardware algorithm and single step through it. In software, only one thing is happening at a time, but in hardware all of the components operate concurrently with the consequence that the system can change state considerably with each clock cycle. This is also complicated on an FPGA based design because almost all of the signals are internal to the FPGA and are therefore not even accessible for testing. In simple applications, key control signals can be routed to I/O pins to enable them to be tested.

Many of these problems may be reduced by thoroughly testing the algorithm in software before implementing it in hardware. It is important that these tests are performed on the algorithm after transformation for FPGA implementation, and not just the original software algorithm. This ensures that the algorithm is correct and the final FPGA implementation step becomes one of verifying that the algorithm is behaving as designed and tested in software. Incremental development techniques can help identify and eliminate bugs in this mapping process. Each operation is implemented one at a time, with the design mapped and placed onto the FPGA and tested before adding the next operation. While rebuilding the FPGA configuration after adding each operation is quite time consuming, it can reduce time overall by simplifying the time required for debugging and testing.

Unfortunately it is not possible to test every possible case before implementing the design. This is especially so when dealing with high speed, real time systems such as required for machine vision. During the initial development and early deployment, it may be necessary to capture the images that cause the algorithm to fail for more thorough testing offline. This requires saving each image before it is processed so that it is available later. Two approaches may be used here. One is to run the system slower, capturing the input image into a frame buffer and from there saving it to an external storage device before executing the algorithm. This may require substantial changes to both the design and operation of the system. A less invasive approach is to have a parallel system that is capable of both recording and playing back a video stream at the full processing rates. While requiring considerably more development effort, such a tool would allow testing at the full operating speed enabling complex dynamic bugs to be investigated.

If the design must be debugged in hardware, one approach may be to route key signals to unused I/O pins to make them accessible from outside the FPGA. This still requires connecting an external logic analyser or oscilloscope to the pins to monitor the signals. Both Xilinx and Altera provide logic analyser cores that may be embedded within a design. These record selected signals in an internal memory block, from where they can be read out and analysed by an external programme.

Whatever debugging and tuning techniques are used, it is important for them to be integrated into the design process and not just added on at the end.

25.8 Summary and Conclusions

Field programmable gate arrays have the potential to significantly accelerate the image processing component of a machine vision system. Most machine vision algorithms are dominated by low and intermediate level image processing operations, many of which are inherently parallel. This makes them amenable to a parallel hardware implementation on an FPGA.

Compared with a software implementation, gains are made in two ways. First, a software implementation is constrained to executing only one instruction at a time. Although the phases of the instruction fetch/decode/execute cycle may be pipelined, and modern processors allow different threads to be executed on separate cores, software is fundamentally sequential. A hardware implementation, on the other hand is fundamentally parallel, with each operation or "instruction" implemented on separate hardware. In fact a hardware system must be explicitly programmed to perform operations sequentially if necessary. If an algorithm can be implemented in parallel to efficiently make use of the available hardware, considerable performance gains may be made.

Second, a serial implementation is memory bound, with data communicated from one operation or instruction to the next through memory. A software processor therefore spends a significant proportion of its time reading its input data from memory, and writing the results of each operation (including intermediate operations) to memory. On an FPGA system, each operation is implemented in parallel, on separate hardware. This allows data to be passed directly from one operation to another, significantly reducing or even eliminating this memory overhead. Memory bandwidth is also considerably expanded, because rather than operating with a single monolithic memory model as software does, multiple small memory blocks are available to be used independently and in parallel.

Despite efforts to make programming FPGAs more accessible and more like software engineering [3], efficient FPGA programming is still very difficult. This is because programming FPGAs is hardware design, not software design. Although many of the languages look like software, the compilers use the language statements to create the corresponding hardware. Sequential algorithms ported from software will by default run sequentially, usually at a significantly lower clock speed than high end CPUs. Relatively simple changes to the algorithm, such as pipelining and loop unrolling enable it to exploit some of the parallelism available, and this is often sufficient to compensate for the lower clock speed of FPGAs. However, the algorithm is still largely sequential unless it has been specifically adapted for parallel execution. The software-like languages are in reality hardware description languages, and efficient design requires a hardware mindset.

The operations within a software based image processing environment have been optimised for serial implementation within that environment. Simply porting a software algorithm onto an FPGA will generally give relatively poor performance, because it will still be predominantly a serial algorithm. Such an FPGA implementation will generally give disappointing results. This is because the performance of an FPGA based design is very sensitive to the quality of the implementation [23]. It is necessary to transform the algorithm from a software based implementation to one that can efficiently exploit the parallelism available from hardware. Such transformation requires three stages: algorithm analysis, computational architecture design, and implementation. Algorithm analysis looks at the whole algorithm to determine the structure. It is desirable, where possible, to make all of the algorithm steps share a common processing mode. This may change the underlying algorithm to one that is more readily able to map efficiently to a hardware implementation. The second step involves designing the computational architecture that is implied by the algorithm. This may require further transformation of the algorithm to result in a resource efficient parallel architecture. The final step is to then map the algorithm onto the architecture to obtain the resultant implementation. This process can be iterative with the algorithm and architecture mappings being updated as different design decisions are made. Good algorithm transformation is currently beyond the capabilities of automated development tools (although pipelining and loop unrolling can be automated to some extent). The design process requires a human in the loop who understands the detailed operation of the whole algorithm and is thinking in terms of efficient hardware design.

This algorithm transformation process has been demonstrated with a relatively simple classification example. While the high-level image processing algorithm is relatively unchanged, at a lower implementation level, it bears little resemblance to its software counterpart. In particular, the memory requirements are significantly reduced; so much so that in this case the design has been reduced from requiring eight separate frame buffers to one where the image is not actually stored anywhere during the processing. The whole processing is performed on the data as it is streamed from the camera. This not only affects the processing speed, but also significantly reduces the latency, with most of the results being output even before the image has been completely input.

The benefits of an FPGA based implementation are obvious, even from this relatively simple example. What is less obvious are some of the pitfalls and limitations of FPGA based design. First, as has been emphasised in this summary, it requires a different skill set to conventional software based image processing design. In itself, this is less critical with the design of machine vision systems as a wide range of both hardware and software skills are required within the development team [9]. Second, the design, development, and debugging of concurrent hardware systems is both more difficult and time consuming than developing the equivalent software based system. This is partly because the system is effectively developed twice, first as software, and then as hardware. Therefore, if a software based system is effective for the task, it is probably not worth considering an FPGA based implementation. Third, the clock rates are typically one to two orders of magnitude lower in an FPGA design than on a high end CPU. Therefore the parallel design must accelerate the algorithm by at least 10–100 times just to break even. Amdahl's law requires that between 90% and 99% of the algorithm be efficiently parallelisable just to run at the same speed as a serial implementation on a high end CPU. To gain any significant real acceleration or reduction in latency, an even higher percentage of parallelism needs to be exploited.

Fortunately, the low and intermediate level image processing operations typically used in a machine vision algorithm are readily parallelisable. An FPGA implementation results in a smaller and significantly lower power design that combines the flexibility and programmability of software with the speed and parallelism of hardware.

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_26,

Abstract: A vision system for gauging two types of automotive parts is described in this article. One of the part types is a power steering connector, in which the depth and width of the groove, and the distance between the start of the groove and the end of the power steering line are gauged. For the second type of part, a crimped connector attached to a brake hose, measurements of interest are the two diameters of the crimp and the bell length, where the hose is inserted into the connector. A standard video camera is used to acquire the image of a back-illuminated part which is digitized and captured with a frame grabber. The basic hardware to accomplish the gauging tasks consists of a standard video camera, light source, frame grabber and industrial personal computer. In order to minimise hardware costs, a standard 50 mm C-mount camera lens and extension tube was used with the video camera. Consideration had been made to use more expensive telecentric optics so that parts placement would not cause a change in magnification with a resulting loss of accuracy. With the 50 mm lens, however, magnification effects were lessened due to the greater standoff distance between camera and part. Combined with a modern personal computer, rapid image acquisition and analysis provides 100% inspection at full production rates. Since the gauging rate exceeds the production rate by a significant factor, a single computer and frame grabber with camera multiplexer can process data in real time from up to four measurement stations simultaneously.

26.1 Introduction

With advances in microelectronics, it is possible to assemble a vision system for less than $1000 with some applications. New personal computers have processing capabilities that were only available in much more expensive workstations several years ago. Advances in multimedia hardware have provided very inexpensive image acquisition capabilities, and improved image analysis techniques have reduced the need for highly regulated (and expensive) illumination sources.

Many applications, of course, cannot be addressed with this type of hardware, especially if extensive image analysis and processing must be accomplished in a short time or if special hardware is required for image acquisition. However, for suitable applications, economical solutions are possible. This chapter describes a low-cost gauging system for two families of automotive parts, a power steering connector and a brake-hose connector.

In order to gauge these parts, a video camera is used to acquire a back-illuminated image or silhouette of the part (see ➋ Chap. 41). The video image is then digitised with a frame grabber and stored in computer memory. The digitised image is processed so that key features in the image are identified and the number of pixels between these features are found and converted to physical dimensions using a calibration factor.

Both part types need to be fabricated correctly. If a given part is out of tolerance, it can significantly degrade the safety and reliability of a vehicle where it has been installed. A back-illuminated image of a power steering connector is shown in ➋ *Fig. 26.1*. Here, the feature of interest is the groove which appears as the "notch" in the narrower part of the profile. ➋ *Figure 26.2* is an image of a brake-hose crimp. The features of interest here are the minimum diameters of the two crimped regions and the location of the leftmost minimum diameter to the end of the fitting. ➋ *Figures 26.6* and ➋ *26.7* provide additional details on these measurements.

The basic hardware to accomplish the gauging tasks consists of a standard video camera, light source, frame grabber and industrial personal computer. A standard 50 mm C-mount

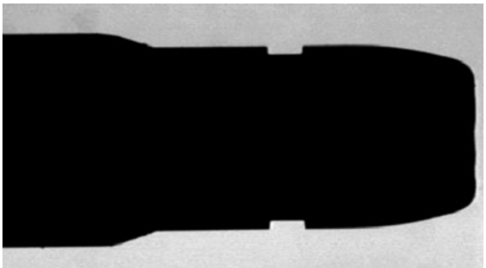

Fig. 26.1
Power steering connector

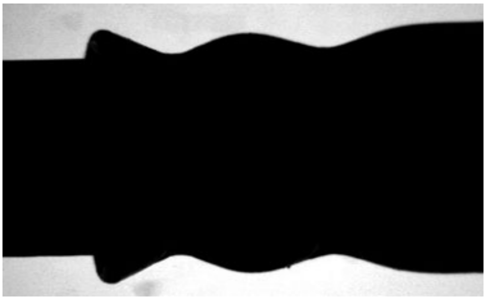

Fig. 26.2
Brake-hose connector

camera lens and extension tube was used with the video camera. For image acquisition, a low-cost frame-grabber card was selected. With a modern personal computer, rapid image analysis can be performed so that every part can be gauged at production rates. In fact, gauging speed exceeds production rates by a significant factor so that a single computer and frame grabber is able to measure parts at up to four stations simultaneously. Each station consists of a video camera and illumination source plus any necessary fixturing hardware. A camera multiplexer is used with the image capture hardware to access image data from each camera.

In order to provide a user-friendly system, a graphical user interface has been developed which displays inspection results, keeps a log file of results, and provides setup and calibration modes. A tolerance file can be created and modified for each station through the interface.

Various aspects of the system are described in the following narrative starting with optics and illumination considerations. This is followed by descriptions of the computer hardware and the gauging algorithms developed for this system. Aspects of the graphical user interface are then presented. In the last section, results and general observations are presented.

26.2 Optics and Illumination

Since the parts were to be back illuminated, it might be assumed that few lighting problems would be encountered. While this is basically true, light reflecting off of the camera lens would sometimes cause bright areas within the silhouetted part and cause measurement problems as

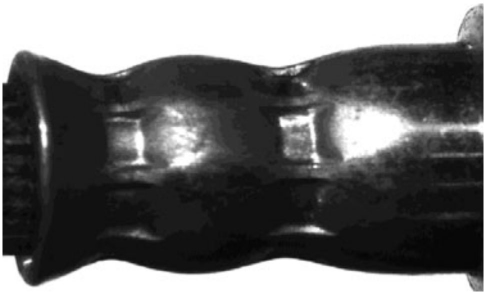

Fig. 26.3
Specular reflections

illustrated in *Fig. 26.3*. To minimise this problem, both software modifications, described later, and optical modifications were made. The classic optical solution, circular polarisation, was employed by inserting a polarizer between the object and camera lens at a 45° angle to the direction of illumination. This ensured that little light could be reflected off of the polarizer onto the part, since the polarizer greatly attenuated light reflected from the camera lens.

Rather than use a highly regulated and expensive light source, the decision was made to provide software compensation for illumination variations as described in Sect. 26.4. The main requirement was that the illumination be fairly uniform, which is not difficult given the small area of the light source. Since available space is limited, the light source needed to be compact. Initially, a fibre optics source was used, which provided excellent lighting and allowed the bulky halogen lamp and transformer to be placed some distance away from the inspection area. However, since this approach was expensive, an alternative and much less costly approach was used. Here, a low-power compact fluorescent lamp was used which is only slight larger than the fibre optics source if the ballast is located at some distance from the lamp.

In order to reduce magnification effects due to object placement relative to the camera, a 50 mm focal-length camera lens was chosen. This increased the distance between the part and camera and ensured that only relatively parallel light rays would be imaged onto the CCD array in the camera. Telecentric optics would have been a better solution but would have increased cost significantly.

26.3 Computer Hardware

As noted in the introduction, the overall system costs needed to be kept very low. Since relatively simple processing is required, reasonably high-powered PC compatible hardware can handle all of the processing. Similarly, suitable image capture hardware is required but can be satisfied with capture cards using chip sets originally developed for multimedia applications. The choice of computer processor is not critical and as noted in the discussion of the software, just about any modern personal computer will be suitable. For obvious reasons, the computer should be appropriately packaged for plant use to provide sufficient protection from the environment and ease of maintenance.

Since any standard video source should work with the image capture card, a wide range of cameras can be used for this application. However, because there is a camera for each of the four stations, costs will be raised significantly if an expensive camera model is chosen. Fortunately, there are low-cost cameras available with the necessary features such as the ability to disable gamma correction and automatic gain control. As noted previously, a camera multiplexer is used to interface the four cameras to the image capture card. USB cameras represent a newer cost-effective option but were not available during the development of this system.

In order to interface the gauging system to production equipment, a digital control card was used with optically isolated inputs and relays to provide high isolation with plant programmable logic controllers or similar hardware. When a part is in place and ready to be measured, a signal is sent to the card to initiate an image acquisition and analysis cycle. The result is sent to hardware which controls the accept/reject mechanism.

26.4 Software Development

Processing requirements for the applications of interest here are basically straightforward since the back-illuminated parts provide very high contrast and don't require complicated grey-scale operations. In order to provide adequate robustness, there are some desirable enhancements that should be provided through processing. These include the ability to handle contaminants present on the illumination source, contaminants on the actual parts, and lighting variations. The ability to accommodate lighting variations is especially important when using a low-cost source like the fluorescent lamp described previously. In addition to the image analysis software, support for accommodating up to four cameras is also required along with a user-friendly interface suitable for plant use.

26.4.1 Image Analysis Algorithms

While sophisticated image processing techniques could be used to reduce illumination dependencies, a routine to provide automatic threshold selection, based on the image histogram, was chosen. Otsu's technique works well for this application and was incorporated into the software [1]. In order to prevent serious errors if the illumination source should fail, or if no part is in the field-of-view, additional tests on the histogram are performed. These tests basically verify that there is a sufficient range of grey levels between the brightest and darkest region of the image.

Other algorithms were also optimised to improve system reliability and robustness. After obtaining the threshold, connectivity analysis is performed. Ideally, only a single large blob should be obtained, but the presence of contaminants on the light source often generates spurious blobs which must be eliminated. Several tests are used to identify the correct blob including size (pixel count) which is the most reliable predictor for blob identification.

Other concerns are that the silhouette of a part being gauged could become corrupted by a contaminant, such as a fibre, or that a new part type may have a somewhat different shape from those that were used to develop the measurement algorithms. Members of a family of parts will have similar shapes but size will vary, as well as the location for particular measurements. This implies that a given algorithm must be sufficiently robust to handle such variations. The approach used here was to convert the contour of the part being gauged into a one-dimensional signature and process this signature to identify key features.

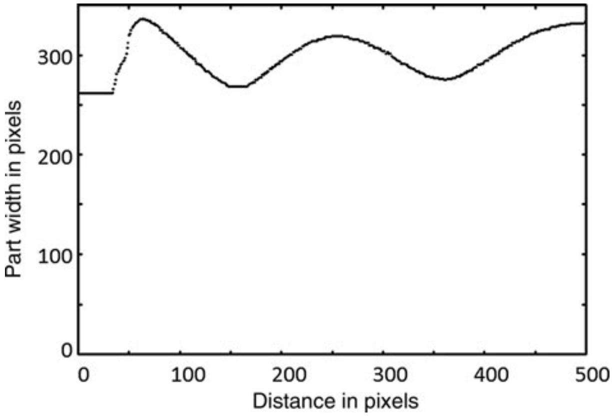

Fig. 26.4
Signature of brake-hose crimp

One-dimensional morphology is very useful both to eliminate distortion caused by contaminants and to identify the key features for measurement [2]. The basic technique for feature detection can be described by considering the signature for the brake crimp which is given in ➋ *Fig. 26.4*.

This signature was obtained by subtracting the bottom edge points from the top edge points of the binarised silhouette of ➋ *Fig. 26.2*. Since the part is symmetrical, the plot looks very similar to the top of the crimped connector. One potential problem here is that even if the part is rotated by even a small amount, the resulting lack of symmetry will adversely affect measurement accuracy. By fitting an ellipse to the binarised image of ➋ *Fig. 26.2*, the angle of the major axis can be found. A transformation is then applied to the edge points to compensate for the rotation.

Applying opening and closing operations with a small structuring element removes any distortions caused by contaminants and video noise. A closing operation is then applied to the signature with a structuring element of around 100 pixels so that the "valley" regions are filled in as shown by the horizontal lines above the signature plot in ➋ *Fig. 26.5*. Subtracting the original signature from the closed signature provides the points shown at the bottom of the plot. Here, the two "humps" correspond to the valley regions to provide an easy way to find the minimum diameters. This may seem to be overly elaborate since relatively simple search routines also work, but it is inherently more reliable over a wide range of connector sizes and shapes.

The other feature that needs to be detected for this type of part is the location where the hose and connector meet on the left side of ➋ *Fig. 26.4*. This can be found by taking the derivative of the original signature. Using the analogy of an electrical signal, this part of the connector has a "fast rise time" with a corresponding large derivative and so is easily detected.

26.4.2 Coding Considerations

These algorithms were all initially developed using the C programming language with a command-line interface. However, since the system was going to be used in a plant environment, a Windows interface was required. A relatively simple approach to achieving this goal was to write the user interface in Visual Basic and have it spawn the existing command-line

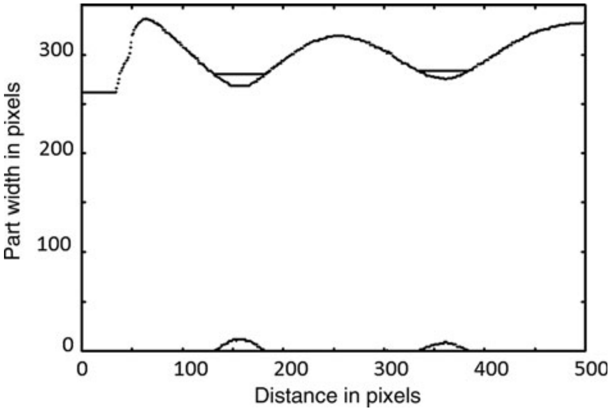

Fig. 26.5
Processing crimp signature

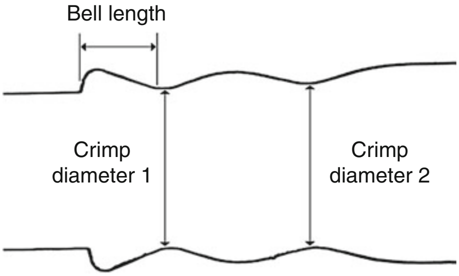

Fig. 26.6
Crimp measurements

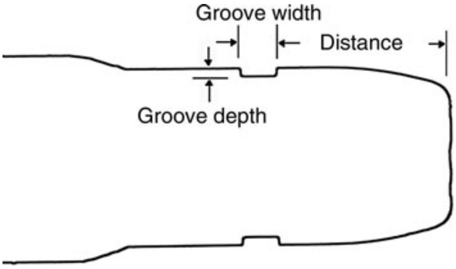

Fig. 26.7
Power steering connector measurements

executable. Visual Basic provides a straightforward means of developing Windows interfaces, and the image analysis code would not have to be rewritten.

While this approach worked, it was not very efficient given the time that was needed to spawn command-line executable code. An alternative technique was to have the analysis programme begin executing and wait to receive a signal that a part was in place which would then be gauged. Data would then be sent to the GUI so that updated results could be displayed. Unfortunately, such programmes did not share resources efficiently under a multitasking environment, so this approach was dropped.

To overcome these problems, the original image analysis code was ported to Borland's C++ Builder so that all of the software would be included in a single executable routine. The image analysis code required little modification for this, except for some C++ wrappers for interfacing to the GUI routines provided by C++ Builder. GUI development with this package was similar to Visual Basic and was straightforward considering the magnitude of work required to develop this type of interface without visual tools. The fully integrated software was much more efficient with processing times of about 1 s for a 133 MHz Pentium processor and would be correspondingly shorter with faster microprocessors. With production rates around of 5 parts/min, the system could accommodate multiple gauging stations as mentioned earlier.

However, enhancing the original gauging system so that it could handle four individual stations raised a number of software issues. Since parts in two or more stations would, on occasion, be arriving nearly simultaneously, some kind of multitasking or scheduling was required. For this reason, the approach employed used threaded code with a new thread created each time a part was ready to be gauged. It may be noted that with modern multi-core processors, very efficient and fast execution is obtained.

26.4.3 Production User Interface

A user-friendly interface was needed for setting up each of the workstations in order to control the image acquisition and processing routines as well as display the results to the user. In addition, it recorded the results in a separate inspection log for the inspected products.

The GUI contains four different forms: tolerance settings, calibration, gauging and process information. The tolerance menu is shown in ➋ *Fig. 26.8* and requires that the user sets three

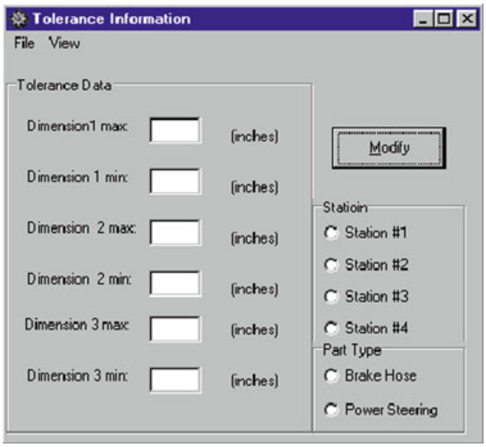

Fig. 26.8
Tolerance menu

values. When the part type is selected, the text changes to identify the actual measurement parameters. The user then selects the station and enters the values which are saved by the system.

The Calibration menu, shown in ➲ *Fig. 26.9*, prompts the user to insert a calibration rod of known diameter horizontally, within the field-of-view of the camera. The system acquires the image and calculates the Y scale factor. The user is then prompted to insert the rod vertically in the field-of-view so that the X-scale factor can be calculated.

Once tolerances have been set and the station calibrated, gauging can be performed using the main interface given in ➲ *Fig. 26.10*. The user needs to select the station, part type and the mode of operation. The operating mode can be automatic for normal production use or single mode for setup and testing. When the part type is selected, the generic text for the three dimensions is replaced by the actual parameters. A running count of accepted and rejected parts is displayed and a log file is maintained which can be displayed or cleared as desired.

26.5 Results and Recommendations

An evaluation of measurement accuracy indicated that consistent measurements within one or two pixels have been achieved. The system has also been tested under various conditions such as no illumination, part missing or part moving during image acquisition. The last condition is especially problematic because the two fields of the interlace can be quite different, resulting in an extremely distorted image. This affects connectivity in an especially adverse manner since a large number of irregular blobs may be generated. If the handling system is functioning properly, this should not happen but software routines to detect this fault were provided.

The interlace problem is one of the many drawbacks with RS-170 technology, although low-cost progressive scan cameras are becoming available. However, problems remain with standard analogue cameras in general, especially for gauging operations. While line-to-line repeatability is very good, progressive scan cameras still suffer from pixel jitter, unless the camera and capture hardware have synchronised pixel clocks. Achieving this is not necessarily easy or inexpensive.

A better solution is to use a digital camera. Low-cost digital cameras suitable for machine vision applications have become available since the original work was performed and would be a much better choice for this and similar applications. Such a camera will improve repeatability, and the potential exists for an order of magnitude improvement in accuracy using grey-scale interpolation techniques. While additional processing would be required, this is not likely to increase processing times given the substantially more powerful processors that are now available.

26.6 Conclusions

The vision system described here is inexpensive and can provide 100% inspection for up to four different measurement stations. It provides sufficiently accurate measurements for the intended applications and features a user interface suitable for production.

27 Automated Handling of Coils with Flying Leads

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_27,

Abstract: During the manufacture of audio equipment, there is a need to use a robot to handle small cylindrical coils with flying leads (i.e. attached at only one end). A minimum of five cameras is needed: one overhead and four others, viewing the sides of the coil. High-contrast images can be obtained using back-lighting. Simple thresholding can then produce "clean" binary images. From the plan view of the coil, it is possible to locate the wire ends in the horizontal, [X,Y], plane.The reasoning needed to choose the best side view is well suited to PQT (➋ Chap. 23) but QT (➋ Chap. 21) would find this more difficult. From the side view, it is possible to derive one horizontal (X or Y) coordinate and the vertical coordinate (Z). Since each side view uses a different coordinate system, it is necessary to translate the side-view results into a "universal" coordinate system. Before this can be done, the system must be calibrated. (Appendix E) By combining overhead and side views, it is possible to locate the ends of both wires in 3-dimensional [X,Y,Z], space. Locating another point close to the end of a wire allows its orientation to be estimated. This is repeated for the plan and side views, giving two angular measurements, [θ,ϕ]. Five parameters [X,Y,Z,θ,ϕ] are needed by a robot to grasp the wire. (Again, a change of coordinate system is needed.) The ambiguity caused by the fact that there are two loose wires can be resolved easily by reasoning in PQT. The task of resolving real or apparent entanglement of the wires is discussed. This requires the interpretation of pairs of images and is, once again, suitable for Prolog-style reasoning in PQT. In this application, there is a high degree of uncertainty due to the flexible nature of the wires. While the image processing is trivial, the use of Artificial Intelligence techniques is essential. The matrix calculations needed to perform the coordinate-axis transformations are well suited to MATLAB and hence QT and PQT.

27.1 The Application

In this chapter, we consider the task of guiding a robot to grasp the flying leads on a small electrical coil, so that it can be connected on a printed circuit board. Once the wires have been located and grasped by the robot, they will be cut to length and then soldered to wire posts. The author encountered this application in a modern part-automated factory. The lack of robotic coil handling was the main barrier to achieving full automation in that plant.

To solve this application in practice, the system requires a far higher level of sopistication than we have space to describe here. To handle the coils properly, a robot with five degrees of freedom and at least five cameras and are needed (➋ *Fig. 27.1*). In addition, a certain degree of intelligence would be needed to interpret the images and plan the robot movements. Therefore, we shall limit our attention here to a limited but essential task: locating the ends of the wires and determining their orientation near the ends, from a single 2-dimensional view from the overhead camera.

27.2 Processing Images from the Overhead Camera

The task is to calculate three position parameters and two angles (➋ *Fig. 27.2*).

Each cameras generates a high-contrast grey-scale digital image. Converting this to binary form is straightforward. The following QT command sequence will suffice if the contrast is high enough:

```
enc,  % Enhance contrast
thr   % Threshold at mid-grey
```

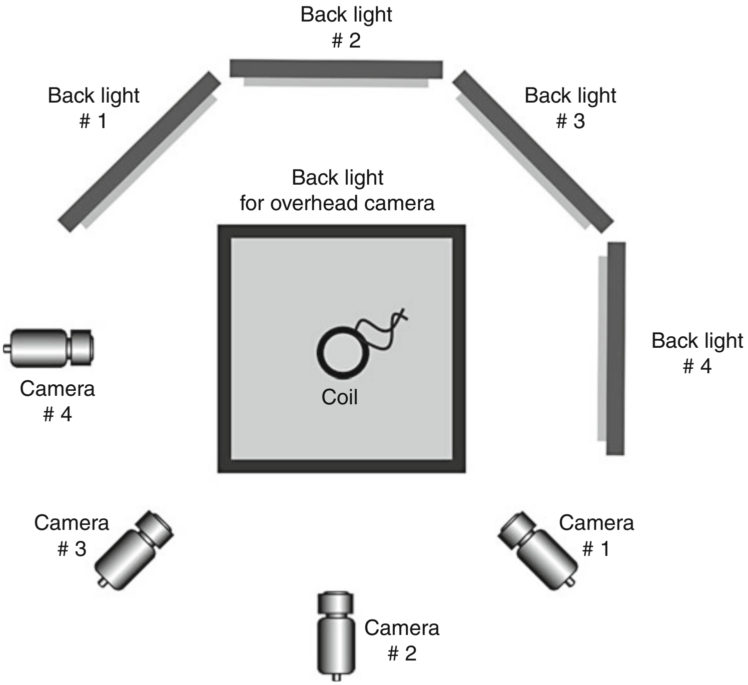

Fig. 27.1
Lighting-viewing arrangement (plan view of the coil). The grey rectangle represents the field of view of the overhead camera. From the plan view, the wire-ends are detected and located. This information is then used to choose the best side-view image. The appropriate back-light source is then switched on and the image captured from the corresponding camera (The back-light for the overhead camera would be switched off first)

If there are significant variations in the intensity of the back-ground, slightly more sophisticated processing would be required:

```
enc   % Enhance contrast
sqr   % Square all intensity values: gives greater contrast for the wires
mdf   % Median filter
crk   % Crack detector: grey-scale closing operator
```

Detecting the ends of the wires is straightforward:

```
thn   % Thinning operator
lmb   % Detect limb ends, i.e., white points with just one white 8-neighbour
```

In order to find the orientation of the ends of both of the wires, we can use the following sequence applied to the binary image (see Fig. 27.3).

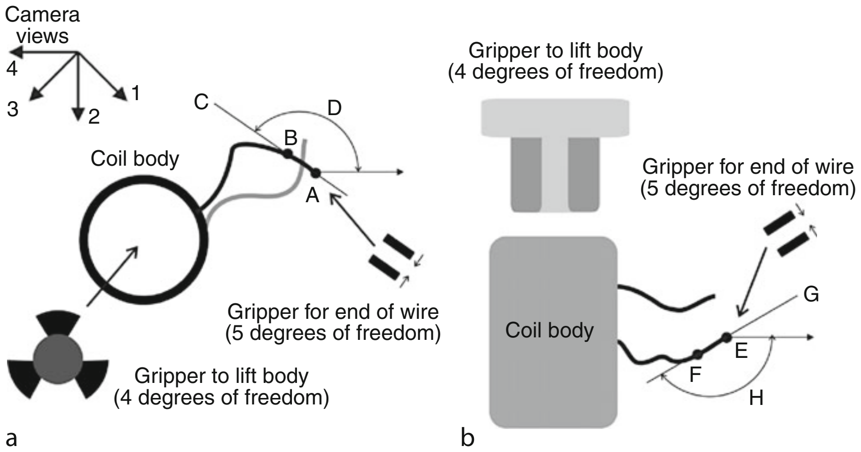

Fig. 27.2

Robotic handling of the coil. (a) *Plan view*. A is the end point of one of the wires. B is another point on the wire close to the end. C is the line joining A and B, while D is the orientation of the line AB. In this situation illustrated here, camera 1 provides the best side view. (b) *Side view*. E is the end of the wire and F is a point near its end. G is the line joining E and F, and H is its orientation. The following parameters are supplied to the robot: position coordinates, [(X_A+X_B)/2, (Y_A+Y_B)/2, (Z_E+Z_F)/2]; angles, [D, H]

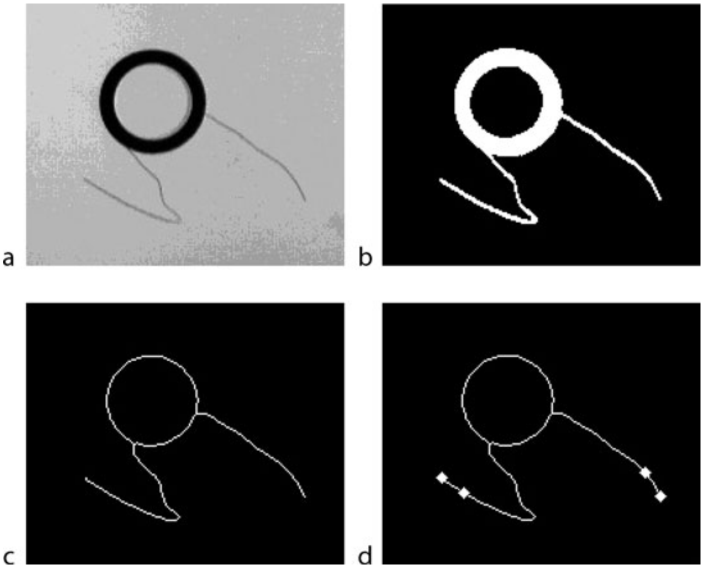

Fig. 27.3

Analysing the plan view to detect and locate the wire ends. (a) Original image. The diameter of the wires is close to the Nyquist limit, making their detection somewhat unreliable; a higher resolution would be advisable in practice. (b) Binary image. (c) After thinning. (d) End point of each wire and another point on the wire close to its end

```
thn                    % Thinning operator
spr(15)                % Recursively remove the limb-end pixels (15 loops)
exr                    % Exclusive OR - isolates the tips of the wires
big                    % Select one tip of a wire
lmb                    % Find ends of that wire tip
big                    % Select one of them (see note below)
[x1,y1]=cgr;           % Centroid
swi                    % Switch images
big(2)                 % Now, choose the other wire tip (see note below)
[x2,y2]=cgr;           % Centroid
theta=atan2(x1,y1,     % Orientation for the robot gripper
  x2,y2),
x0=(x1+x2)/2;          % X-coordinate for the robot gripper
y0=(y1+y2)/2;          % Y-coordinate for the robot gripper
```

(*Note: This naive programme does not distinguish one wire end from the other. To do so is straightforward but these details would divert us from the main point.*)

27.3 Further Analysis

The calculation described so far is only able to provide some of the information needed by the robot. It is necessary to use the position coordinates of the tip of the wire and the centre of the coil body to decide which side-view camera to use. Processing the image from the side camera will follow in a similar manner to that just described. This will provide the vertical position (Z axis) and the second angular coordinate required by the robot, as described in ➲ *Fig. 27.2*. There are three complications:

1. The overhead view must be used to decide which side view should be analysed.
2. It is not immediately obvious how the two wire ends in the plan image are related to those in the side view image (➲ *Fig. 27.4*). It may not be resolvable from a single side view.
3. The wires may appear to cross each other (➲ *Fig. 27.5*). This problem has no totally satisfactory solution, although heuristic rules might help in many cases.

These factors make it necessary to deploy a programme capable of intelligent reasoning. This type of computation is beyond the capabilities of a language like QT but is exactly the type of situation in which PQT excels. Since a full discussion of the solution is both long and tedious, we shall omit the details. Let it suffice to say that PQT does not offer a complete solution as it employs heuristics that we know will fail *occasionally*. This is not disastrous as we can often use very general (catch-all) rules to avoid situations that might otherwise lead to disasters, like machines jamming. However, such rules are often slightly inefficient/wasteful. For example, we might resort to a rule such as the following:

- *If the entanglement of the wires cannot be resolved automatically, divert the coil for reworking by hand.*

An alternative catch-all rule that we might employ is

- *If all else fails, throw the coil away.*

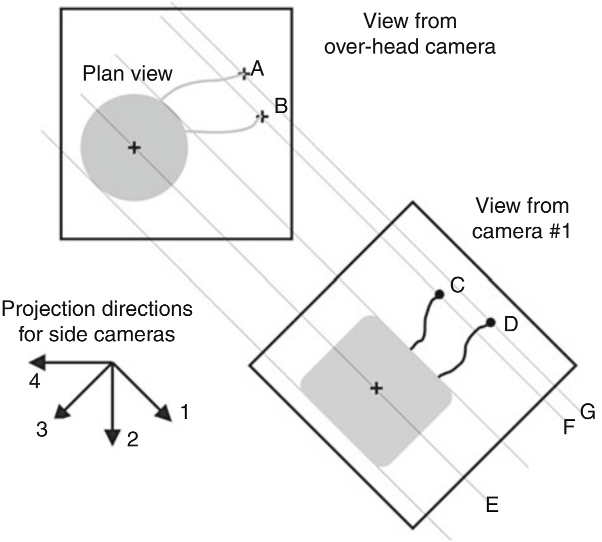

Fig. 27.4
Matching the wire ends found in the plan and side images. First, wire ends A and B are identified and located in the plan view. From this image, we first determine which camera (in this case, number 1) is the best one to use for the side view. In addition, knowing that the coil body is cylindrical allows us to predict the general form of the side-view image but with some unresolved questions. The centroids of the coil body lie along line E. Wire-end A is known to match a wire end in the side-view image somewhere along line G. Similarly, we can predict that we shall find a wire end, corresponding to B, somewhere along line F. When we examine the side-view image, we find that there is indeed a wire end (C) lying along line F and another wire end on line G. Since we can now associate A with D and B with C, we can uniquely locate both wire-ends in 3D space

Stating a rule in such a stark way is, of course, emotionally unwelcome to any factory manager. Neverthless, it may still offer a cost-effective approach, particularly if the unit cost of the coils and frequency of severe wire entanglement are both very low.

Another very serious issue that must be resolved is that of calibration. We must be able to measure image features seen in one view and compare them with measurements derived from another view. Furthermore, the robot coordinate axes must be related to those of each of the cameras. Calibration requires careful thought and planning but it is not intrisically difficult; it is simply an exercise in relating (six) different sets of coordinate axes with each other. The use of specialised calibration targets will help a lot. Their use and design requires human intelligence and we cannot supply general rules without have a specific application in mind. The subject of calibrating a simple robot vision system (overhead camera and a robot with three degrees of freedom) is covered in Appendix E.

It is worth remembering that here, as in many other applications of robot vision, a few tricks can be useful. For example, if the wires seem to cross one another, as in ➋ *Fig. 27.5c*, it might be possible to disentangle them by using the robot to place a smooth rod to pull them gently apart. (This is akin to using a single finger to unravel a loosely tangled pile of string, simply by pulling. If this manoeuvre fails, it is sensible to remove the finger and give up the

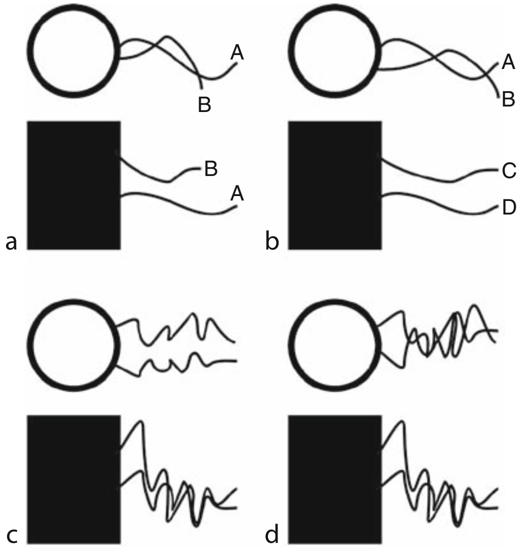

Fig. 27.5

Analysing pairs of images. (a) Fully resolvable situation. Both images show that wire-end B is markedly closer to the body of the coil than A. (b) Partially resolvable situation. The two cross-over points visible in the plan image do not cause problems, as there are no cross-overs in the side view. Since A and B are at the same distance measured horizontally from the coil body, there is an unresolved ambiguity: does A correspond to C or D? A second side view might be able to resolve this. (c) As in (b). Even though there are multiple cross-over points in the side image, the plan image shows that the wires are not tangled. (d) Unresolvable. There are multiple cross-over point in both images. In this case, the coil could be set aside for human examination and possible reworking, or simply discarded

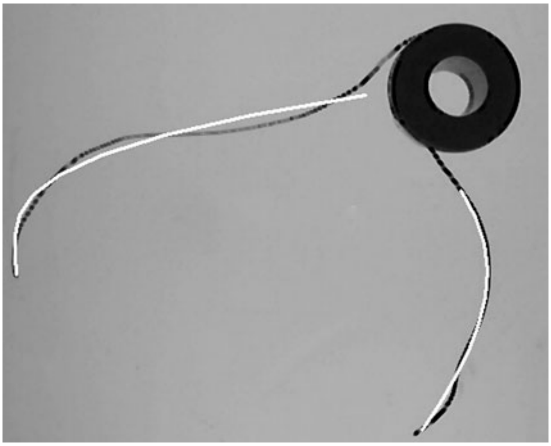

Fig. 27.6

Fitting (third order) polynomial curves (separately) to the wires

attempt.) Obviously, this stratagem will not always work, but it is certainly worthwhile trying, particularly when it is known beforehand that there is unlikely to be anything worse than very simple entanglement.

Sometimes, a wires may become severely kinked. If this is possible, it is sensible to use a curve-fitting algorithm to find a smoother representation of their general trend. For example, in ➋ *Fig. 27.6*, a third order polynomial curve has been fitted to each wire. Using this, rather than the skeleton of the wire itself, may provide a less erratic measure of the orientation of the wire at the pick-up point. In this example, the author chose to use the vertical axis for the independent variable in the polynomial series. He also defined the limits of variation of the independent variable and order of the polynomial. Clearly, these choices would all have to be automated in practice, emphasising the point that handling objects with loose wires is an exercise in Artificial Intelligence, rather than the use of standard image processing techniques.

28 A Telecentric Vision System for Broach Verification

John W. V. Miller[1] · *Spencer D. Luster*[2] · *K. D. Whitehead*[1]

Abstract: A common machine vision task is to verify that a product has been properly fabricated or assembled. In the following chapter, a vision system is described for confirming that a type of gear has been machined properly. The main problem in this application is the relatively large depth of the gear which results in a more complex image than the desired silhouette of the part. The resulting image shows a portion of the inner wall due to the varying magnification because some points on this wall are closer to the lens than others. Employing telecentric optics, however, greatly simplifies the problem since only light rays parallel to the optical axis create the image so that a good silhouette of the part is obtained. Gear teeth can then be isolated using mathematical morphology techniques to verify that the part has been properly broached.

28.1 Introduction

Broaching is a common cutting operation during the manufacturing of metal components including gear teeth. While this technology is very mature and produces high-quality parts, occasionally, problems are encountered which include parts that have not been broached or broached more than once. These types of problems are caused by improper parts handling in which processed and unprocessed parts are mixed. When this happens, the potential consequences are severe since improperly broached parts may not be detected and are incorporated into finished assemblies. Often the faulty part is detected at this point so that it can be replaced at additional cost. In some instances, however, the assembly functions normally, and results in a failure later with greatly increased costs and customer dissatisfaction.

Human inspectors have traditionally been used to identify this type of problem before an improperly broached part is used in an assembly. However, this approach is not sufficiently accurate since inspectors can make mistakes. A vision system that would detect if a part had been properly broached can eliminate this problem if it is reliable enough.

In principle, this is a relatively straightforward task since a back-illuminated gear provides a high-contrast image which can be analyzed by a vision system. However, because gears with internal teeth may have significant depth, the inner walls are visible which makes the vision task considerably more difficult as shown in ➋ *Fig. 28.1*. The walls are visible due to magnification which changes as a function of distance from the camera. A feature close to the camera will appear to be larger than an identical feature at a greater distance. This type of problem can be solved by using telecentric optics which provides constant magnification and reduces constraints on the working distance. Another advantage of telecentric optics is that it provides constant perspective so that the object does not have to be precisely aligned with the camera. It may be noted that a definite asymmetry exists in the gear wall of ➋ *Fig. 28.2* because of a slight misalignment between the gear and camera. There are several ways to attain telecentric results which are discussed in the next section.

28.2 Telecentric Optics

A telecentric system is one in which one or both of the pupils (object and image space) are located at infinity and the principal ray enters or leaves the system parallel to the axis. Another way to think of this is to remember the definition of a lens focal point. Rays of light that are

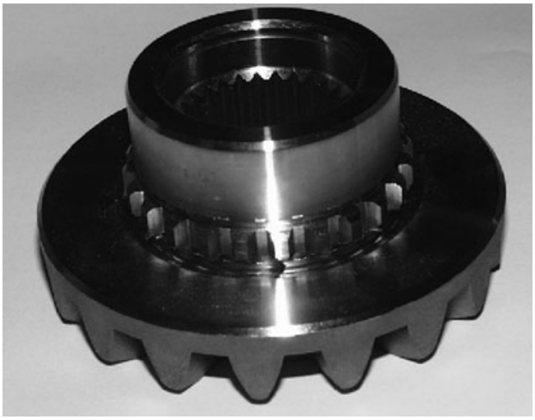

Fig. 28.1
Gear with internal teeth

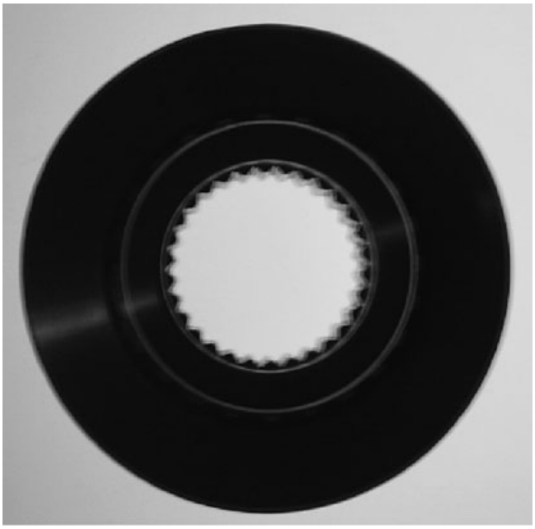

Fig. 28.2
Back-illuminated gear

parallel to the optical axis of a lens will enter the lens and converge to the focal point which is true at least for the paraxial or "thin lens" case. Also, rays of light that enter a lens after passing through the focal point will emerge parallel to the optical axis. So, if a small aperture or stop is placed at a lens focal point, only light that is nearly parallel to the optical axis can either enter or emerge from the system, depending at which focal point the stop is placed. Such an arrangement is defined to be telecentric and the aperture is the telecentric stop. ➲ *Figure 28.3* shows the three types of telecentric systems: object space, image space, and both [1].

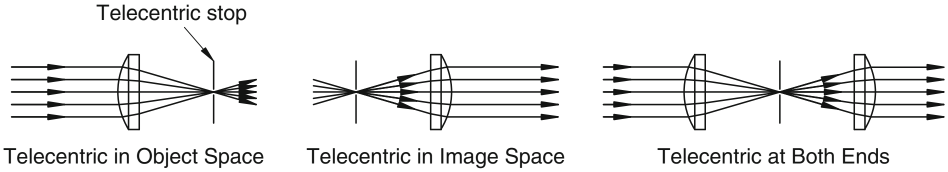

Fig. 28.3
Telecentric systems

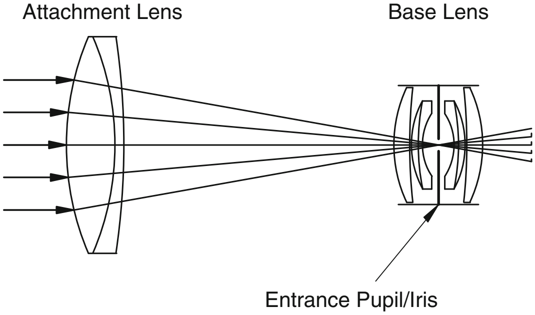

Fig. 28.4
Typical telecentric optics

28.2.1 Telecentric Approaches

There are a number of ways to build a system that is telecentric in object space. The general layout for a popular design that is commonly used in commercial and custom-designed telecentric lenses is shown in *Fig. 28.4*. Using currently popular terminology, the primary or "base" lens is placed such that its entrance pupil (iris) is at the back focus of the "attachment" lens. The pupil/iris of the base lens thus serves as the telecentric stop. This provides a compact design that is easily constructed for a large range of magnifications.

There are some other advantages that are somewhat less well covered in the literature. These include the ability to perform Schlieren-like inspection, as well as the potential for reducing edge location errors, especially for highly specular, thick objects such as gear teeth. A reasonable question concerns how "telecentric" is the system. In addition, the adjustments for obtaining better results also can be addressed. The drawing in *Fig. 28.5* contains some useful information in this regard.

Here parallel rays of light are shown entering the lens, but they are not parallel to the optical axis. Of course they still converge to a point at the focal plane of the lens. The input angle that allows parallel rays of light to converge to a point located at the edge of the telecentric stop is the acceptance angle, α, of the system. As α gets smaller, the system is more telecentric. What this means is that the depth of field increases, perspective error decreases, and magnification becomes more constant. Essentially all of the advantages of telecentric optics improve up until the point at which diffraction limits performance. Also, of course, light collection decreases because only light rays that are almost perfectly parallel with the optical axis are admitted.

28.2.2 Optics for Gear Inspection

For the application of interest here, only relatively modest performance was required but it was very important that the vision system be easy to assemble, set up, and maintain. With the object space implementation for telecentric optics, the camera lens provides the needed telecentric stop (camera aperture) and it is only necessary to position the attachment lens carefully relative to the base lens. The drawback with this approach is that only relatively small fields of view are economically accommodated since the attachment lens must be larger than the field of view and of relatively high quality.

The alternative approach is better for larger fields of view since the collimating lens for the light source can be an inexpensive Fresnel lens. The aperture must be positioned accurately relative to the lens and this is more difficult than the object space implementation to set up. Since the gear hole size was approximately 2 in., the object space implementation was selected.

Using this setup, the gear walls disappear and a clear view of the gear teeth is obtained as illustrated in ➲ *Fig. 28.6*. ➲ *Figure 28.7* shows a part which has not been broached and appears significantly different from the broached part. These images are much easier to analyze for

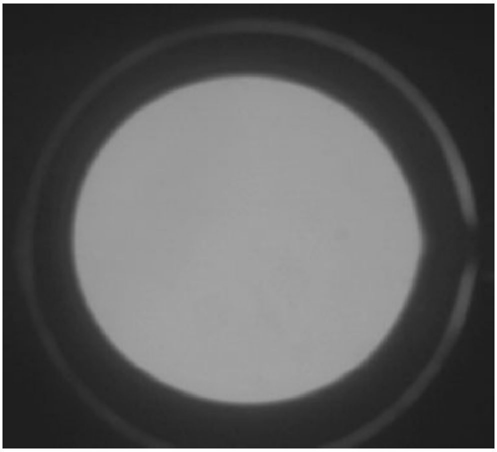

Fig. 28.7
Telecentric view of unbroached part

broach verification. It may be noted that the quality of the attachment lens was relatively low and it had significant distortion at the edges. This can be corrected either by using a better lens or a larger lens since distortion is greatest near the edges. This was not a critical consideration for the application because it was only necessary to detect the gear teeth. A better lens would be required if actual measurements were to be taken.

28.3 Image Analysis

While it is trivial for a person to tell the difference between these two images (*Figs. 28.6* and *28.7*), it is necessary to develop a robust technique for detecting the broach pattern. One such approach is based on mathematical morphology in which images are analyzed using special graphical patterns called structuring elements. The detection of gear teeth by this technique was one of the early uses of mathematical morphology and is very reliable [2]. In the approach used here, a gray-scale closing operation is used to eliminate the dark teeth.

28.3.1 Gear Teeth Detection Algorithm

The broach pattern in figure can be identified using a structuring element that is large enough to cover the bright regions between the splines. By performing a gray-scale closing operation with this structuring element, a new image is obtained which resembles the unbroached part in *Fig. 28.7*. By taking the difference between the original and processed images, the image given in *Fig. 28.8* is generated. The broach pattern is quite visible after this operation. This may be contrasted to *Fig. 28.9* which shows the results of applying this algorithm to a part that has not been broached.

Otsu's thresholding method was then used to binarize the image [3]. By using an automatic thresholding routine, the probability of problems with light level variations is minimized.

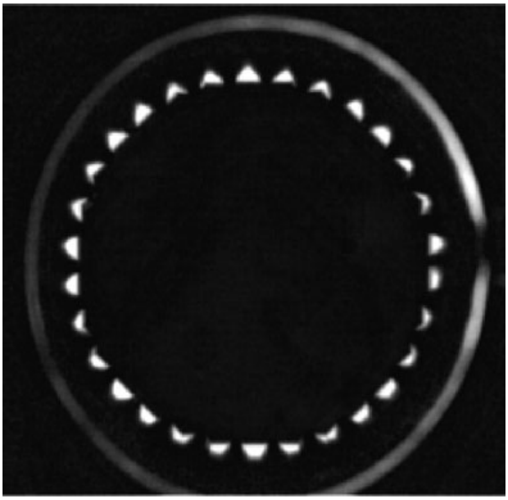

Fig. 28.8
Difference between closed and original image

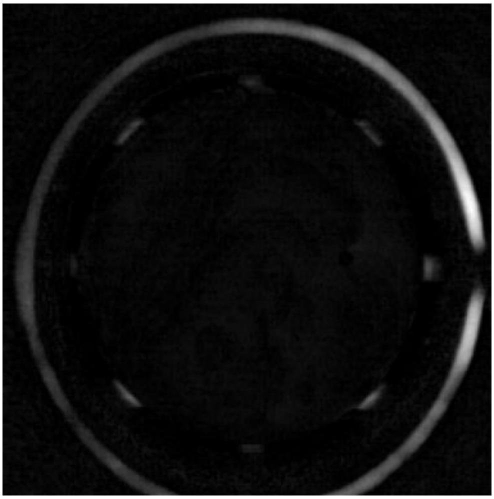

Fig. 28.9
Difference image for unbroached part

Otsu's method works well in many vision applications and always appeared to give good reliable results here as illustrated in *Figs. 28.10* and *28.11*.

Connectivity is performed to provide a list of blobs (connected groups of pixels). Two basic operations are employed here in which the image is converted to run-length format and then the runs are assigned to blobs.

A recursive operation is performed in which a run is initially assigned a label followed by a search of candidate runs on the next line to see if they should be linked to the newly created

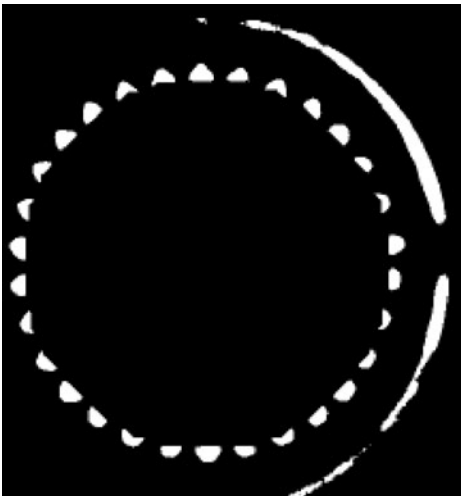

Fig. 28.10
Binarized image of broached part

Fig. 28.11
Binarized image of part that has not been broached

blob. If a run is found that should be assigned to the current blob, it is added and a new search for runs to link is initiated. When no more runs can be assigned, the next available unassigned run is assigned a new blob label and the process is repeated.

This continues until all runs have been assigned to blobs. This approach has two advantages. First, there is no need to re-label runs when two labels have been assigned to runs which ultimately will be assigned to the same blob. This is because runs are assigned to a single blob until all available runs have been properly assigned. The second advantage is that the assignment list of runs is properly ordered. This can save additional processing for some vision applications although it was not needed for the application of interest here.

After connectivity, the blob count is recorded and features are extracted from each blob to determine whether or not the given part has been properly broached. Key features here are blob area and aspect ratio since the gear teeth will be relatively similar in area and aspect ratio. The blob count is also a very good indicator of broached parts since parts that have not been broached will have relatively few blobs. After each blob is tested, the program decides whether the part has met the criterion for good parts. A portion of a ring is also detected but it is actually caused by the optical configuration and would not appear with better masking. It should be noted that the ring features are very different from teeth features. Similarly, some distortion of the teeth is also apparent and likewise would be considerably reduced less with improved optics.

28.4 Results and Conclusions

The current algorithm provides a very robust approach for determining if a part has been broached. Both the blob count and blob features are very reliable indicators with essentially total reliability at least in a laboratory setting and should be very effective on the plant floor. It is somewhat harder to characterize how well double broached parts will be identified since only a few samples were available and there can be considerable variation between parts that have been double broached. In general, teeth are considerably reduced in size when this happens so that blob area can be used to identify a part that has been broached twice. With the current optics, this should still be very reliable in most cases and using a better attachment lens will improve discrimination for marginal cases. Since double-broached parts are relatively rare anyway, even the current optics should be very satisfactory. The lack of insensitivity for part placement relative to the camera is a significant advantage of telecentric optics. The use of automatic thresholding is also expected to enhance robustness of the vision system. Voltage fluctuations and long-term light changes should not affect performance adversely within reasonable limits.

Abstract: The Crosshead Inspection System (CIS) utilizes machine vision technology for on-line inspection of a crosshead which is a diesel engine component. The system includes three functional modules:

1. Part handling subsystem presents parts for inspection and accepts or rejects them based on signals from the image analysis software.
2. Image acquisition hardware consisting of optics, light sources and two video cameras to collect images of inspected parts.
3. Image analysis software to analyze images and send pass/fail decision signals to the handling subsystem.

The CIS acquires and inspects two images of each part. The upper camera generates an image of the part's top surface, while the lower camera generates an image of the so-called "pockets" on the part bottom. Both images are acquired when a part-in-place signal is received from the handling system. The surface inspection camera and light source are positioned at opposed low angles relative to the surface. Irregularities manifest themselves as dark regions on the surface. These regions are detected, measured and compared to user specifications. The pocket inspection function detects the presence of tumbler stones in which the contrast of these stones is enhanced with circularly polarized lighting and imaging. The graphical user interface of the CIS provides easy setup and debugging of the image processing algorithms. A database module stores and archives part inspection statistics for later evaluation. The inspection rate is sixty parts per minute.

29.1 Introduction

Metal engine components often must be fabricated within very specific highly constrained specifications. In the case of crossheads, which are used in diesel engines, the pockets and flat region on the top of the part are especially critical. The top surface, especially, needs to be very flat and free of defects. The pockets, into which rods fit precisely, also need to be defect free with no residual debris from earlier manufacturing processes. Traditionally, human inspectors sort parts but defects are sometimes missed and sorting is inconsistent since the reject criteria are highly subjective.

A system for automatic inspection of crossheads overcomes these limitations to enhance product quality while lowering labor costs. While this is conceptually a relatively straightforward application, a number of factors increase the difficulty of developing a suitable system. For example, part size varies considerably which affects the handling system, illumination, and algorithms. Certain manufacturing processes change over time that alters the basic appearance of parts and affects the contrast of key features.

The following paper describes such a system that is currently used in production including strategies for handling different parts and dealing with cosmetic variations in appearance. In the next section, the basic approach is described which is followed by a discussion of the algorithms that were developed. Finally, results are presented.

29.2 Basic Approach

Illumination is a critical aspect for the inspection tasks of interest here since parts have highly variable reflectance properties. This is especially true for the pockets since the various types of polishing operations can dramatically change their appearance. The flat surface, however, is the most critical aspect of the inspection and requires a very carefully designed and optimized optical setup.

29.2.1 Optics and Lighting

The top-surface defect types to be detected generally fall into three physical categories. The first appears as a simple, reasonably sharp edged dig or divot, often with a dark diffuse bottom. The second defect type appears as fine, high aspect-ratio scratches. The third, so-called "soap marks," are very shallow, smooth-sided dents that result from excess die compound being in place during the forming process. These defects retain the same surface reflectance as adjacent good areas. It is this last defect category, in conjunction with the varying nominal surface texture and reflectance variations that presented the greatest challenge in terms of detection.

The final form of the optical design for the top surface inspection was very low angle (as measured from the part surface) illumination with exactly opposed imaging (grazing illumination). This technique provides high contrast to detect the shallow, smooth soap-mark defects while still providing good contrast for the other defect types. Such a technique also reduces the effects of surface texture and reflectance variations. At very low angles, most reasonably smooth surfaces become highly specular according to the Fresnel equations. As an example, paper, which is normally considered fairly diffuse, appears as a good specular reflector when viewed at a very low angle with an opposed low angle light source. In addition, the angular extent of the illumination needs to be adjusted to balance good defect detection with low sensitivity to small angle variations due to part handling. These tradeoffs were achieved with a variable sized horizontal slit in front of a diffuse light source as shown in *Fig. 29.1*. Finally, in order to provide the most efficient light collection, a lens was placed in front of the diffuse light-source. Assuming that the part top surface is a plane mirror, this lens is configured so that the image of the slit is formed at the small entrance pupil of the camera lens. In this way all of the light that reflects from such a hypothetical mirror enters the lens. For the real part surface, any defect feature that causes a redirection or absorption of the light will generate a dark spot in the image including the shallow and otherwise nearly undetectable soap marks.

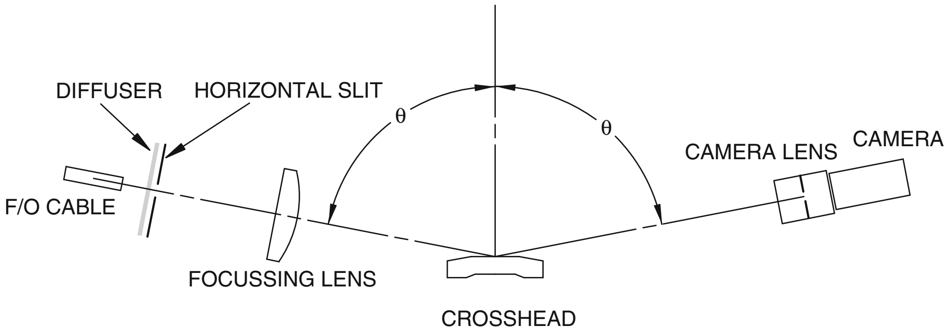

Fig. 29.1
Surface inspection optical setup

The pocket inspection, while nominally more straightforward, provided its own challenges. The main defect to be detected is the presence of tumbling stones in the pockets. These stones are generally light to dark brown in color and have a reasonably diffuse surface. After repeated processing applications, however, they can get quite dirty, and appear very dark. A secondary but still important *potential* defect type is the presence of gross cracks at the bottom of the pocket. By eye these appear as dark canyons. The metal pockets of the crosshead themselves are generally reasonably specular, but they have an even greater variation in surface reflection than the top surface.

Under conventional direct illumination and monochrome imaging, the stones can appear to have the same brightness as the bottom of the pocket. Even using color imaging, the dirty stones may be almost indistinguishable. An initial approach to enhance the stone contrast was to use a linear polarizer in front of the light source and a crossed linear polarizer (analyzer) in front of the camera lens. By this method, specular reflections can be almost completely eliminated. Linearly polarized light that reflects from a diffuse surface is, to a certain extent, re-randomized, and some component of this reflected light can pass through the crossed analyzer. In this way the diffuse stones, almost regardless of color, can be made to appear as bright objects against a dark background.

Unfortunately, such a technique leaves some gross cracks almost undetectable. The problem is that the specular pocket bottom appears as dark as the non-reflecting crack. One method of correcting this problem is to rotate the polarizer or analyzer slightly to allow some specular light to be transmitted to the camera. Mechanically and from a maintenance point of view, however, this is not optimum. Disassembly or replacement of optical components would require a difficult realignment of the linear polarizers.

The final solution was to use a single circular polarizer in front of the light source and camera as shown in ➲ *Fig. 29.2*. In certain respects a circular polarizer (CP) behaves in the same

way as a linear polarizer with a crossed analyzer. Light that passes through the circular polarizer and is specularly reflected from an object is blocked from passing back through the CP. The CP, however, is more dependent on light wavelength for proper performance. When used in broad band white light, as is the case for this application, some portions of the light spectrum pass through the CP and back when specularly reflected. The stones, whether clean or dirty, remain as the brightest objects to be observed. The pocket bottom remains darker, but not black. The gross cracks, by virtue of not reflecting any light, are seen as black features. Furthermore, the CP is not sensitive to rotational orientation and may be disassembled for cleaning or replaced with no need for critical realignment.

29.2.2 Image Acquisition and Analysis Hardware

Two standard CCD cameras were used to acquire images of the flat surface and pockets. The camera video was digitized using a frame grabber that could accept up to four cameras. A standard personal computer analyzed the data.

29.2.3 Handling System

The custom handling system was designed to accommodate four different crosshead designs with as little changeover time as possible. The motor-and-cam operated system has an in-feed stage consisting of a simple conveyor. Currently, parts must be arranged manually on this long conveyor into a single line. The system was designed, however, to accommodate hopper storage and vibratory bowl feeding in the future.

Once the parts are in line, the conveyor feeds them to a nest for positioning. Here the direction is changed and parts are oriented side by side as shown in ➲ *Fig. 29.3*. A pusher rod connected to the main cam slides the parts down one at a time until they reach the inspection station where an inductive sensor provides a *part-in-place* signal to the inspection system. A second pusher arm, connected to the same cam, slides the part out, once more moving in a direction parallel to its long axis. The crosshead then travels down a chute that has an electro-pneumatic diverter at the end. Before the part reaches the diverter, the inspection system provides an accept or reject signal to the diverter.

In order to change part types, the in-feed conveyor position must be adjusted and a nest for the new part mounted. This changeover only requires about 10 minutes.

It should be noted that the original handling concept included independent computer control of the in-feed, pusher arms, and out-feed mechanisms. The customer, however, preferred purely mechanical cam operation. Their opinion was that this was more reliable and more easily debugged. Such a concept also limits the flexibility of the system and part reject timing became a critical challenge.

29.3 Analysis Algorithms

As in many machine-vision applications, conflicting requirements include data processing, reliable inspections and keeping development and equipment costs under control. A general-purpose image processing library developed at the Edison Industrial Systems Center was

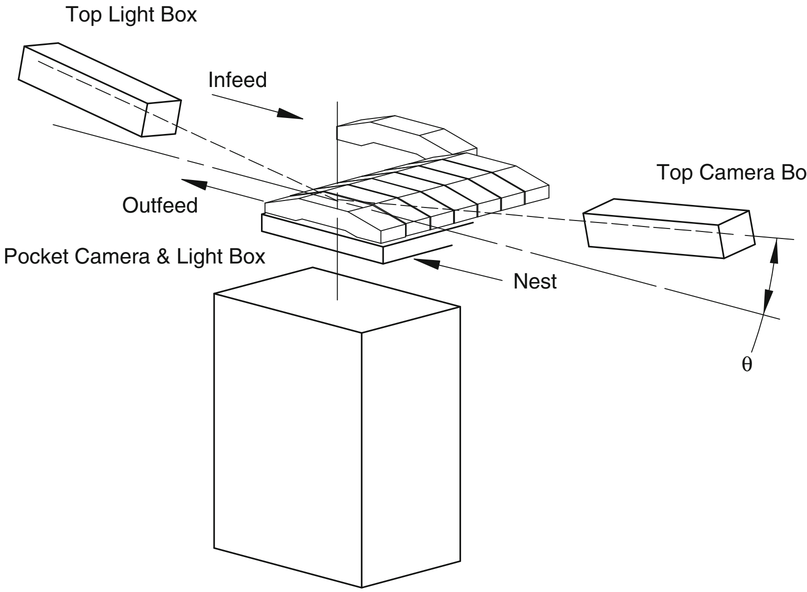

Fig. 29.3
Crosshead inspection system inspection setup

employed here [1] to speed development and allowed the use of a personal computer for image processing and data analysis.

29.3.1 Surface Inspection

The surface inspection algorithm consists of two main parts: finding the location of the surface for inspection (for smaller parts, several of them may be visible in the image) and then analyzing the surface image. The algorithm consists of the following steps:

1. Find a suitable threshold for binarizing the image
   (a) Create a histogram of the image
   (b) Fit a mixture of two Gaussian distributions to the histogram
   (c) Set threshold midway between peaks of Gaussians
2. Identify the surface
   (a) Threshold the input image using value found in the previous step
   (b) Find the largest blob – valid blob area limits are determined during calibration
   (c) Smooth the blob's boundary
   (d) Shrink blob boundary inwards per user-specified setting to create a region of interest (ROI)
3. Inspect surface area
   (a) Threshold image within the ROI – use the same threshold as in the previous step
   (b) Detect blobs and compute their size and depth attributes and compare each blob's attributes against user defined-rejection criteria

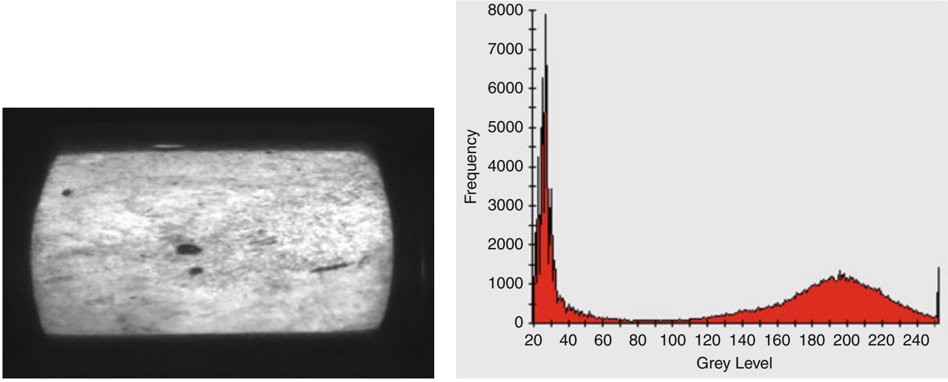

Fig. 29.4
Image of the crosshead surface (*left*) and the corresponding histogram

That thresholding algorithm is based on the *optimal thresholding* method [2]. The method assumes that the image contains two values combined with a additive Gaussian noise. The mixture probability function is

$$\begin{aligned} p(z) &= P_1 p_1(z) + P_2 p_2(z) \\ P_1 + P_2 &= 1 \end{aligned} \tag{29.1}$$

Where $p_1(z)$and $p_2(z)$ are Gaussian distributions. An example of an actual physical distribution of gray level values is shown in *Fig. 29.4* which is close to a mixture of two Gaussian distributions. The user can specify a balance parameter that shifts the threshold towards the brighter or darker peak.

The surface area is found by thresholding the image. The edges of the surface blob are smoothed using one-dimensional morphology [3] and eroded to remove noise at the edges of the surface. This blob defines the region of interest for inspection of defects on the crosshead surface. The dark regions, represent potential surface defects which are also detected by thresholding.

29.3.1.1 Setup and Calibration

Figure 29.5 illustrates the setup and calibration screen for surface inspection. The surface calibration algorithm is used to estimate the surface area of a good part and determine actual dimensions from pixel values. The setup screen is also used to alter inspection parameters. Values calculated by the inspection algorithm are displayed in the log window and can be used to adjust sensitivity parameters.

29.3.2 Pocket Inspection

The original pocket inspection algorithm segmented the image of each pocket to detect the pocket rim, sidewall and bottom. However due to significant variations in the pocket surface finish and pocket size, the detection algorithm and optical setup were not sufficiently robust. After discussions with the client, it was decided to concentrate on the detection of stones that represented the main quality consideration. To address this objective, a cross polarization optical setup was implemented. The image processing requirements were simplified to calculating the mean gray level and standard deviation within each pocket's ROI. Example images of the pockets with no polarizer are shown in ➋ *Fig. 29.6* while images using a cross-polarizer are shown in ➋ *Fig. 29.7*. As may be seen, the polarizer significantly enhances the contrast of the stone in ➋ *Fig. 29.7*.

29.3.2.1 Setup and Calibration Screen

The setup and calibration screen for pocket inspection in shown in ➲ *Fig. 29.8*. Pocket calibration is used to determine the nest hole locations through which pockets are visible. The user is asked to place a diffuser in the place of a part. The resulting image is processed to create two ROIs corresponding to the hole locations. The setup screen is also used to alter inspection parameters. Values calculated by the inspection algorithm are printed in the log window and can be used to adjust the algorithm's setup parameters. The average gray level is used to detect stones in pockets while the gray-level standard deviation detects missing pockets (pockets that are filled with metal).

29.3.3 Database

The Crosshead Inspection System program saves inspection statistics to a local Paradox database which contains the number of good and failed parts processed each day for each part type. The data can be exported in text or Excel format to a file or copied to other database through the ODBC interface.

29.4 Results

The Crosshead Inspection System described in this paper has proven to be robust in detecting crosshead surface defects and tumbling stones in crosshead pockets. An automotive part manufacturer in Northwestern Ohio currently uses the system for on-line inspection of four types of crossheads at a rate of sixty parts per minute.

Abstract: The major aim of this chapter is to detail the technology associated with a novel industrial inspection system that is able to robustly identify the visual defects present on the surface of painted slates. The development of a real-time automated slate inspection system proved to be a challenging task since the surface of the slate is painted with glossy dark colours, the slate is characterised by depth profile non-uniformities and it is transported at the inspection line via high-speed conveyors. In order to implement an industrial compliant system, in our design we had to devise a large number of novel solutions including the development of a fully customised illumination set-up and the development of flexible image-processing procedures that can accommodate the large spectrum of visual defects that can be present on the slate surface and the vibrations generated by the slate transport system. The developed machine vision system has been subjected to a thorough robustness evaluation and the reported experimental results indicate that the proposed solution can be used to replace the manual procedure that is currently employed to grade the painted slates in manufacturing environments.

30.1 Introduction

Over the past three decades, the deployment of vision-based solutions in the development of automatic inspection systems has witnessed a substantial growth. This growth was motivated in part by the increased flexibility attained by the vision-based industrial inspection solutions when applied to the classification of the manufactured products with respect to their aesthetical and functional characteristics and equally important these systems opened the opportunity to control the production process by evaluating the statistics that describe the efficiency of the overall manufacturing process. In this context, it is useful to mention that slate manufacturing is a highly automated process where product inspection being the solely task that is still performed by human operators. In this process, the human operators analyse the slates visually when they emerge via a conveyor from the paint process line and they make a judgement whether the produced units have a surface finish of acceptable quality or not. If defective slates are detected during visual inspection, they are removed from the production line and put aside for rework or rejection. Although the in-line manual inspection generates accurate results when applied to product quality assessment, it is highly reliant on the pictorial information perceived by the human visual system (HVS) [1–3] and consequently it is critically influenced by the experience and the acuity of the human operator. In addition to this, it is important to note that the performance of the human operator is not constant and moreover the manual inspection represents a monotonous work that cannot be used in conjunction with high-speed product manufacturing lines. In this context, Tobias et al. [3] list some of the key factors that justify the adoption of machine vision systems in industry. These are increased productivity, improved product quality, absence of human inspectors performing dull and monotonous tasks, high-speed inspection (matched by high-speed production) and reduced human labour costs. In particular we would like to stress that the incorporation of automation in manufacturing industry is not necessarily about the displacement of labour, but more as an answer to the expectation of an increasingly educated labour force and the compliance to the recent realities of the world economy [4].

However, the design of industry-compliant machine vision systems is far from a trivial task as several issues including the mechanical design, development of an appropriate illumination set-up, optimal interfacing between the sensing and optical equipment with the computer vision component have to be properly addressed in order to accommodate all challenges that are encountered in a typical industrial environment [5–8]. In this regard, the aim of this chapter is to detail the development of a fully integrated machine vision system that has been specifically designed to assess the surface quality of the painted slates. In this chapter we will discuss in detail the design choices that were made in the development phase of the proposed vision sensor and we will also describe the algorithmic solutions that were implemented to accommodate the large variation of the structural and paint defects that are present on the surface of the painted slates. This chapter is organised as follows. ➤ Section 30.2 discusses the related systems that have been documented in the literature. ➤ Section 30.3 provides a description of the typical slate defects and the discussion is continued in ➤ Sect. 30.4 with the brief presentation of the developed slate inspection system. In ➤ Sect. 30.5 the adopted illumination set-up is detailed. ➤ Section 30.6 details the image processing inspection algorithm, while in ➤ Sect. 30.7 the challenges introduced by factory conditions are analysed. ➤ Section 30.8 presents the experimental results, while ➤ Sect. 30.9 concludes this chapter.

30.2 Related Vision-Based Inspection Systems

Although the application of machine vision solutions in the development of industrial systems is a well-documented topic of research, we were not able to identify any relevant work on the inspection of painted slates. However, following a detailed search on the specialised literature, we were able to find a large number of approaches that have been proposed to address the automatic inspection of ceramic tiles [3, 9–15], which are products that have several common characteristics with painted slates. Thus, although the manufacturing processes for slates and ceramic tiles are different, both products have rectangular shapes, have textured surfaces and they are transported at the inspection point via conveying means [2]. Also, the defects associated with ceramic products resemble characteristics that are common with the visual defects that are specific for painted slates, but the range of defects (types and sizes) for ceramic products is substantially reduced when compared to the large variety of slate defects.

The works in the field of ceramic tile inspection reviewed in this chapter employed a large spectrum of different imaging sub-systems and processing techniques to detect the visual defects that may be present on the surface of the product. One issue that has to be accommodated during the development phase of the developed inspection systems was the relative large range of structural and paint defects that can be encountered during the manufacturing process. In order to address this challenging scenario, the advantages associated with the multi-component inspection process start to become apparent. In this regard, the vast majority of reviewed systems approached the inspection process in a modular fashion where each component has been customised to identify a specific category of defects. To further improve the performance of the defect identification module, a critical issue was the adoption of appropriate opto-mechanical and sensorial equipment and the optimisation of the illumination set-up. Thus, most ceramic inspection systems employed line-scan cameras to minimise the spatial non-uniformities during the image acquisition process, and this option was also motivated by the fact that conveying means were invariably used to transport the products to the inspection line. (The use of standard array CCD/CMOS cameras was rarely noticed and this imaging solution has been primarily employed in the development of prototype systems.) The use of line-scan cameras has alleviated to some extent the requirement to devise complex illumination arrangements, as the light intensity has to be maintained uniform only along a narrow stripe area (that is imaged by the line-scan sensors). To this end, the ceramic inspection systems examined in our review employed either diffuse [9–12, 16] or collimated lighting set-ups [1, 2, 12, 16].

In line with the optimisation of the opto-mechanical components, the development of robust image-processing procedures to detect the visual defects proved to be a key element to the success of the overall inspection system. Our survey on ceramic tile inspection revealed that two approaches were dominant, namely, approaches that perform the identification of the visual defects using either morphological techniques [1, 13, 16–20] or inspection solutions based on texture analysis [2, 14, 21–25]. From these approaches, the morphological-based implementations proved prevalent as they offer efficient implementations that are capable of real-time operation. In this regard, Boukouvalas et al. [10] employed 1D convolvers in the horizontal and vertical directions to identify the line and spot defects on the surface of the coloured ceramic tiles. In their implementation, the filter coefficients are tuned to capture a narrow range of line widths and this fact substantially complicates the generalisation of this approach if it will be re-engineered to encompass the wide variety of visual defects present on the surface of the slates. This work was further developed by the authors in [11, 12] where they developed more involved techniques that have been applied to inspect the coloured and patterned ceramic tiles. In [11], the authors introduced a clustering approach that has been applied to segment the image data captured from a patterned tile into background and foreground information. In this study, the authors were particularly concerned with the development of an intensity correction procedure that aimed to alleviate the spatial and temporal non-constancies that were inserted by the imperfections in the illumination set-up and non-linearity response of the imaging sensor. Although the authors did not provide numerical results to quantify the accuracy of the proposed approach, this paper is a good example that illustrates the range of problems that need to be addressed in the implementation of machine vision systems. A different approach was proposed in [10] where the authors discussed the application of Wigner distributions to the inspection of patterned tiles. Although this approach is interesting as it can be applied to the inspection of a large palette of ceramic products, it has less relevance to slate inspection as the surface of the painted slates is characterised by a mild non-regularized texture. Peñaranda et al. [9] proposed an alternative approach that has potential to be applied to slate inspection. In their paper, the authors proposed an inspection algorithm that evaluates the local grey-scale intensity histograms as the main discriminative feature in the process of identifying the defective image regions. Unfortunately, when we applied this solution to slate inspection, this approach proved unreliable since we found out that the greyscale distributions vary considerable from slate to slate when they emerge from the paint line. In addition to the inter-slate greyscale intensity variation, the low statistical impact of the small defects on the profile of the intensity distributions precludes the use of a priori patterns that are able to encompass the variations within image regions of acceptable finish quality. A related approach was proposed by Boukouvalas et al. [12] where colour histograms have been employed to sample chromato-structural properties of patterned ceramic tiles. In this work, the authors attempted to address a large range of issues including the evaluation of robust similarity metrics, spatial and temporal colour normalisation and the development of a computationally efficient hierarchical colour representation scheme. A few years later, this approach was further developed by Kukkonen et al. [14] where they extracted ten local features from the local distributions calculated in the hyper-spectral domain. The main motivation to use hyper-spectral data resides in the fact that it samples in a more elaborate manner the spectral properties of the ceramic tiles than the standard RGB data [26], but the experimental results reveal that the best performance was achieved when normalised *rgb* chromaticity values were used for classification purposes.

As mentioned earlier, a distinct area of research was concerned with the application of texture-based approaches in the development of product inspection systems. Approaches that are included in this category include the work of Tobias et al. [3], Ojala et al. [27], Mäenpää et al. [21] and Mandriota et al. [25]. These methods addressed a large range of industrial inspection applications and the most promising technique when evaluated in conjunction to the inspection of painted slates was the *local binary pattern* (LBP) approach that was initially developed by Ojala et al. [27]. To this end, in a recent publication [2], we have developed an automatic slate inspection system where the texture and tonal (greyscale) information were adaptively combined in a split-and-merge strategy. The experimental results proved the effectiveness of this approach (99.14%), but the main limitation was the large computational time required to process the slate image data.

From this short literature survey, we can conclude that the development of a robust algorithm for slate inspection is a challenging task since a large number of issues relating to the opto-mechanical design and the selection of appropriate image processing procedures have to be addressed. During the development phase of the proposed prototype, we were forced to adopt a modular approach as the slate's greyscale information shows a heterogeneous distribution with substantial inter-slate intensity variations. Moreover, in our design, we had to confront other challenging issues including the depth profile variations (slate bowing) and vibrations that were introduced by the slate transport system.

30.3 Description of the Visual Defects Present on the Surface of Painted Slates

The slates are manufactured using a mix of raw materials including cement, mineral, and synthetic fibres and after they are structurally formed and dried, they are automatically painted on a high-speed line. While the primary function of the slates is to prevent water ingress to the building, they also have certain aesthetical functions. Consequently, the identification of visual defects is an important aspect of the slate manufacturing process and to answer this requirement inspection procedures are in place to ensure that no defective products are delivered to customers. Currently, the slates are manually inspected by human operators and they make a decision as to whether each individual product is defect-free and remove the slates that are not compliant to stringent quality criteria. To this end, the products meeting the quality criteria need to be correctly formed (having an undistorted rectangular shape with minor deviations from a planar surface) and their top surface should be uniformly painted in dark grey with a high gloss finish (the characteristics of the manufactured slates are listed in ➲ *Table 30.1*).

An interesting aspect associated with the manual slate inspection is to evaluate the frequency of the minor and repetitive faults that may occur when the slates are painted. This information can be used to correct the improper settings of the high-speed paint line and to allow the efficient sorting of the finite products into batches with uniform characteristics.

As the slate manufacturing process entails two major production stages, namely, the slate formation and slate painting, the visual defects can be divided into two broad categories: substrate and paint defects. Thus, substrate defects include incomplete slate formation, lumps, depressions and template marks, whereas paint defects include no paint, insufficient paint,

Table 30.1
The main characteristics of the manufactured slates

Dimension	Nominal (mm)	Tolerance (mm)
Length	600	±3
Width	300	±3
Thickness	4.0	±0.1
Local flatness profile	±0.1	±0.1
Concavity	±0.05	±5
Convexity	±0.05	±5

paint droplets, orange peel, efflorescence and paint debris. The substrate and paint defects may have arbitrary shapes and their sizes range from 1 mm^2 to hundreds of square millimetres. ➲ *Table 30.2* details a comprehensive list of most common visual defects present on the surface of defective slates, where for each defect type a brief description is provided.

To further aid the reader in the process of interpreting the variability of the visual defects that may occur during the slate manufacturing process, a number of representative paint and substrate defects are depicted in ➲ *Figs. 30.1* and ➲ *30.2*, where ➲ *Fig. 30.1a* illustrates a defect-free slate image section.

30.4 Overview of the Developed Slate Inspection System

In order to devise a flexible machine vision solution, we have adopted a modular approach in our design. The prototype slate inspection system was built to closely replicate the manufacturing environment and consists of three main modules. The flowchart detailing the logical connections between constituent modules is illustrated in ➲ *Fig. 30.3*. All modules of the developed inspection systems are controlled by an industrial PC, which is also the host of the image processing software that has been designed to perform the classification of the slates into acceptable and defective products.

The first module consists of the product feeding and the mechanical interface (slate transport system). In our implementation, we have employed a 2 m long belt-driven industrial conveyor manufactured by Noreside Conveyors and Elevators (Ireland) that has been constructed to minimise the vibrations during the slate transport. An important issue was the selection of the belt material that minimises the amount of reflective light arriving back at the camera. After a careful selection, we have chosen a belt that is coated with a matte black rubber material that has low specular properties. To minimise the lateral drifts and slate rotations, a guide was placed on one side of the conveyor.

The second module of the slate inspection system is represented by the optical and sensing equipment. In the development of our slate inspection sensor, we have used a Basler L102 2K-pixel line-scan camera which is fitted with a 28 mm standard machine vision lens (aperture set to 2.8). The line-scan camera operates at a scan frequency of 2.5 kHz. To allow a facile calibration of the sensing equipment with the illumination unit, the line-scan camera was attached to a micropositioner that allows fine adjustments to the camera view line with respect to the *xyz* coordinates. The camera set-up is illustrated in ➲ *Fig. 30.4*. The interface between the

Table 30.2
A brief description of the visual defects

No.	Defect type	Defect size	Description
1	Lumps	$2.0 < \{L,W\} < 50$ $\pm 0.1 < H < \pm 3.5$ mm	Excess material on surface. Often conical shape
2	Depressions	$2.0 < \{L,W\} < 50$ $\pm 0.1 < D < \pm 3.5$ mm	Insufficient material on surface. Often inverse conical shape
3	Holes	$\phi = 4.5$ mm	Holes are present to assist insertion of nails. Absence indicates fault
4	Incomplete slate	Any $W \neq W_{\text{expected}} \pm 3.0$ mm Any $L \neq L_{\text{expected}} \pm 3.0$ mm	W, L dimensions not conforming to production specification
5	Poor quality edge	$W = 0.2$ mm * $L > 10$ mm	Edge not straight or having a feathery feel
6	Template mark	$0.5 < \{L,W\} < 600$ mm $0.1 < \{D,H\} < 3.0$ mm	Excess material on the slate surface caused by damage to forming template
7	Template mark II	1.0 mm $< d <$ all slate	Texture variation on the slate surface, usually roughness
8	Insufficient paint	20 mm $< \{W, L\} <$ all slate	Shade variation due to insufficient paint usage
9	Missing paint	2 mm $< \{W, L\} <$ all slate	No paint or incomplete painting
10	Droplet	$2 < \{W, L\} < 15$ mm $0.05 < D < 0.5$ mm	Excess paint on surface, dried and cracked
11	Efflorescence	Area > 25 mm^2	Contaminant on surface preventing the correct adherence of paint
12	Paint debris	$2 < \{W, L\} < 50$ mm	Dried paint debris encrusted on slate surface giving a rough texture
13	Orange peel	$20 < \{W, L\} <$ all slate	Shade variation caused by overheating the slate
14	Barring	$W = 10 \pm 5$ mm $20 < L < 600$ mm	Shade variation caused by uneven heating of slate
15	Spots	$1 < \{W, L$ ø$\} < 5$ mm	Small areas presenting shade variation
16	Nozzle drip	$W = 10 \pm 5$ mm $20 < L < 600$ mm	Shade variation caused by uneven paint delivery from nozzle
17	Wax mark	$5 < \{W, L\} < 50$ mm	Splash of wax on top surface

camera and the industrial PC computer was facilitated by a Euresys frame grabber. Another important component of the optical and sensing module is represented by the illumination set-up. In our implementation, we have designed a collimated light arrangement that relies on the strong reflective properties of the slate's surface (full details about the implementation of the illumination set-up used in our design will be provided in the next section of this chapter). The last component of this module is represented by a proximity sensor, which has the role to trigger the image acquisition process prior to the arrival of the slate at the inspection line.

The final module of the system performs the identification of the visual defects in the image data captured by the line-scan camera. While the development of a single procedure to identify all types of defects detailed in *Table 30.2* was not feasible, the proposed inspection algorithm has been also designed in a modular fashion where each component has been tailored to identify one specific category of defects (the proposed inspection algorithm will be detailed in Sect. 30.6). The developed prototype slate inspection system is illustrated in *Fig. 30.5*.

30.5 Illumination Set-Up

The strategy used to image the slate relies on the strong reflective properties of the slate surface. In our experiments, we have tested several illumination set-ups involving diffuse and collimated lighting arrangements. Initially, diffuse lighting techniques were explored as this illumination technique generates a uniform wide light band that offers a facile camera calibration. Thus, the first experiments were carried out using an aperture fluorescent light system with a cylindrical focusing lens (TSI Model AFL9000), where light is dispersed equally in a 60° arc. One important aspect when designing our illumination set-up was the identification of the lamp angle of incidence that generates the strongest optical signal that is reflected back to the line-scan camera. In our experimental trials, we have discovered that the optimal optical response was achieved when the lamp angle of incidence was set at 40° and the camera was symmetrically located at 40° relative to the slate position. With this arrangement, the camera exposure time was set to 2 ms and at this setting the moving direction pixel resolution was approximately 2 mm when the conveyor was operated at

production line speeds. This resolution is not sufficient to identify the small and medium-sized visual defects and our additional tests confirmed that the light intensity produced by diffuse lighting techniques is substantially lower than that required to properly image the slates at the inspection line speed. Consequently, our efforts were concentrated on the development of an alternative illumination unit that involves a customized collimated lighting approach.

The collimated illumination solution adopted in our implementation is building on the fact that the paint defects have reduced gloss levels (except paint droplets) than the slate areas of acceptable quality. Substrate defects are associated with errors in slate formation and the appearance of these visual defects also results in a reduction of light arriving at the line-scan sensing element. The illumination arrangement comprises two Fostec DCR III 150 W lamp controllers, a Fostec 30″ fibre optic light line and a cylindrical lens. A schematic description of the devised illumination set-up is illustrated in ➋ *Fig. 30.6*. The lamp angle of incidence has been set to 45° and the camera view angle was located symmetrically to 45°. The lamp intensity level was set to approximately 80% with respect to the maximum level and the camera exposure time was set to 400 μs at a scan frequency of 2.5 kHz. This setting allows us to image the slate

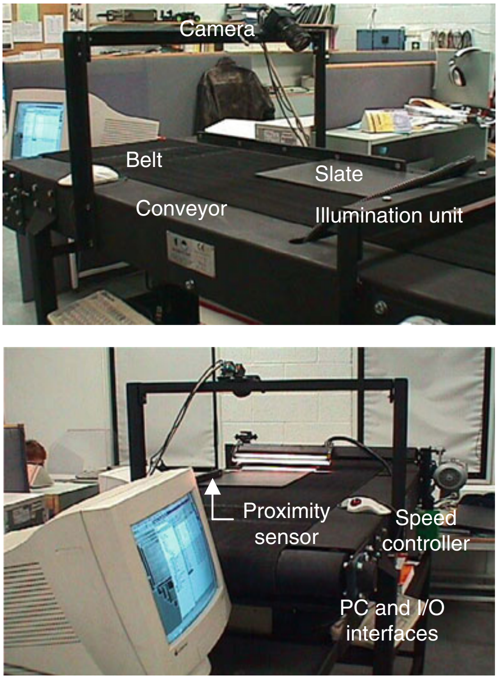

Fig. 30.5
The prototype slate inspection system [1]

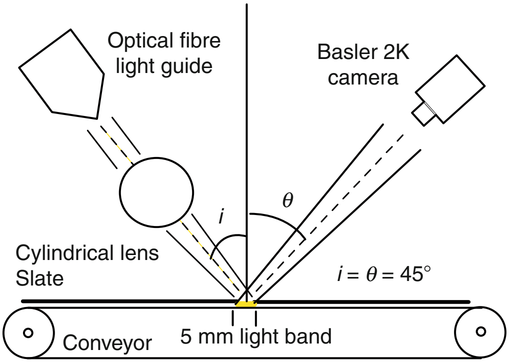

Fig. 30.6
Schematic detailing the developed illumination set-up

with a cross pixel resolution of 0.221 mm and a moving pixel resolution of 0.244 mm. This pixel resolution is sufficient to properly image the entire range of defects that are present on the surface of the painted slates.

Although the illumination set-up detailed in ➜ *Fig. 30.6* generates sufficient illumination levels required for image acquisition at production line speeds, one issue that we encountered was the narrow band of the focused collimated light. Indeed, when we positioned the lens to attain perfectly focused collimated light, the resulting light band was only 5 mm wide (see ➲ *Fig. 30.6*) and the process required to align the camera line view for a distance of 30″ requires adjustments with a precision of less than 1° ($\delta\theta < 1°$). To facilitate such adjustments, we mounted the camera on a micropositioner as indicated in ➲ Sect. 30.4. However, the alignment of the camera line view to the longitudinal axis of the light band was not the only issue we had to confront during the development phase of the illumination set-up. One of the most challenging problems was the variation in depth profiles across the slate due to slate bowing that is sometimes associated with slates that have acceptable quality with respect to inspection criteria. The small slate bowing was found to range from negligible to 5 mm over the slate length and up to 2 mm along the slate width. Although the variation in depth profile does not affect the functionality of the product, it has introduced a substantial challenge that has to be accommodated by the proposed illumination solution. While the depth profile non-uniformities raise and lower the absolute position of the projected light band with respect to the camera line view, this practically compromises the image acquisition process. To give some insight into the problem generated by slate bowing, if we consider that the incidence of the light band and the camera view angle are set symmetrically to 45° as illustrated in ➲ *Fig. 30.6*, if the slate raises the light band with 1 mm, then the reflected light is shifted to 1.5 mm in opposite direction with respect to the camera view line. Since the slate possesses some elasticity, a pneumatic solution that forces the slate into a uniformly planar shape during inspection would be feasible. However, there are several disadvantages associated with such mechanical solutions that can be used to force the slate into the nominally flat shape. The first is related to the fact that the painted surface can be easily damaged when the pneumatic device is operated at high production line speeds, and secondly the development of such mechanical system would be problematic taken into consideration the non-smooth characteristics of the underside of the slate. As a mechanical solution to force the slate into a uniform flat position proved unfeasible, we elected to defocus the lens that is used to collimate the light generated by the Fostec fibre optic light line. This produces a wider light band but this is achieved at the expense of reduced collimation. To compensate for the reduced intensity levels caused by de-collimation, we used the spare capacity in the lamp controller. Following a simple trigonometric calculation, the lens has been defocused to generate a 25 mm wide light band, an increase that is sufficient to accommodate the slate bowing effects in the range [0, 5 mm] and the vibrations caused by the slate transport system.

The last issue that we confronted during the development of the illumination set-up was the implementation of a software routine that was applied to compensate for the non-linearities in the horizontal profile (longitudinal axis) of the light band. As the fibre optic light line is 30″ long, the profile of the light band shows stronger illumination levels towards the central position when compared to the intensity level supplied at the left and right extremities of the slate. This is illustrated in ➲ *Fig. 30.7a* where the unprocessed horizontal light profiles for three reference slates are depicted. To compensate for this uneven response of the illumination unit, we have subtracted the mean intensity level (calculated from all reference slates that are used to train the system) from the unprocessed data and the obtained results are averaged with respect to each pixel position to compute the light compensation map. This light compensation map encodes the deviations from the expected mean intensity level, and it is directly used to linearise the unprocessed horizontal profile (see ➲ *Fig. 30.7b*). The application of the horizontal profile linearization reduced the light variation in the horizontal direction from 20% to 2.5%. The linearisation of the response of the illumination unit in the moving direction was deemed unnecessary, as the light intensity variation in the vertical axis shows negligible variation due to de-collimation.

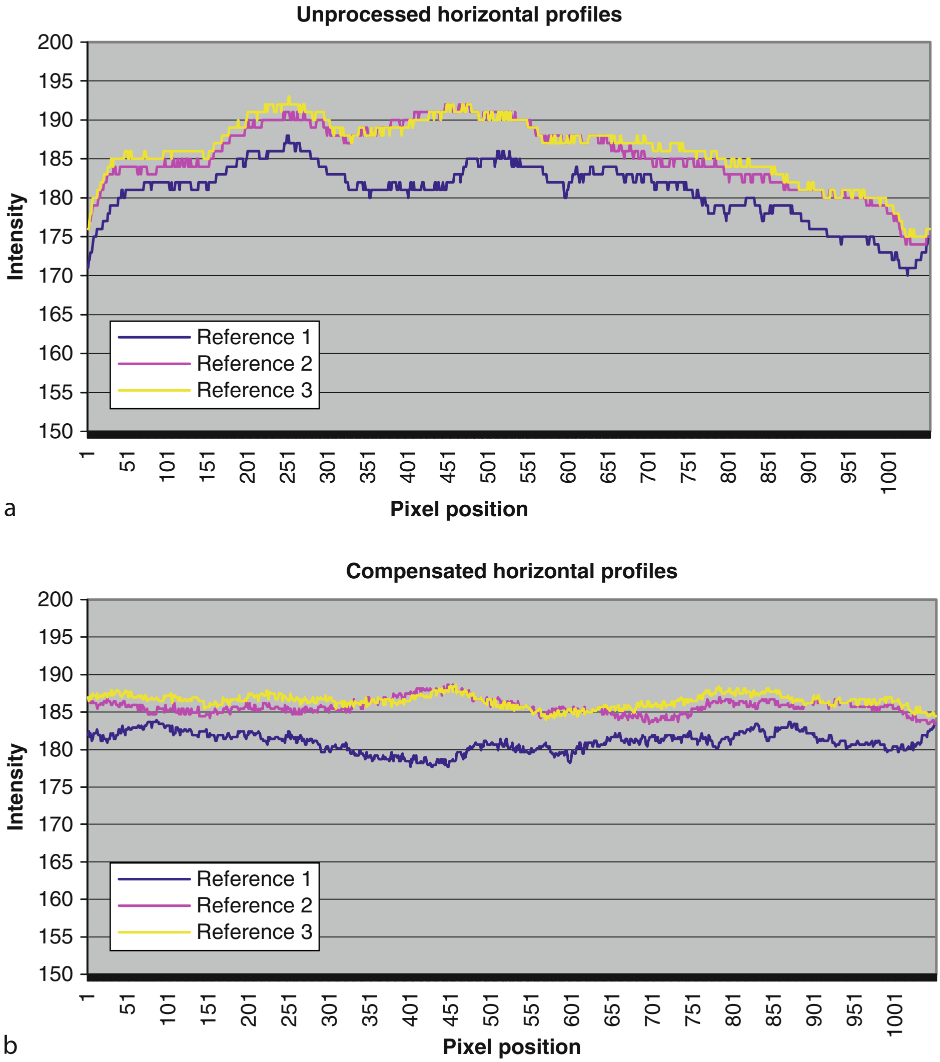

Fig. 30.7

Compensation for the non-linearities in the response of the light unit along the horizontal direction. (a) Unprocessed horizontal light profiles. (b) Compensated horizontal light profiles

30.6 Slate Inspection Algorithm

As indicated in Sect. 30.4, the slate inspection algorithm has been designed in a modular fashion where each component has been optimised to identify one category of visual defects. This approach was appropriate as the modular architecture allows facile system training and more importantly the parameters that need to be optimised for each component can be easily adjusted if changes are made on the specification of the finite product. To this end, the proposed algorithm involves five distinct computational strands that were tailored to address specific inspection tasks. Full details about each image processing component of the developed inspection algorithm will be provided in the remainder of this section.

30.6.1 Segmentation of Slate from Image Data and the Nail Hole Verification Procedure

The first step of the slate inspection algorithm involves the segmentation of the slate from the image data. The identification of the slate boundaries was facilitated by cutting slots in the conveyor base and ensuring that the width of the belt is less than that of the slate. This design choice was implemented to ensure that no light arrives back at the line-scan camera when the slate is not imaged and to provide a sharp rise in the optical signal when the slate arrives at the inspection line. Thus, a simple threshold operation is sufficient to robustly segment the slate data and the segmentation process is followed by the identification of the edges and the four corners of the slate. To avoid computationally expensive procedures required to optimise the image acquisition process, a proximity sensor was employed to activate the line-scan sensor prior to the arrival of the slate at the inspection point.

Once the corners of the slate are identified, the next operation verifies if the nail holes are correctly positioned with respect to slate boundaries. The nail hole detection involves a threshold-based segmentation technique since the intensity of the optical signal associated with the nail hole is substantially lower that that given by the slate surface. The developed nail hole checking procedure starts with the identification of the hole that is located on the left-hand side of the slate surface. The detected *xy* co-ordinates of the nail hole are compared to pre-recorded values and if the procedure passes inspection conditions then the algorithm proceeds with the verification of the remaining two nail holes that are located close to the right-hand side top and bottom slate corners. If the nail checking procedure triggers the absence of a nail hole or an incorrect nail hole placement with respect to slate boundaries, the slate is classed as defective and put aside for rejection or re-work. If the nail holes are correctly positioned, then the algorithm fills them with adjacent slate surface pixel information to prevent the identification of visual faults when the slate data is subjected to the automatic inspection process. ➲ *Figure 30.8* describes graphically the nail verification procedure.

30.6.2 Identification of the Visual Defects

Prior to the development of the computational modules for visual defect identification, we have analysed the grey level signals associated with reference and defective slates. The experimental trials indicated that the mean grey levels associated with acceptable slates from similar production batches can vary up to 20 grey levels where the overall mean value is 167. To clarify the source of this greyscale variation among reference (non-defective) slates, we evaluated the intensity data using different image acquisition approaches. From these experiments, we concluded that these variations were not caused by the imperfections in the sensing and optical equipment but rather due to an acceptable variation in the slate surface paint colour. Thus, the image processing procedures that will be investigated have to be sufficiently robust to accommodate this level of inter-slate greyscale variation. In order to identify the computational components of the inspection algorithm, we have analysed the grey level signals associated with paint and substrate defects and a summary of the test results is shown in ➲ *Table 30.3*.

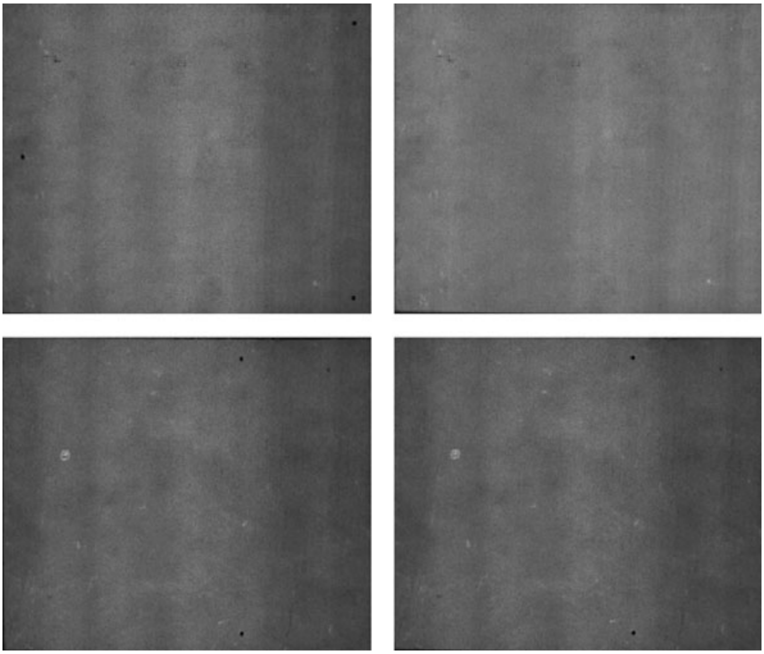

Fig. 30.8
Nail hole verification procedure. (*Top row*) Slate that passes the nail hole verification test. (*Bottom row*) Slate that fails the nail hole inspection procedure. In the last column, the images resulting after the nail hole inspection procedure are displayed. Note that the image that passes the nail hole verification test has the nail hole areas filled with pixels information from adjacent slate surface data to be ready for defect inspection

This analysis allowed us to evaluate the impact of the visual defects on the overall intensity data distribution. Our study revealed that the vast majority of defects have a negligible influence on the overall slate intensity data distribution, and this finding clearly indicates that it would be desirable to inspect the slate image in small subsections, as the relative impact of the defect on the grey level statistics is substantially increased. To this end, the slate image was divided into segments of 128 × 128 pixels and each segment needs to be individually processed.

Based on the analysis of the greyscale values associated with reference and defective image sections, we have devised an algorithm which consists of four distinct computational strands – in this approach each component has been designed to strongly respond to a narrow category of visual defects. The block diagram of the developed slate inspection algorithm is depicted in *Fig. 30.9* and the main components can be summarised as follows:

- Global mean threshold method
- Adaptive signal threshold method
- Labelling method
- Edge detection and labelling method

Each component depicted in *Fig. 30.9* is applied to each 128 × 128 segment of the slate image and the results are compared to experimentally determined thresholds. Each component of the slate inspection will be detailed in the remainder of this section.

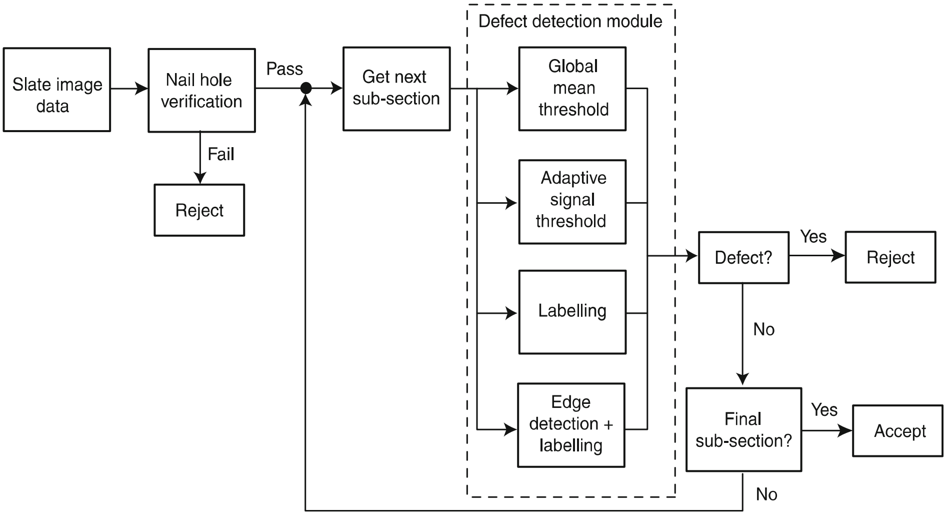

Fig. 30.9
Overview of the slate inspection algorithm

30.6.3 Global Mean Threshold Method

This component has been developed to evaluate the mean grey level of the image section with the aim of identifying the gross defects that may be present on the surface of the slate. In this regard, the mean value for each subsection is compared to an experimentally determined mean value and this approach proved to be effective in detecting a range of defects including missing paint, orange peel, efflorescence, insufficient paint and severe shade variation.

In spite of its simplicity, this method proved to be the most reliable in detecting defects that cover large areas of the slate surface, defects that have a dramatic impact on the greyscale distribution when evaluated at local level (see ➔ *Fig. 30.10*). To increase the robustness of the proposed method, a global mean threshold has been employed to identify defects such as missing paint and orange peel, and grade-specific thresholds were experimentally determined for the identification of low contrast defects such as efflorescence, insufficient paint and shade variation.

30.6.4 Adaptive Signal Threshold Method

Our experimental measurements indicated that the slate texture induces a greyscale variation for non-defective image sections in the range [mean − 30, mean + 30]. When analysing the 128 × 128 image sections for visual defects, to avoid the occurrence of false positives we need to locate the paint and substrate defects outside the range [mean − 40, mean + 60]. By thresholding the image data with these values, a relative large category of visual defects can be robustly identified [1]. The defects detected by this method include missing paint (where less than 50% of the image section is defective), localised paint faults such as paint debris, droplets, spots and structural defects generated by an improper slate formation.

This method has not been found useful in detecting low-contrast visual defects such as barring and elongated depressions whose grey levels are within the greyscale variation generated by the slate texture. Representative paint and substrate defects that are detected by the adaptive signal threshold method are depicted in ➔ *Fig. 30.11*.

30.6.5 Labelling Method

The aim of this method is to identify the visual defects that cover a relative small area with respect to the overall size of the analysed 128 × 128 image section. This method consists of several steps that are illustrated in ➔ *Fig. 30.12*.

The first step of the labelling method converts the image corresponding to the analysed slate section into the binary format by applying a local adaptive threshold operation [28]. The aim of this step is to identify the relative bright and dark regions with respect to the local grey mean value. The second step involves the application of a binary opening operation with the aim of removing the small unconnected regions that are caused by the non-regularized slate texture and the image noise. The third step involves the application of the labelling by area operation [28, 29] to provide a unique label for each disjoint white blob in the image resulting from the morphological opening step. Since the small blobs are often associated with the slate texture, the largest blobs are of interest as they are generally caused by visual defects. Thus, to reduce the impact of the randomly distributed blobs that are generated by the slate texture, we compute the area of the ten largest blobs and this feature is used to discriminate between

Overview of the labelling method

reference and defective image sections. This method proved effective in identifying high-contrast defects such as droplets, paint debris, spots, efflorescence and template marks. A small collection of visual defects that are identified by the labelling method is depicted in *Fig. 30.13*.

30.6.6 Edge Detection Method

The last component of the inspection algorithm has been designed to specifically detect the narrow elongated defects, as the previously described methods were not sufficiently accurate in identifying this type of slate faults. As this defect identification method is based on the application of first-order derivative operators (Sobel edge detector), prior to edge extraction the image data is subjected to median filtering. The experimental measurements carried out

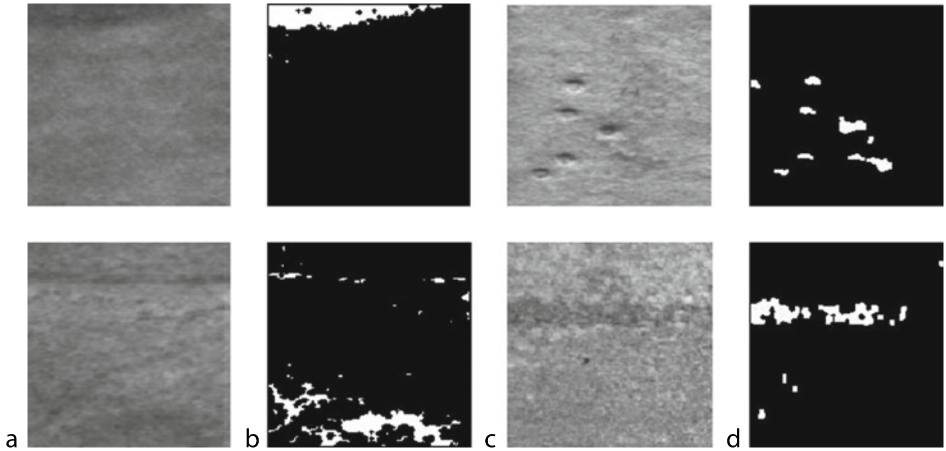

Fig. 30.13
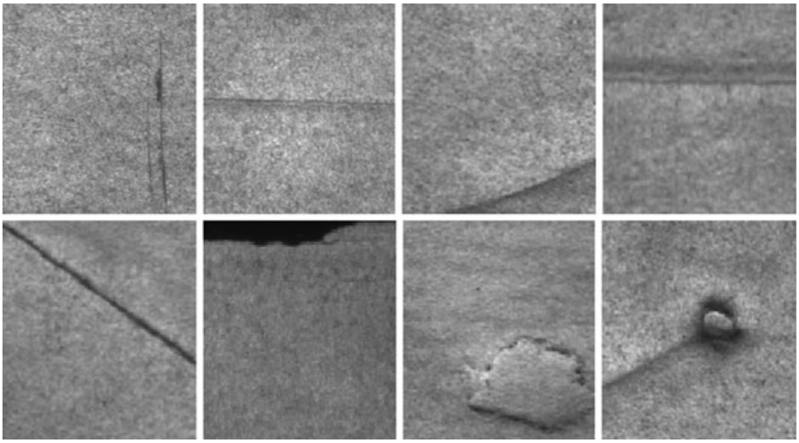
Visual defects identified by the labelling method. (a, c) Defective slate sections. (b, d) Resulting images after the application of the labelling method. ***Top row*** **– paint defects such as shade variation and paint droplets.** ***Bottom row*** **– substrate defects (template marks)**

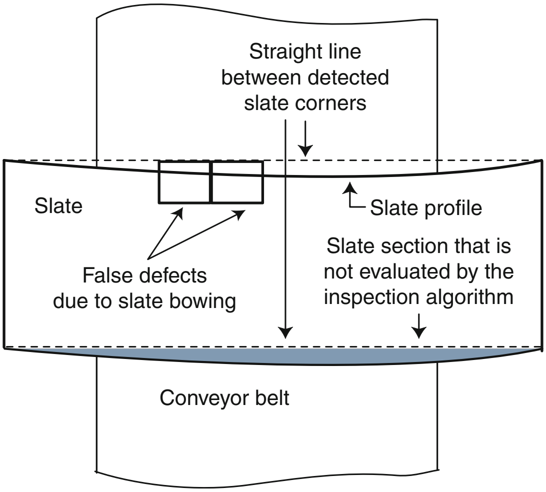
during the development phase revealed that narrow defects such as depressions and elongated substrate marks have a shallow intensity profile and as a result gaps are present in the resulting edge structure. To compensate for this issue, a morphological closing operator is applied and the resulting data is labelled by area for further analysis. Similar to the approach used for labelling method, the largest ten components were retained and their collective area is used as a discriminative feature to grade the slate section under analysis as acceptable or defective. *Figure 30.14* depicts some representative defects that are identified by the edge detection method.

30.7 Effect of Slate Bowing on Slate Inspection

The slate inspection algorithm detailed in Sect. 30.6 performs the identification of the visual defects on each 128 × 128 segment of the slate image. To facilitate the tiling of the slate image into sub-sections, the slate was approximated with a rectangle that is obtained by connecting the corners of the slate that have been identified during the slate segmentation process (see Sect. 30.6.1). This procedure worked very well when applied to flat slates, but generated false triggers when applied to slates that are affected by depth profile variations (slate bowing). These false positives are caused by the displacements between the straight edge obtained by connecting the slate corners and the curved edge of the imaged slate. This slate edge positioning errors lead to an incorrect image tiling and this generates situations when the 128 × 128 image segments include non-slate image data (background information), while on the opposite side of the slate there are sections of the slate that are not investigated by the inspection algorithm (see the shaded area in *Fig. 30.15*). This is illustrated in *Fig. 30.15* where the problems caused by slate bowing are illustrated. An example that shows the occurrence of false positives due to slate bowing is depicted in *Fig. 30.16*.



◘ Fig. 30.14
Visual defects identified by the edge detection method. (*Top images*) Paint defects. (*Bottom images*) Structural defects



◘ Fig. 30.15
False defects generated by slate bowing

To address this issue, the procedure applied to identify the slate edges has been modified in order to accommodate the deviations that occur from the straight edge when imaging slates that are affected by depth profile variations. In this regard, the edge that is generated by connecting the slate corners is divided into shorter lines with 30 mm length and the location of these short segments is identified with respect to the segmented slate data. Using this approach, the image tiling process ensures that the image sub-sections are placed adjacent to these segments and as a result no slate data will be missed by the inspection algorithm or false positives generated by the incorrect positioning of the image sub-segments with respect to the real edge of the slate.

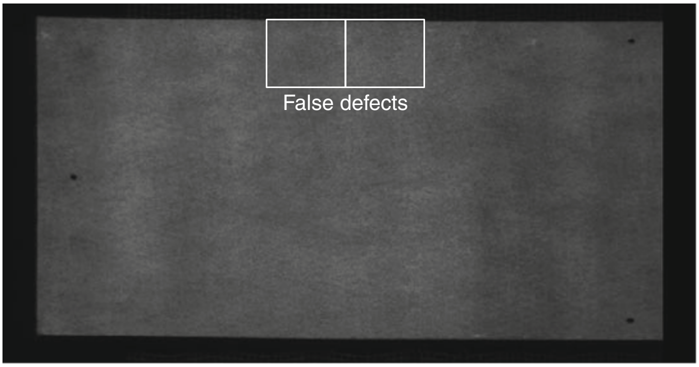


Fig. 30.16
Example illustrating the false defects caused by slate bowing effects

30.8 Experimental Results

The conveyor speed was set at 38 m/min and the camera exposure was set to 400 μs giving a scan frequency of 2.5 kHz. The variability of the conveyor speed has been measured by imaging a reference slate in succession and the experimental results indicate that the variation profile of the conveyor speed induced a 0.8% variation in the pixel resolution in the moving direction [1]. The variation in the pixel resolution due to inconstancies in the conveyor speed has negligible effects on the image acquisition process and it was found that it has no negative effects on the inspection results.

Since the inspection algorithm detailed in Sect. 30.6 entails the optimisation of a large number of threshold parameters, the system has been trained using 400 slates. The developed slate inspection system has been tested on more than 300 unseen slates that are sampled from different production batches. The slates used in the experimental activity were graded into acceptable and defective units by an experienced operator based on a comprehensive visual examination. The proposed system was able to correctly grade the acceptable slates with an accuracy of 99.32% (148 slates) and the defective slates with an accuracy of 96.91% (162 slates). A detailed performance characterisation is provided in *Table 30.4*. To qualitatively and quantitatively illustrate the performance attained by the proposed system, in *Table 30.4* the detection rate for each category of defects listed in *Table 30.2* is provided.

As indicated in *Table 30.4*, the lowest performance of the slate inspection system was achieved in the identification of depressions, which is a subclass of substrate defects. The system failed to identify a defective slate containing a shallow depression that was positioned parallel to the moving direction axis. To fully clarify the impact of these defects on the inspection results, we imaged the slate with the short edge facing forward (slate rotated with 90°). Using this slate orientation, the system was able to identify the defect as it produced sufficient contrast when compared to adjacent non-defective areas of the slate. We envision that the detection rate for this type of substrate defect can be substantially increased if the slate is imaged in two orthogonal directions. The inspection system was also not able to identify two small template marks with an area of approximately 1 mm^2. These defects were missed as their statistical impact on the greyscale distribution of the 128 × 128 slate segment was very limited and the relaxation of threshold conditions for labelling method was not an option since it will

Table 30.4
Summary of detection rate for each category of visual defects

Type	Undetected	Detected	Accuracy (%)
Missing paint	0	4	100
Insufficient paint	0	9	100
Efflorescence	0	15	100
Shade variation	0	12	100
Nozzle drip	0	14	100
Droplets	0	8	100
Dust	0	4	100
Wax	1	7	87.5
Template marks	2	33	94.28
Template marks II	0	5	100
Lumps	0	13	100
Depressions	1	3	75
Bad edge	0	18	100
Misc. types	1	12	92.30
Total	5	157	96.91

lead to a substantial increase in the number of false positives. Typical inspection results are depicted in *Fig. 30.17* where white boxes are used to mark the defective image sections. Additional results are illustrated in *Fig. 30.18* where reference and defective image sections are depicted and the images resulting after the application of the four computational strands of the inspection algorithm are also shown (for the sake of completeness, the pixel count for each method of the inspection algorithm is provided).

30.9 Conclusions

The major objective of this chapter was the introduction of a machine vision system that has been developed for the automated inspection of painted slates. Since the development of an industry-compliant inspection system requires the identification of optimal solutions for a large spectrum of problems relating to opto-mechanical and software design, in this chapter we provided a comprehensive discussion about each component of the system and we emphasized the difficulties that we had to confront during the development phase of the inspection sensor. The illumination set-up proved in particular challenging as we had to devise a solution that is able to provide sufficient illumination intensity that allows imaging the slate at production line speeds, but at the same time it is able to accommodate non-idealities such as slate depth profile variations and vibrations that are introduced by the slate transport system.

The experimental data indicates that automatic slate inspection can be achieved and the installation of the proposed inspection system in a manufacturing environment is a realistic target. The evaluation of the inspection prototype in a factory-style manner was an important part of the development process, as it allowed us to sample, address and optimise a large

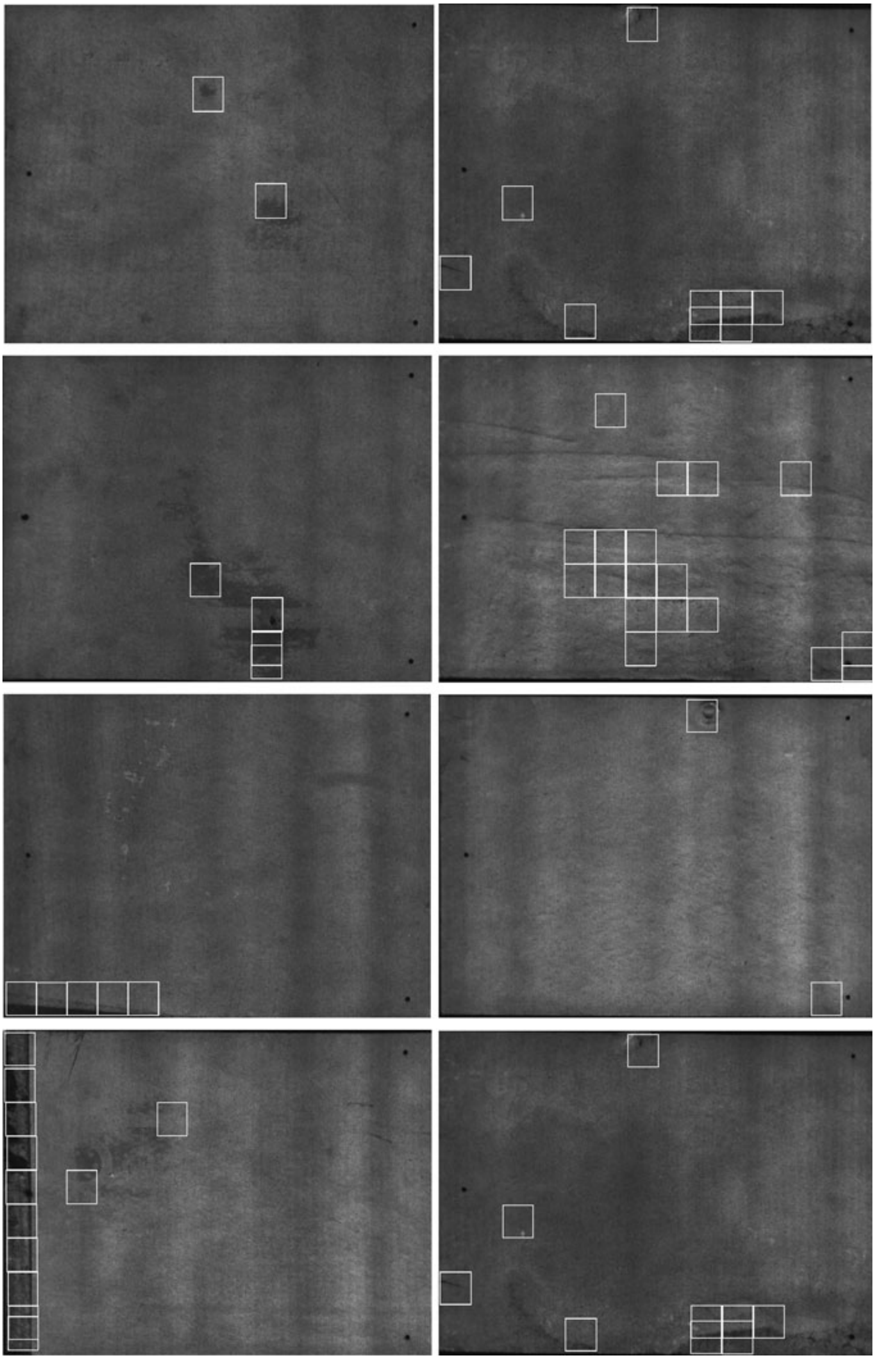

Fig. 30.17

Identification of the visual defects on a selection of defective slates that exhibit a large variety of paint and substrate defects

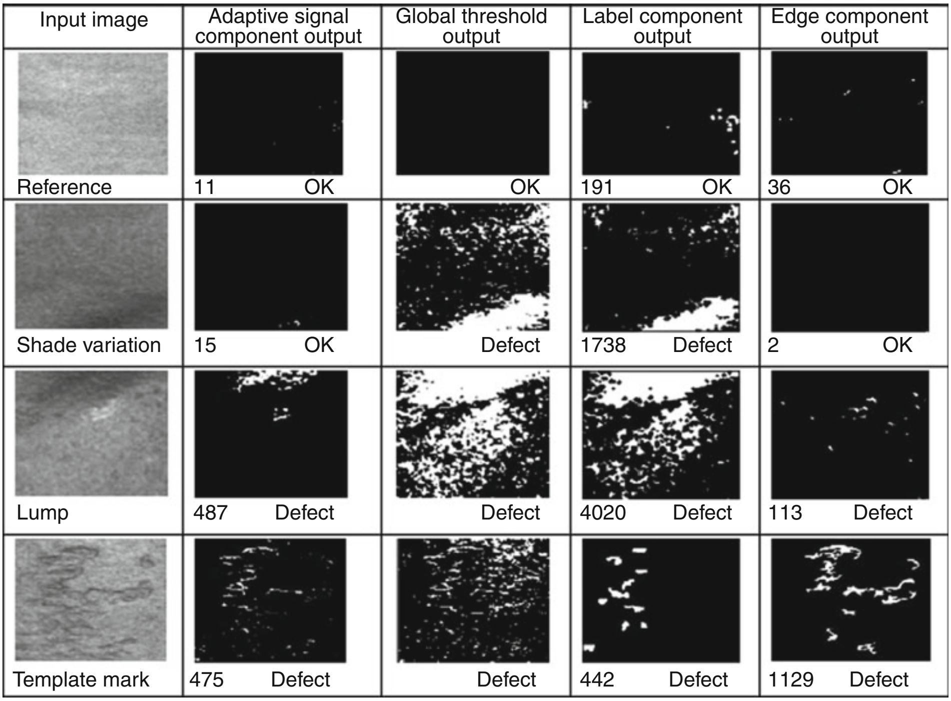

Fig. 30.18
Output of the inspection algorithm for a small set of reference and defective slate sections

number of hardware and software design choices that are required for robust slate inspection. The proposed inspection system attained 96.91% overall accuracy in detecting the visual defects present on the slate surface and this level of performance indicates that the devised machine vision solution can be considered as a viable option in replacing the existing manual inspection procedure.

Acknowledgements

We would like to acknowledge the valuable contribution of our industrial partner during the development phase of our slate inspection system and Enterprise Ireland for its generous financial support.

31 Inspecting Glass Bottles and Jars

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_31,

31.1 Introduction

Despite the popularity of plastic containers, glass bottles and jars remain important for sealing and preserving food products, toiletries and pharmaceuticals. The raw materials are abundant and inexpensive. Although it is brittle, glass is strong and chemically inert, resistant to microbial attack and impervious to water, oil, alcohol, etc. It can be moulded to form a wide variety of useful shapes. It also has the attractive feature of being transparent, which allows the contents to be presented in a visually appealing way. It can also be coloured for cosmetic effect.

Glass is ubiquitous, yet it is potentially dangerous, particularly if it breaks and the resulting shards are swallowed. There is a wide range of defects in moulded glassware used for food and drink (bottles, jars, cheap tumblers, dishes, bowls, etc.) that should be considered:

- Malformations (These are often due to moulding faults as when molten glass is injected into the mould when it is too hot, or sticks to the mould as it opens.)
- Cracks, checks and crizzles (The latter do not penetrate right through the glass wall.)
- Inclusions (These might typically be stone-like fragments of refractory materials that have broken off the lining of the crucible holding the liquid glass.)
- Air bubbles
- Loose glass fragments (For example, a vial breaks during manufacture and scatters flakes and slivers, contaminating nearby containers.)
- Spikes (These are "stalagmites" of glass, found typically in jars and other items that are made by pressing or a *press-blow* manufacturing process. They occur on the base or side walls of a jar.)
- Bird-swings (These are horizontal filaments of glass that span across the inside of a bottle. Physically, they resemble stalagmites and stalactites that have joined together. They result from a faulty *blow-blow* manufacturing process. They occur only on the side walls of a bottle.)

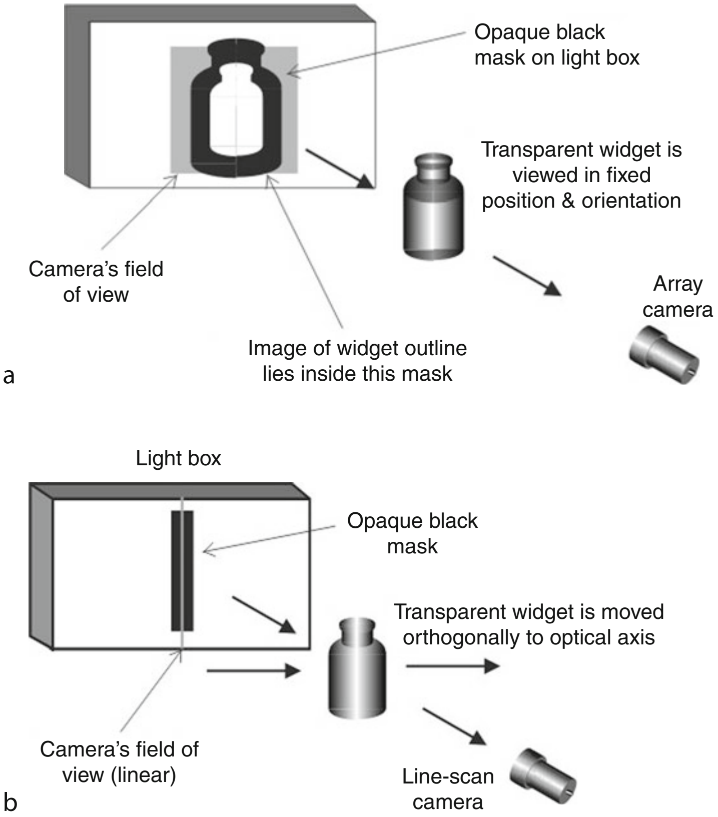
This is a much simplified catalogue of defects that are known to arise in everyday bottles, jars, tumblers. Loose glass fragments, in the form of thin strands, flakes and slivers can occur virtually anywhere. In this short chapter we can only consider a few of these defects; our intention is to highlight the potential for applying Machine Vision, even in an area, such as this where the product is often difficult to illuminate and view. Some defects are euphemistically called *critical* in the glass industry: in lay terms *dangerous*!

Many of the faults that occur in glassware can only be detected properly by optical means. They cannot, for example, be detected by touch. However, a modern manufacturing line produces bottles at a speed that exceeds a human being's ability to inspect them reliably. Recall the cartoon in ➋ Chap.1, showing a (male) human inspector distracted by a fair damsel. (Female inspectors are also susceptible to distraction!) Thus, there is a need for automated visual inspection equipment that can meet this need. In this chapter we briefly explore the subject and will consider some of the topics that a vision engineer designing an inspection system for glass-ware must address.

31.2 Lighting and Viewing

There are several possible methods for inspecting glassware:

- Back-illumination. The light source, bottle and camera are in line.
- Dark-field illumination (➋ *Fig. 31.1*).



Opaque black mask on light box

- Injecting light into the fully formed product from a small number of carefully chosen "point" sources.
- Observing self-emission in the Near-Infra Red wave band, from hot glasss (i.e. after moulding but before annealing.

These are all described in detail and illustrated in Chap. 40 and will not be discussed further. From a vision engineer's perspective, one of the most important features of glass is its clarity and refractive properties (refractive index is about 1.5–1.7). Care must always be taken to shield a glass object from ambient light during inspection. This rule should be followed whether it is being examined automatically or by eye. Failure to do so will result in poor quality images with highlights occurring in a host of unexpected places. This is caused by direct surface reflection and "ducting" of light by total internal reflection through the body of the product.

Both line-scan and standard (array) cameras have been used for glass inspection. A line-scan camera allows a distinctive form of dark-field illumination to be used. As the camera's field of view is a very thin rectangle, light can be injected into the glass wall very close to it. There is no direct counterpart using an area-scan camera. Moreover, many bottles and jars have

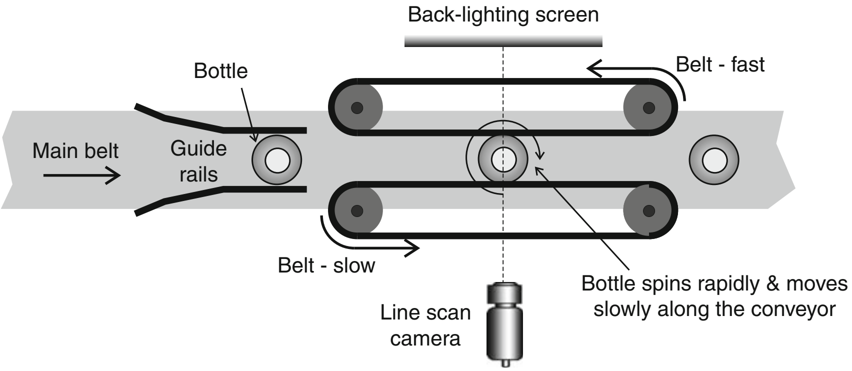

Fig. 31.2
During inspection a round bottle is held between two contra-rotating belts. If the speed of these belts is carefully chosen, the bottle rotates rapidly as it advances slowly along the belt. (It is transported by the side belts and slips on the conveyor.) Hence, a line-scan camera is able to sense local features, such as bird-swings, stones, cracks, etc., wherever they occur around the cylindrical surface of a jar or bottle.

a circular cross section. Again, a line-scan camera offers a unique opportunity in providing an all-round view, which is useful for detecting local defects (➲ *Fig. 31.2*).

Some of the images in the chapter show vignetting and lens distortion, which a telecentric lens would avoid (➲ Chap. 6). This is why the sides of the bottle in ➲ *Fig. 31.3* do not appear parallel. The close-up view of the mouth of a bottle (➲ *Fig. 31.4*) shows another problem: circular features are seen as ellipses of varying eccentricity, depending on their vertical position. In some cases, the effect is that of looking up and sometimes looking down. Again, a telecentric lens would avoid this, viewing all such features precisely side-ways on.

31.3 Bottle Shape

Shape and size measurement is an obvious requirement for both bottles and jars. We shall illustrate various ideas with reference to a back-illuminated bottle. First, however, we must consider how we generate a binary image on which appropriate dimensional measurements can be taken. Consider the bottle shown in ➲ *Fig. 31.3a*. This a typical circularly symmetrical bottle and will serve to illustrate how we derived a suitable algorithm, using the QT interactive image processing system (➲ Chap. 21). As we shall show later, the same procedure has subsequently been applied quite successfully to other glass containers and to images obtained using dark-filed illumination.

31.3.1 Pre-processing

First, of all, we must admit that ➲ *Fig. 31.3a* is not a particularly good of a bottle but it suits our purposes. The background intensity is highly variable as shown in ➲ *Fig. 31.3b* and *c*.

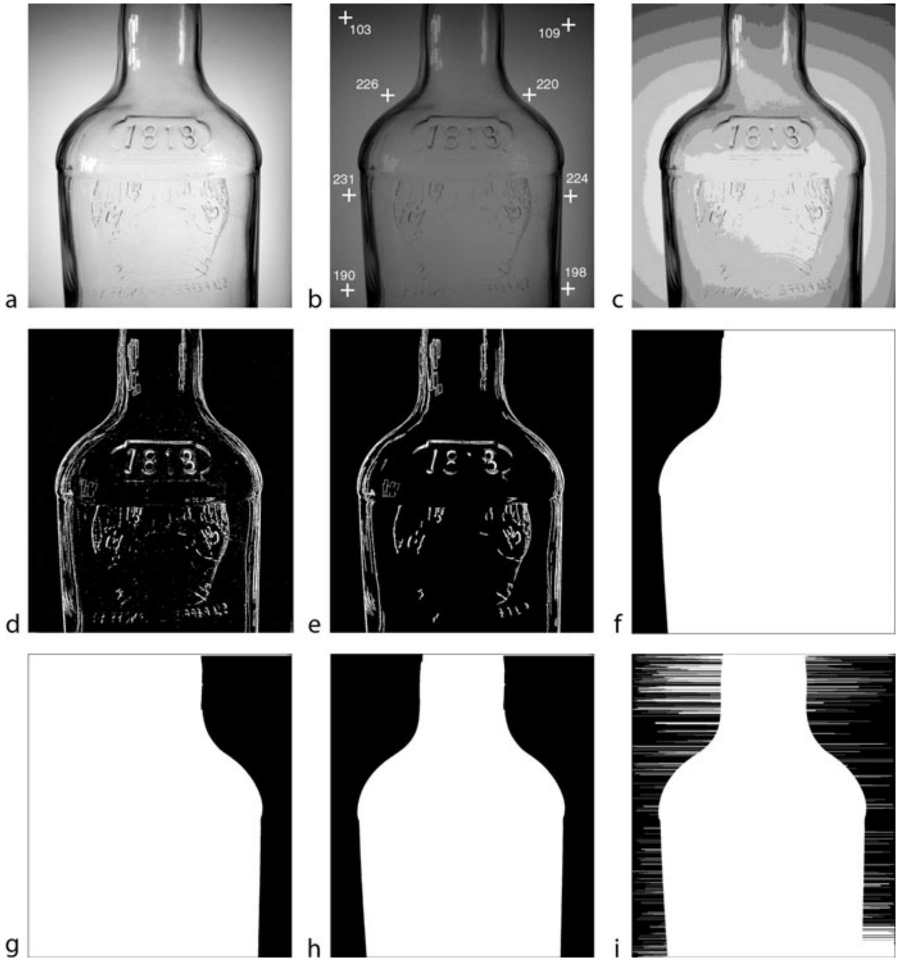

Fig. 31.3

Preliminary processing steps, tracing the outer edge of a bottle. (a) Original image. Back lighting. (b) Background intensity changes over a wide range. Numerals indicate intensity values in the original image. (c) Posterised image, emphasises the variable background intensity. (d) Edge detector. (e) Noise removal. (f) ''Shadow'' projecting to the right [QT: *rox*]. (g) Shadow projecting to the left. (h) ANDing the two ''shadow'' images. (i) Effects of noise pixels outside the bottle profile. This shows why kgr is needed.

This is due to the use of a multi-purpose lens from a digital photographic camera. There is too much ambient light, which causes glinting on the neck and left shoulder. While our casual approach to image formation seems to ignore the lessons so earnestly expressed elsewhere in this book, there is a serious point to be made: the algorithm we have devised is robust and is able to cope easily with these avoidable artifacts. This is in contrast to simple thresholding

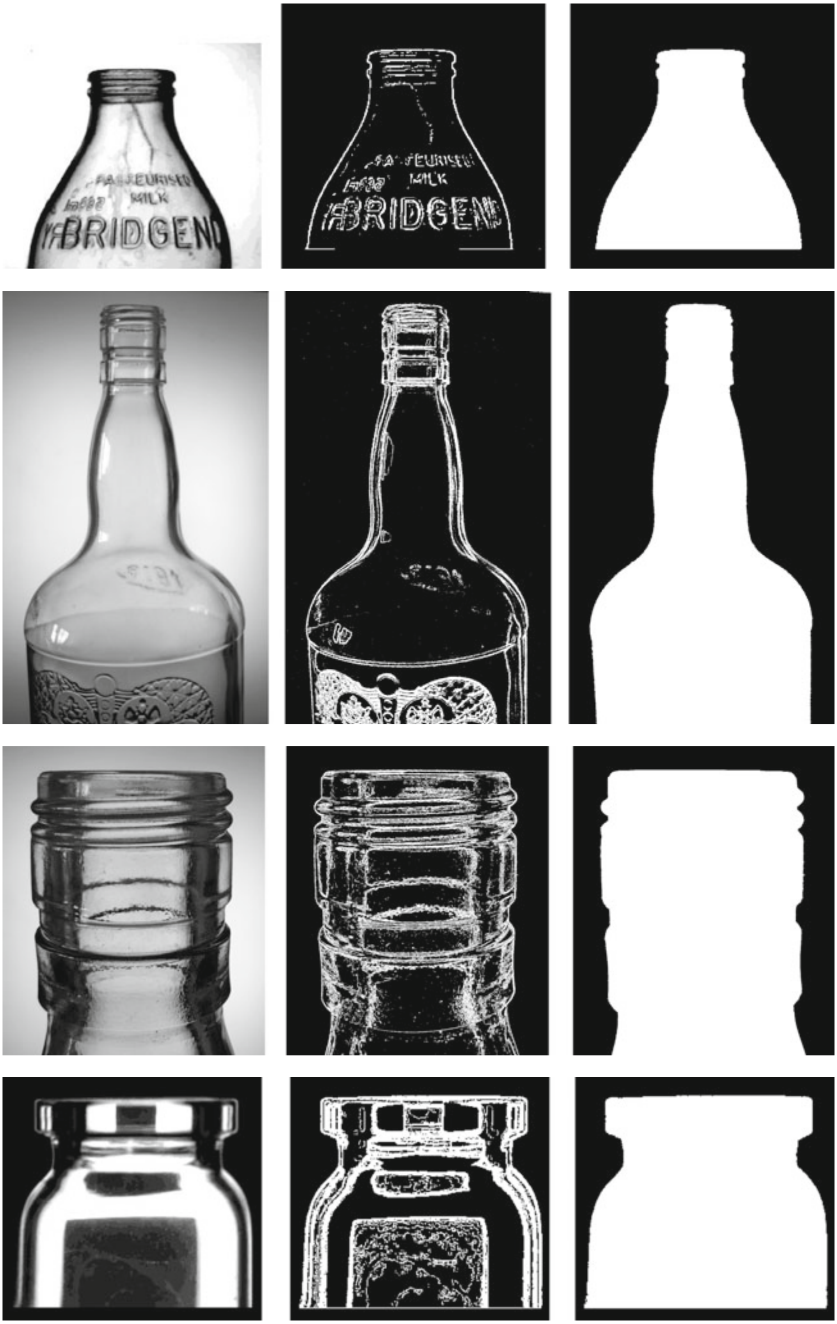

Fig. 31.4

Testing algorithm robustness. The bottom row relates to a brown vial with dark-field illumination. Notice the parallax effect, which is particularly pronounced in the third row. Highlights due to glinting (*second row*) have no effect on the profile but would if they appeared at the edge of the bottle

which is too unreliable. After a short period of experimentation, the following procedure was devised using QT:

```
lnb,       % Largest neighbour
sub,       % Subtract. This & previous command forms edge detector. Other
             options available
neg,       % Negate
enc,       % Enhance contrast
thr(100),  % Threshold (➔ Fig. 31.3d)
kgr(100),  % Keep only big blobs (➔ Fig. 31.3e). ➔ Figure 31.3i shows
             benefits of this operation)
rox,       % Row maximum (➔ Fig. 31.3f )
wri,       % Save image
swi,       % Switch Current & Alternate images
lrt,       % Flip image horizontally
rox,       % Row maximum
lrt,       % Flip image horizontally (➔ Fig. 31.3g)
rei,       % Read image saved earlier
mni,       % AND images together (➔ Fig. 31.3h)
```

Having established an effective algorithm for generating a "solid" profile image, we can now begin to measure the shape of the bottle.

31.3.2 Vertical Sides

There are four important measurements:

(a) Are the sides straight?
(b) Are the sides parallel?
(c) Are the sides vertical?
(d) Is the seperation between the sides correct?

An important point to note is that, at any given moment, we know what type of bottles the factory is making. Hence, we know the ideal dimensions of the bottles we are inspecting. Hence we can use absolute position measurements in the vertical direction.

A simple test can be based on two horizontal scan lines, one positioned just below the shoulder and the other just above the base (➔ *Fig. 31.5*). For simplicity, we shall consider only one side (left). Let us suppose that these scan-lines are at heights Y1 (lower) and Y2 (upper). We need only scan along these two lines to find the corresponding X-coordinates. Call them X1 and X2. The angle of the side wall is then given by

$$\theta_{\mathrm{left}} = \tan^{-1}((\mathrm{Y2} - \mathrm{Y1})/(\mathrm{X2} - \mathrm{X1})) \tag{31.1}$$

A similar calculation yields θ_{right}, the angle of the other side wall. Clearly, θ_{left} and (180 −) should be very nearly equal. The tilt of the bottle can be estimated by finding

$$(\theta_{\mathrm{left}} + \theta_{\mathrm{right}})/2 \tag{31.2}$$

Ideally, this should be 90°.

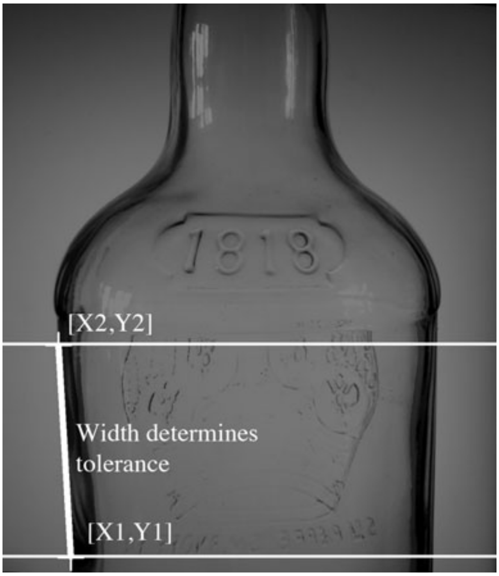

Fig. 31.5
Measuring the angle and straightness of the side walls. Y1 and Y2 are fixed in the knowledge of the product dimensions. To check the straightness of the side wall, draw a thick line [QT: *vpl(X1,Y1,X2,Y2,255), dil(tolerance)*]. The edge of the bottle should be confined to this thick line

The straightness of the side walls can be checked very easily in the following way (➋ *Fig. 31.5*).

- Draw a white line between [X1,Y1] and [X2,Y2].
- Expand this line using binary dilation.
- The amount of dilation determines the tolerance band.
- The edge of the bottle should lie entirely within this thickened line.

A more robust procedure uses regression to fit the straight line (➋ *Fig. 31.6*). This can be used to measure the angle of the side wall and check its straightness in the same way as already described.

31.3.3 Neck and Shoulder

The physical strength of a bottle is determined in large part by the radius/radii of curvature of its neck-shoulder region. This parameter is particularly important if a downwards thrust is applied during capping. Using similar edge-sampling techniques to those already described, it is possible to fit circles and polynomial curves. In ➋ *Fig. 31.7a* and *b*, just three edge points were used to calculate the circle parameters. (QT: *fcd*. Notice that the QT command *pft(y1,y2, no_of_points,2)* fits a general 2nd-order curve; it is not constrained to be a circle.) A polynomial curve can be fitted in a similar manner (➋ *Figs. 31.7c* and ➋ *31.8*). The following M-function shows how the parameters of 3-point circles and polynomials can be calculated. (The QT function *pft* works in a similar way on the second half of *bottle*.)

```
function bottle

  imshow(current)
subplot(1,2,2) ,            % Display image
  imshow(alternate)
```

31.3.4 Symmetry, Tilt and Gross Misshapes

In order to verify that a bottle is upright and symmetrical, we use a simplified (i.e. one-dimensional) version of the medial axis transform (Chap. 13). The QT function *mch* finds the mid-point of each *vertical* white chord in a binary image. Hence, to generate the white pixels in *Fig. 31.9* we applied the following QT command sequence to the binary image in *Fig. 31.3h*

```
yxt     % Interchange X and Y axes because mch works on vertical chords
mch     % Mid point of vertical chord
mch     % Repetition is necessary because mch does not finish the job on
          large images
yxt     % Interchange X and Y axes - restore image to original orientation
```

For a well-made bottle, the points generated in this way should all lie on, or very near, a vertical white line. A straight line (*L*) can then be fitted to these points, by regression analysis. *L* is, of course, an estimate of the axis of symmetry. Its orientation is a measure of the tilt. Flipping the image about *L* allows the symmetry to be checked (*Fig. 31.10*).

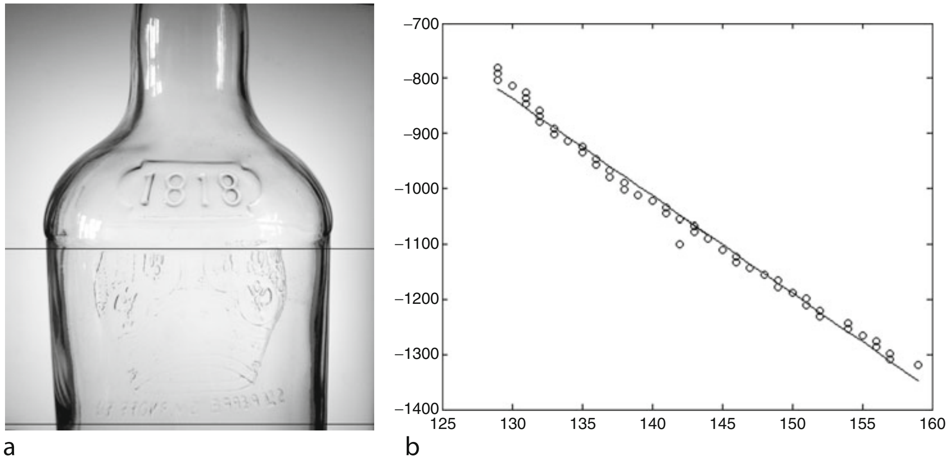

Fig. 31.6

Using regression analysis to fit a straight line to (*the left-hand edge of*) a bottle. (a) Edge pixel coordinates within the limits indicated by the two black lines formed the input for the regression analysis program. (b) Straight line fitted to the edge pixels. Numbers indicate coordinate values, relative the top-left corner of the image [QT: *pft(780,1320,50,1)*]

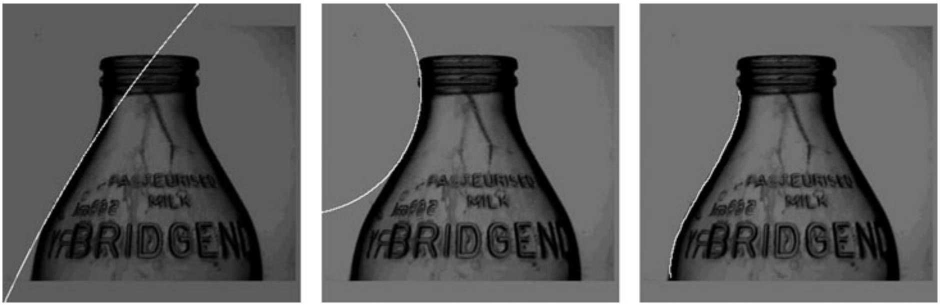

Fig. 31.7
Fitting circles to the neck-shoulder region using just three pixels. (a) Shoulder. This circle was fitted using just three edge pixels. [QT: *fcd*] (b) Neck. (c) 3rd-order polynomial function. This and (b) were generated using *bottle*, listed in the text

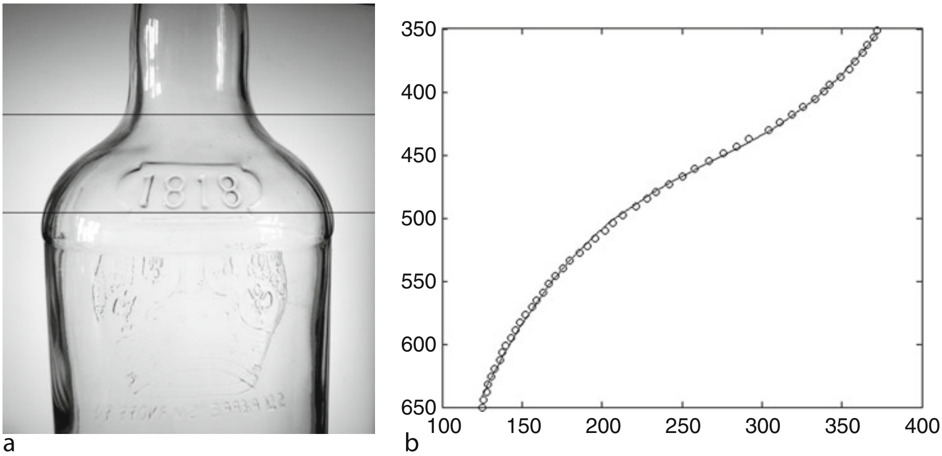

Fig. 31.8
Fitting curves. (a) Original image. The black lines indicate sampling limits. (b) 3rd-order polynomial function [QT: *pft(390,650,50,3)*]

If the neck of the bottle were bent to one side, *L* would not fit all of the white points accurately.

Another simple but effective check can be made at the same time, by measuring the length of each horizontal chord across the bottle. This yields a graph like that shown in *Fig. 31.11*. This can easily be compared to the ideal width profile and will immediately warn us, for example, if the bottle has collapsed under its own weight when it was in a semi-molten state. *Figure 31.12* shows the kind of defect that can be detected in this way.

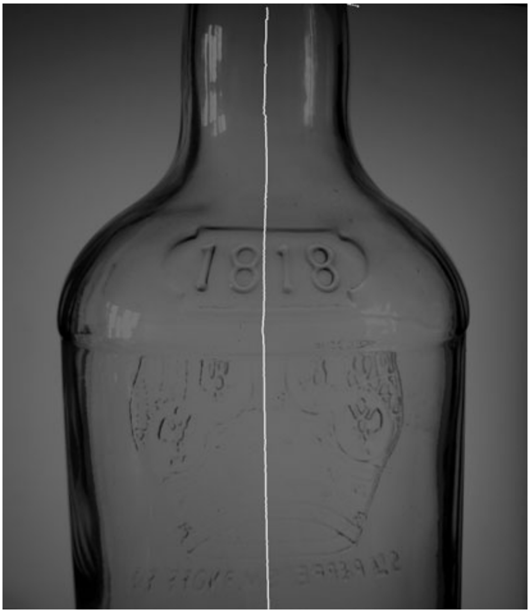

Fig. 31.9
Central axis, used for verifying that the bottle is tilted and symmetrical

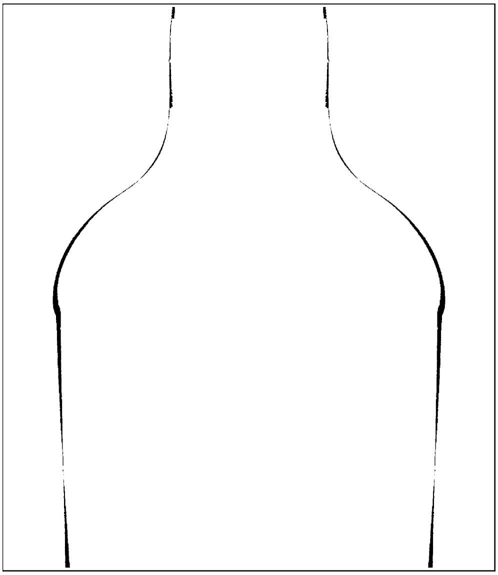

Fig. 31.10
Checking whether a bottle is symmetrical. Flipping the binary image about the axis of symmetry shows the differences between the two sides of the bottle. Simply counting the black pixels gives a crude measure of symmetry

31.4 Other Features

In addition to shape, there is a variety of other important features on bottles, jars, tumblers and other glass containers. It is impossible to cover these in full here. Hence, we shall simply demonstrate that Machine Vision can be used effectively in other ways.

31.4.1 Measuring Filling Level

Checking that a glass vessel is fully charged is clearly of interest, particularly in industries such as food, toiletries, cosmetics and pharmaceuticals. Two distinct approaches seem promising. In the first, the meniscus is detected by exploiting the fact that it produces a dark horizontal streak with back-lighting (➲ *Fig. 31.13*). Integrating the intensity along the rows of the image produces a one-dimensional array of numbers from which the height of the meniscus can be calculated. The meniscus position corresponds to a local minimum in this array. When the meniscus lies within the neck–shoulder region, this method is less reliable, although it is effective in ➲ *Fig. 31.16*.

In the second method, we make use of the fact that a filled round bottle forms a crude cylindrical lens, which may be used to distort a pattern, such as a series of vertical parallel lines, placed behind it. In ➲ *Fig. 31.14*, the tumbler is a simple cylinder, with no embossing. It is a straightforward matter to detect the sudden change in the width and spacing of the dark stripes. A slightly different approach is taken in ➲ *Fig. 31.15*, where a single magnified stripe "fills" the jar, up to the meniscus but not above it. The vertical position of the transition can be detected by the function *jar_fill_level*, defined below. This is based on run-length coding (*rlc*) and thresholding (*thr(X)*) to find horizontal cords that have more than *X* white pixels. (The value of *X* is chosen to be a little greater that the width of the stripe as it appears where there is no water present.) Here is the listing of *jar_fill_level*.

```
function y = jar_fill_level
% Find the the filling level in a jar. [1/0]

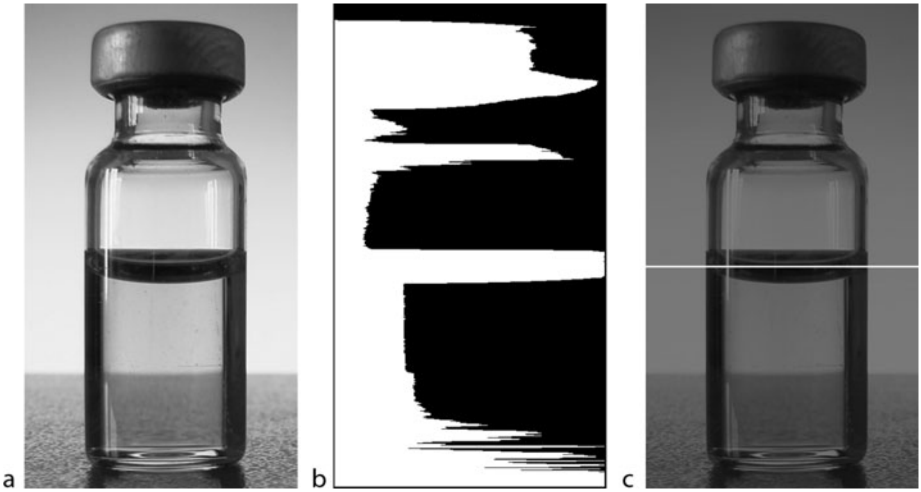

Fig. 31.13
Filling level in small clear glass vial. (a) Original image. Back lighting. (b) Plot of total intensity in each row [QT: *rin, csh, wgx,sub, thr*]. (c) Centre line of the dark horizontal streak due to the meniscus [QT: *rin, thr(X), thn finds the centre line*]

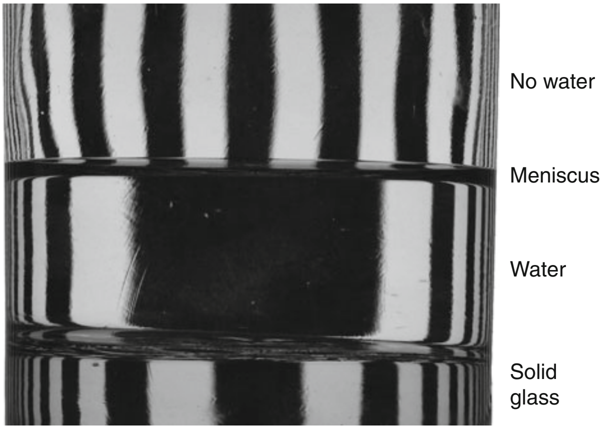

Fig. 31.14
Distortion of a striped background pattern by a partially filled cylindrical tumbler with vertical straight sides, a thick bottom of solid glass but no embossing. Notice that the width and spacing of the dark stripes is changed by the water, which forms a cylindrical lens

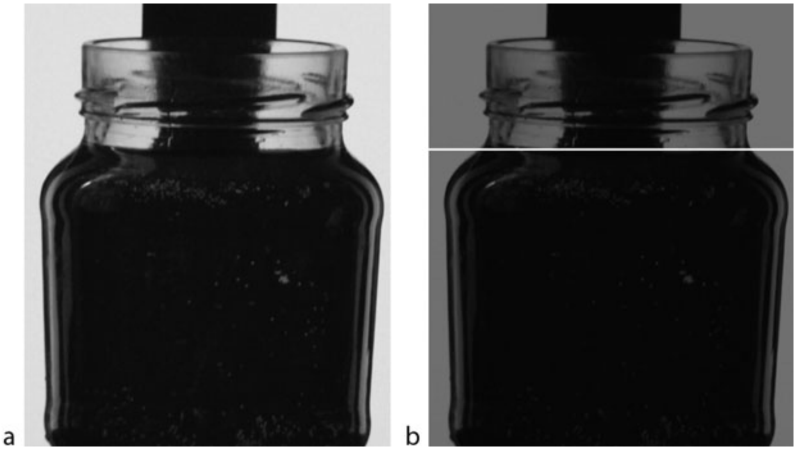

Fig. 31.15
Second method for finding the filling level. (a) Original image. A single black stripe is magnified by the glass-air ''lens'' so that it fills the whole width of the jar. The background stripe is visible at the very top of the image. (b) The white line is the output of *jar_fill_level*

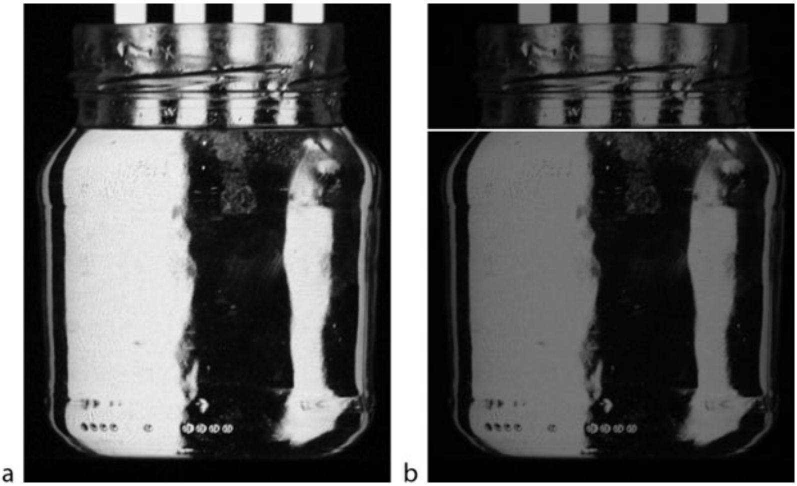

Fig. 31.16
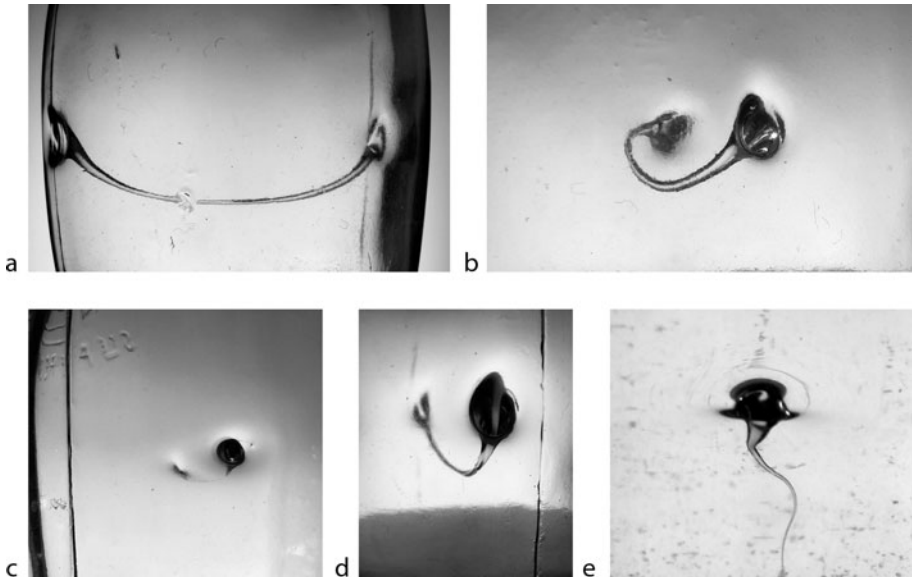
Detecting changes in stripe width/spacing using morphology. (a) Original image. The poor definition of the edges of the broad black stripe does not adversely affect this method. (b) Filling level detected [QT: *wri, enc, thr, eri(200,1), [x,y] = tlp; zer, [w,h] = dgw; vpl(1,y,w,y,255), rei, swi,adi,mxi*]

An alternative algorithm detects changes in the width and spacing of the stripes using morphology. The structuring element should be in the form of a horizontal line, one pixel high. ➲ *Figure 31.16* illustrates this.

31.4.2 Bird-swings, Spikes, Embossing

A bird-swing is a critical defect that occurs in bottles. It consists of a filament of glass that spans the interior of the bottle and is attached at two diametrically opposed points on the side wall. The roots of the filament are conical. This is important as the roots deflect back-lighting and cause a dark shadow. A spike is like a stalagmite of glass attached at only one end and may occur on the base or side wall of a jar. Once again, the root has a conical form. Bottles are made by a blow-blow process and jars by a press-blow process. Hence, they are susceptible to different types of defect. A bird-swing/spike, in a stationary bottle/jar is easily detectable by human eye. However in a factory, when the product is moving at a high rate (perhaps exceeding ten bottles/jars per second), this is not so easy. People get bored and tired on repetitive inspection tasks and are easily distracted. For these reasons, a human inspector will not detect all critical defects with resulting product safety and liability concerns.



◘ Fig. 31.17
Critical defects due to excess glass. Back illumination. (a) Bird-swing viewed from the side. Notice the conical roots of the filament, which can be several millimetres thick or as fine as a human hair. The latter is more dangerous. (b) Bird-swing, viewed near end-on. This is the preferred viewing angle. (c) Bird-swing. The dark vertical streak is the shadow of the moulding seam. (d) Bird-swing. The dark patch at the bottom is the image of the table-top. (e) Spike (The author's daughter narrowly missed injury from this defect, which occured in a milk-bottle. The tail of the spike is finer than a human hair.)

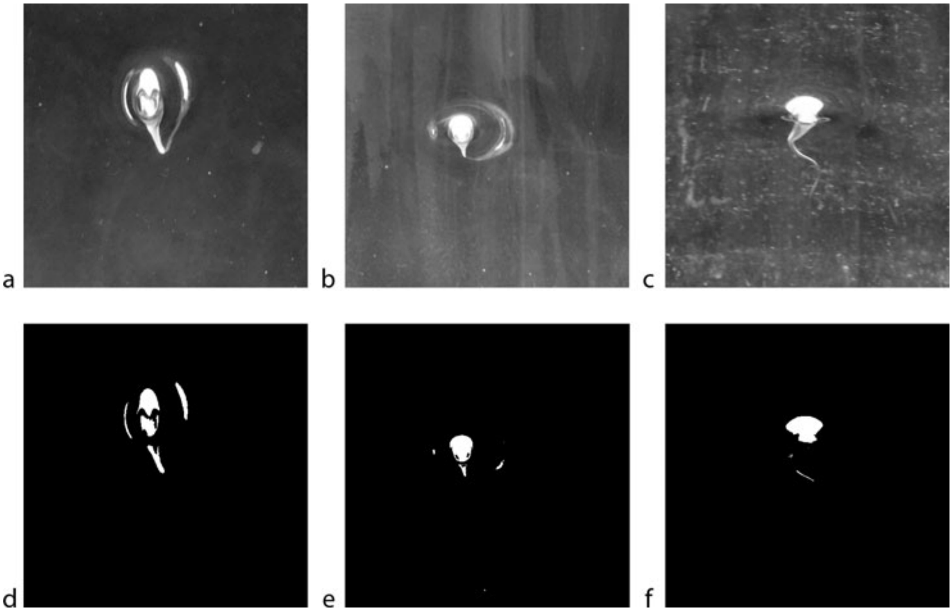


Fig. 31.18

Dark-field illumination produces total internal reflection on bird-swings and spikes. The high contrast produced in this way makes simple fixed-parameter thresholding straightforward. (a) Original image: bird-swing. (b) Original image: bird-swing. (c) Original image: spike. (d) Bird-swing, thresholded. (e) Bird-swing, thresholded. (f) Spike, thresholded

Two series of bird-swing/spike images are shown in *Fig. 31.17* (back-lighting) and *Fig. 31.18* (dark-field illumination). In view of the high contrast, simple thresholding is able to detect both types of defect quite successfully, with either type of illumination. To be sure that thresholding is independent of lamp brightness variations, it is always good idea to normalise the intensity scale first. (QT: *enc*. As is emphasised throughout this book, this is good practice, since light levels can vary as lamps age or supply voltages vary. People are insensitive to such changes.) However, *Fig. 31.17* and *Fig. 31.18* are unrepresentative in showing bird-swings and spikes in clear areas, where there is no embossing. It is evident in *Fig. 31.4* (two top rows), that embossing can also produce high contrasts. This means that, in order to detect bridswings/spikes, we have to examine the embossing for deviations from the norm. This is not always easy or reliable. This is one situation where the product might usefully be designed with inspection in mind. Since bird-swings and spikes are both potentially dangerous types of defect, anything that aids their detection is welcome.

31.4.3 Cracks

Cracks need no introduction. Crizzles or checks are like cracks but do not penetrate right through the glass. Both can be seen, either as dark streaks, if they block light from a back-illumination source, or very bright if they deflect light by total internal reflection at the fracture

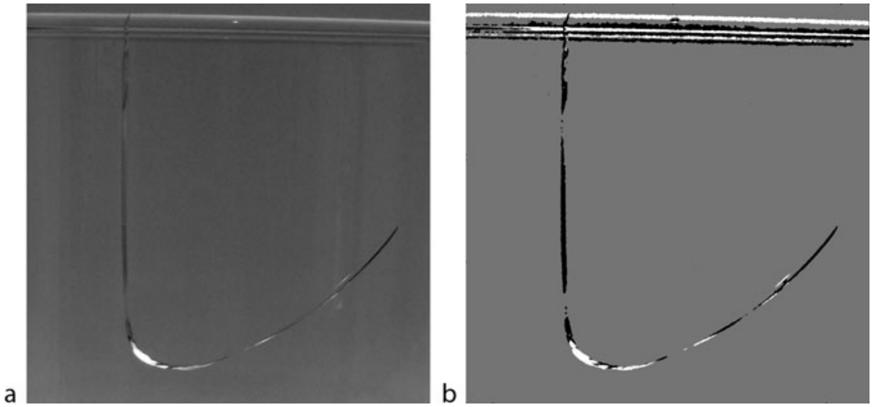

Fig. 31.19

Crack, plain-sided tumbler. (a) Original image. Notice that the crack, which is continuous, sometimes appears dark, bright or totally disappears. (b) Dark and light streaks highlighted separately [QT: *crack2(11,135,50,4)*]

surface. If the crack is viewed edge on, it may not be visible at all see (Fig. 31.19a). It is always worth experimenting with the angle of the lighting viewing arrangement, to optimise the contrast created by cracks. Sometimes, cracks form preferentially in one direction, rather than another. In this case directional lighting from one side (or top/bottom) may produce the best results.

The morphological closing operator (QT: *crk*) is an effective way of detecting dark (or bright) streaks produced by cracks. Here is a more complete algorithm that includes noise-reduction filtering.

```
function crack(a,b,c,d)
% Demonstration: Detect cracks manifest as dark streaks. Bright streaks
  are ignored [0/0]
global current
global alternate
% Default parameters were set to detect the crack in a ferrous component:
  QT image no. 41
if nargin == 0
          a = 5;
          b = 145;
          c = 50;
          d = 4;
end
original = current;
crk(a)    % Adjust parameter to taste: bigger for wider cracks
thr(b)    % Fiddle with this parameter
kgr(c)    % Discard blobs with area < c pixels
dil(d)    % Dilate, noise reduction filter - part 1
ero(d)    % Erosion, noise reduction filter - part 2
```

```
rbe             % Remove blobs touching image border
alternate = original;
subplot(1,2,1) , imshow(current)
subplot(1,2,2) , imshow(alternate)
```

In order to detect cracks in glass that can be either bright or dark compared to the background, it is necessary to apply *crack* twice, before merging the results (➜ *Fig. 31.19b*).

```
function crack2(a,b,c,d)
global current
global alternate
original = current;
mdf(5)            % Median filter, noise reduction
wri(1)            % Save original image
crack(a,b,c,d)    % Defined above - detecting dark streaks
wri(2)            % Save intermediate result for later
rei(1)            % Read original image
neg               % Negate
crack(a,b,c,d)    % Defined above - detecting bright streaks
neg               % Negate
rei(2)            % Read intermediate result saved a little while ago
adi               % Add images
neg               % Negate (Purely cosmetic function: keep original
                    dark-bright polarity)
alternate = original;
subplot(1,2,1) , imshow(current)
subplot(1,2,2) , imshow(alternate)
```

As the author was searching for a suitable algorithm, several others were investigated using QT. (This is exactly what QT was designed to do.) Convolution (high-pass) and DOLP filtering are obvious alternatives producing results that are roughly comparable to those created by *crack* and *crack2*. However, they are certainly no better and are often inferior.

31.5 Final Remarks

In this short chapter, we have only touched on the subject of inspecting glass-ware. We have not considered embossing, stress, loose glass fragments, etching, decorative cutting, engraving, glass–metal seals, glass–glass fusion, coloured glass, air bubbles (accidental and intended), crizzles, staining, surface dirt and inclusions. Inspecting optical components is a highly specialised subject and relies heavily on high-purity lighting from lasers. Inspection *through* glass is also important. In this, we include products such as glass instrument covers, computer display screens, automobile wind-screens, head-lamps, etc. Clearly, glass inspection is a big and important subject. However much work we do, there will always be new challenges where the quality and safety of glass products needs to be improved.

32 Stemware Inspection System

Abstract: A system for the inspection of stemware for geometrical defects and glass imperfections is described in this paper in which cameras at three stations are used for enhanced defect detection. Internal glass quality, contaminants and optical nonuniformity are evaluated at the first station. The second station inspects the glass rim and stemware shape and detects internal defects such as cracks. The third station inspects the stemware base for geometrical and internal defects. Glass irregularities are optically enhanced using a striped illumination pattern and detected using morphological processing. Geometric inspection is enhanced through the use of converging illumination at the second station, while the third station utilizes telecentric optics. Progressive scan cameras and frame grabbers capable of simultaneous image capture are used at each station. The system software comprises six modules consisting of the system manager, I/O manager, inspection module for each station, and stemware sorting and logging module. Each module runs as a separate process. Applications communicate with each other through TCP/IP sockets, and can be run in one or more computers. Two personal computers are used for the system described here.

32.1 Introduction

The manufacturing of glassware requires good process control to maintain high quality which in turn requires good product monitoring. Traditionally, human inspectors have performed this task, unfortunately not very effectively or consistently. Glassware defects are often subtle and can be caused by a variety of factors. Defects include misshapen ware, surface contamination, cracks, and inclusions which may simply be cosmetic or affect the structural integrity of the ware. In either instance, quality considerations dictate that defective ware with such defects should be rejected.

The objective of the inspection system described here is to provide 100% inspection of stemware for these defect types. Three different stations perform the inspection operations, a body inspection station, a base station and the sidewall/rim inspection station. In each of these, special illumination and optics are used to enhance the associated defect types. For the body and sidewall/rim stations, cameras acquire images of stemware from three angles to provide complete coverage while the Base Station uses two cameras. An overview of the system, including the Reject Station is shown in ➔ *Fig. 32.1*.

The Body Station inspects internal glass quality such as contamination and waviness using a vertical-line pattern placed over the light source which will be distorted by the optical characteristics of the sidewall of a given piece of ware. Excessive distortion is generally indicative of a defect, which is detected by analyzing the resulting captured image with appropriate algorithms. Contamination caused by chemical residue is detected at this station by the presence of numerous small dark or bright nonuniformities contrasted against the brighter or darker regions of the striped background.

The Sidewall and Rim Station inspects the rim, geometry of the stemware body and stem, and internal defects such as cracks and certain refractive defects that are difficult to detect in the body station. A uniform illumination source is used here to back-light the ware but special optics are used so that the light is highly collimated. This provides very high contrast between the edge of the ware and the background illumination so that ware shape can be measured very accurately. Refractive defects are also easily detected with this type of illumination.

The Base Station evaluates the base geometry and detects defects in this region. The ware is inverted so that an unobstructed view of the base is obtained. The light sources are similar

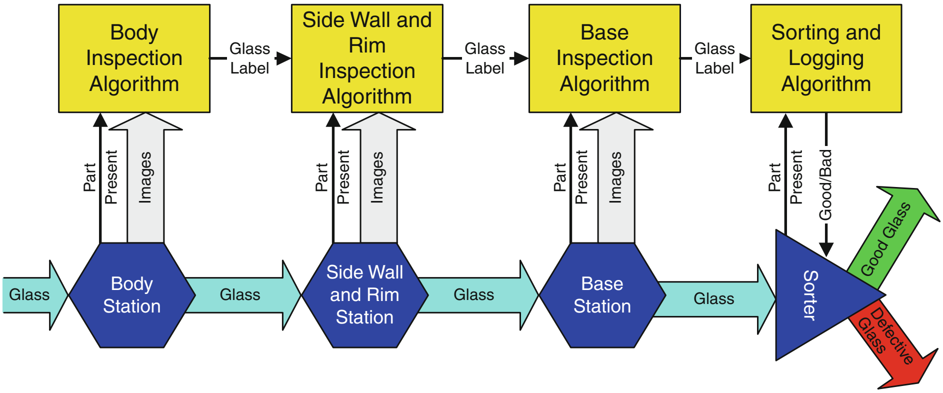

Fig. 32.1
Inspection and sorting components

to those used in the Sidewall and Rim station so that the rim edge has high contrast and refractive defects can be detected.

Shuttered progressive-scan cameras and frame grabbers capable of simultaneous image capture are used at each station since the ware moves at a relatively rapid rate past the cameras. Shuttering the cameras minimizes motion blur and progressive scanning eliminates interlace distortion.

The system software is comprised of six modules: system manager, I/O manager, inspection module for each station, and stemware sorting and logging module. Each module runs as a separate application, which communicate with each other through TCP/IP sockets. This allows the software to be run in a multiple- or single-processor configuration efficiently. Currently two Windows NT workstations are used.

32.2 Optical and Illumination Considerations

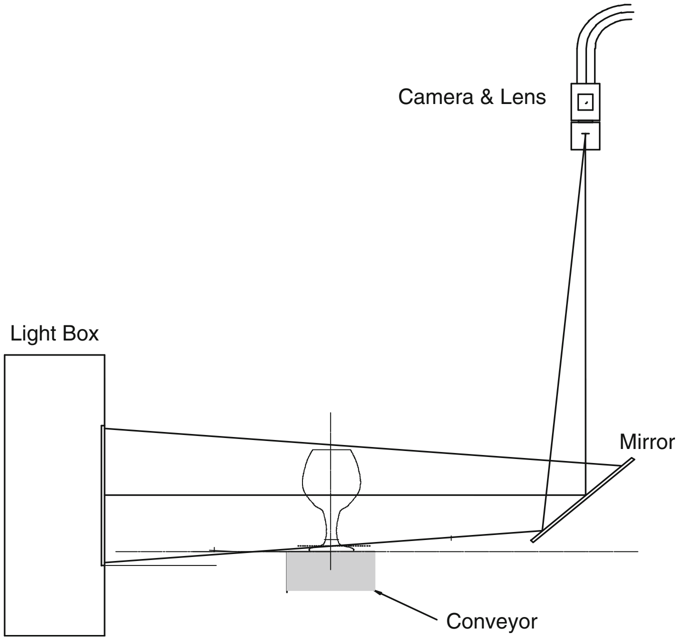
The optical layout was designed to

- Maximize sensitivity to defects
- Minimize problems associated with magnification
- Keep illumination sources reasonably small as well as the overall volume needed for the inspection system

Mirrors are used extensively to fold optical paths. An example of this can be seen in *Fig. 32.2*.

32.2.1 Body and Sidewall/Rim Stations

These stations each include three identical imaging and lighting systems whose views of the stemware are separated by 120°. This angular separation is intended to allow viewing of all inspection areas of the ware. Each system includes three progressive scan area camera each with a c-mount lens and a diffuse light source. Each source consists of a halogen lamp, fiber optic



■ **Fig. 32.2**
Arrangement of camera and light source for sidewall inspection

cable, and diffuser. A large Fresnel lens is used to image the diffuser onto the camera lens plane and a mirror folds the optical path to minimize overall system size.

32.2.2 Base Station

The station includes two identical imaging and lighting systems whose views of the stemware are separated by 180°. Each camera views the upside-down stemware at an angle of about 30° from horizontal. With this configuration, the base appears as an ellipse but only the top half of the ellipse is used for measurement and defect detection. Each system includes a single array area scan camera with a large aperture telecentric lens and a large area diffuse light source [1]. The view angle for the base station was chosen to provide the best base image possible without interference from the body of the stemware, particularly for short, wide ware such as brandy balloons (snifters). ➲ *Figure 32.3* shows the basic layout.

32.3 Image Analysis Algorithms

A variety of image analysis techniques is needed for the range of defects that occur with glassware. Mathematical morphology is used extensively since glass defects typically have structural features that distort light in unusual ways due to their refractive properties. After potential defects have been isolated by morphology, connectivity analysis is used to identify defects.

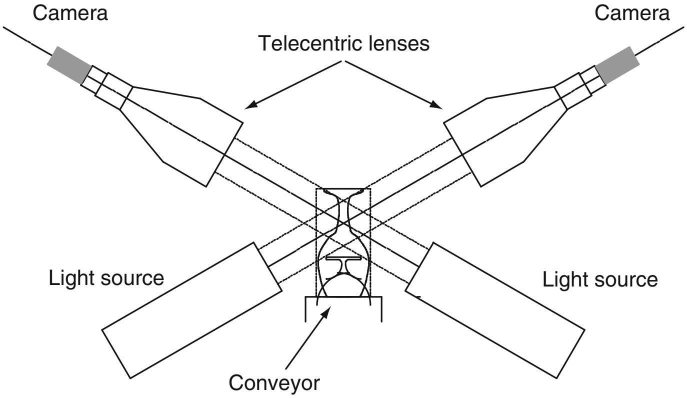


Fig. 32.3
Arrangement of camera and light source for base inspection

32.3.1 Detection of Refractive Defects

Refractive defects present a significant challenge because acceptable glassware exhibits a wide range of refractive properties. Also, what is considered acceptable for one type of glassware may be totally unacceptable for another. It was important to provide adjustable parameters and setup aids to provide adequate flexibility.

Several different types of illumination were employed to improve the detection of this class of defect. A vertical striped pattern, used in the body inspection station, is sensitive to many of these defects, especially when they cover an extensive portion of the sidewall but exhibit relatively mild refractive properties. For example, one type of defect, designated as *wavy*, causes excessive bending of the striped pattern over large areas of a glass as illustrated in ➲ *Fig. 32.4*. A long structuring element, which is parallel to the striped pattern is used to detect such distortions. The length of the structuring element can be used as a sensitivity adjustment. Virtually all glassware exhibits significant waviness in the lower part of the sidewall so this region is masked off.

For smaller, more refractive defects, the stripe pattern was distorted over a relatively small area as illustrated in ➲ *Fig. 32.5*. Here a small dark region and even smaller bright region are visible near the top of the glass centered horizontally. Morphological opening and closing operations can isolate both defects by removing them and subtracting the processed images from the original images.

Not all refractive defects can be detected with this pattern and light source, however. In the sidewall/rim inspection and base stations, highly-collimated illumination is used in part to isolate the glass edge and is discussed in the following section. This light source is very effective for finding refractive defects since they divert light away from the camera and appear as dark regions.

➲ *Figure 32.6* illustrates how a small defect can be detected with this light source. A morphological closing operation is used to detect the defect [2]. A masking algorithm is used to identify the very dark edges and other regions of the ware so that a large portion of the sidewall can be inspected. The rim is also inspected using this view for bumps and other irregularities using morphology.

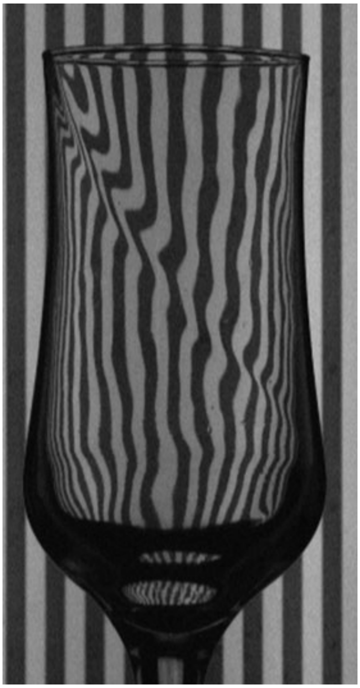

Fig. 32.4
Wavy glass

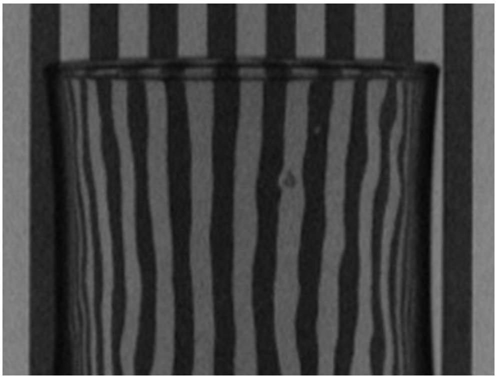

Fig. 32.5
Small defects

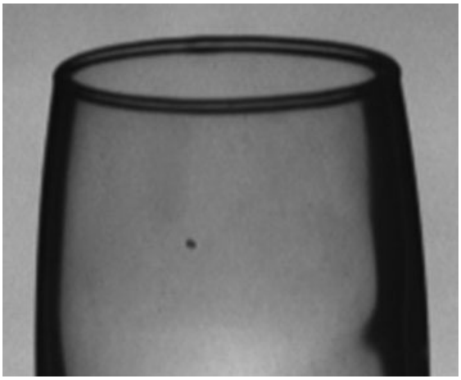

Fig. 32.6
Small defect

32.3.2 Geometrical Inspection

Glassware can be misshapen if there is a problem with certain manufacturing parameters such as temperature. While this type of product does not require high precision, glassware must not appear to be irregular. With the collimated illumination provided in the sidewall/rim and base inspection systems, edges are very distinct and can be detected with very good accuracy using simple thresholding.

Once the edge points of the sidewall have been obtained, they are processed to obtain an estimate of the centerline of the ware by finding their average. Regression is used to determine if the centerline deviates significantly from vertical. Curvature of the centerline indicates that the glass is leaning.

The overall shape of the ware is typically not very critical but some means to characterize the acceptability is needed. To address this issue, software was developed so that the system could be trained using ware designated as *acceptable*. This was accomplished by generating a signature created by subtracting the left edge from the right edge of the sidewall. Using a number of glassware samples, an average signature was generated that could be used to identify glasses that were significantly different. A similar approach was used for the base station.

32.4 User Interface

The user interface is a critical aspect of the inspection system since the sophisticated image analysis algorithms used need to be set up properly for good results given that operators cannot be expected to understand the intricacies. Borland's C++ Builder was used to create the various user screens since it provides tools that allowed them to be created rapidly. In addition, since the C language was used, interfacing to the various image analysis routines was very easy. Each inspection station has its own setup window with a number of tabs so that parameters can be adjusted as needed. In addition, camera images are displayed and graphics can be superimposed over the images to aid in setup. The inspection algorithm of each of the stations can be configured and debugged using the main setup screen.

32.4.1 Setup Screens

An example of a setup screen is given in ➲ *Fig. 32.7* which is used for the Body Station. A station setup screen is divided into four sections, image view panel, command panel, parameter setup panel, and debug log panel. The command panel allows the operator to perform a number of actions that include

- Processing the displayed image
- Enabling a live view from the cameras
- Loading a previously stored image
- Saving a captured image
- Saving the current setup information

Images are captured by enabling and then disabling the live view option which may then be saved if desired. These features provide operator flexibility and the ability to track how production is varying over time. Setup time is also greatly reduced by recalling previous setup information.

The parameter setup panel is used to configure an inspection algorithm. It typically contains several pages that can be selected by pressing the appropriate tab. The parameter setup panel is synchronized with the image view panel. Parameters are adjusted for each camera view separately with only a few parameters common to all camera views. To access parameters for a desired camera view, the operator selects the corresponding tab in the image view panel.

Parameter names which are displayed in color can be graphically illustrated in the image view panel. The color corresponds to that of the line in that panel. Modification of a parameter can be automatically updated by checking the appropriate box to allow updates to be displayed simultaneously.

The debug log panel displays debug information from the inspection algorithms. Display of debug information can be disabled using *Enable Debug* check box. When debugging is disabled, only the total execution time of the inspection algorithm is displayed. Note that debugging increases execution time and is not indicative of execution time in production mode. Check boxes *Step through* and *Save images* control display and automatic saving of debug images.

32.4.2 Body Station

As noted previously, the body station inspects for the presence of refractive defects, chemical residue and waviness in the glass sidewall. A number of important parameters need to be set here including top and bottom boundaries for the type of glassware being inspected, the defect threshold, and defect area and density. The density of a defect is the average gray level of the corresponding blob after processing.

Parameters are also provided for detecting contamination which appears as small, locally scattered spots and are detected by the "Scatter" tab. They may be brighter or darker than the

local background. Parameters include total particle count and a value for combining blobs in close spatial proximity. Similarly, the "Wavy Glass" tab allows parameters related to measures of waviness to be adjusted.

32.4.3 Sidewall and Rim Station

Parameters for the sidewall and rim station are adjusted in the same manner as the body station. Parameters differ since other measurements are taken, especially with respect to ware shape and rim measures. Nominal values and allowable deviation from these values can all be adjusted here. These include geometrical measures such as rim thickness, regularity and differences from a reference shape. The reference shape can be established by running a series of acceptable ware through the system in training mode.

32.4.4 Base Station

Similarly as in the side wall and rim station, the shape of the stemware base can be trained by presenting examples of acceptable ware. Allowable deviations of the inspected shape compared to the learned one can be adjusted. The difference between learned and inspected shape is displayed in the upper part of the diagnostic image, see ❯ *Fig. 32.8*. The region of interest for defect inspection inside the base is defined in the relation to the outside silhouette to the base: the silhouette is shrunk inwards to define the ROI.

32.5 Results and Conclusions

The system has been rigorously tested in the laboratory using a wide variety of defects and appears to provide highly reliable defect detection. It is currently being installed in a plant so no production results are as yet available. Inspection time for any given inspection (with three cameras) is under 100 ms with up to an additional 60 ms required for image acquisition. Total inspection time for all three stations is well under 600 ms as required to meet production specifications.

In general, this system provides 100% inspection of stemware for a wide range of defects including sidewall and rim defects, misshapen and improperly sized ware, and base defects. Lighting techniques have been optimized to enhance the contrast of defects and also provide high-quality images for performing geometrical measurements. Shuttered progressive scan cameras provide a means of capturing sharp images of glassware moving down a production line. Software has been optimized for speed and performance so that a wide range of defects can be detected at real-time rates.

33 Restoration of Missing Boundary Segments in Shattered Glass

John W. V. Miller · Malayappan Shridhar · T. Peatee
The University of Michigan-Dearborn, Dearborn, Michigan, USA

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_33,

Abstract: Analysis of shattered automotive glass for determining particle size, shape and count is legally required to demonstrate that safety criteria have been met. Manual methods are labour intensive, subjective and prone to errors. This paper presents an approach for automating this analysis. Problems associated with missing boundary segments can cause serious errors unless corrective measures are applied. Techniques for efficient extraction of particle boundaries and restoration of missing segments are presented.

33.1 Introduction

A problem commonly encountered in machine vision applications is the analysis of cellular or interconnected patterns in which the features of interest are either separated by the cell boundaries or are the boundaries. In either case, an important part of the analysis is the isolation and identification of the boundaries using some type of segmentation algorithm or boundary detection scheme. Applications which require this type of processing include analysis of biological cells and crystal grain studies [1]. The analysis of shattered glass, which has a similar appearance, is the topic of this paper.

If the cell boundaries are incomplete or have areas with poor contrast, analysis becomes much more difficult. Missing boundaries will cause adjacent regions to merge during connectivity resulting in fewer 'cells' with larger areas and highly irregular shapes. For this reason, it is necessary to detect the broken boundaries and reconstruct them before meaningful analysis can be performed. A strategy for accomplishing this is presented here with the emphasis on the analysis of images of shattered automotive safety glass.

Due to legal requirements concerning specifications on tempered safety glass, destructive testing on a given number of glass panels taken from production is routinely performed. In a typical test, a glass sample is shattered and certain statistical information is manually extracted from it. Statistics, such as the particle count in regions of the panel with largest and smallest particle sizes and length of longest shards, are commonly gathered.

With the current method, application of an adhesive transparent film is applied to the sample to prevent the pieces from scattering during testing. The sample is then placed over a sheet of photo-sensitive print paper and shattered. The print paper is then exposed with a high-intensity light source and developed. Manual identification of two 5 × 5 cm regions, one with a high particle density and the other with a low particle density, is performed along with manual counting of the particles within these regions. Manual measurements are also done to obtain statistical shape information. This process is labour intensive, error prone and does not provide fast feedback. If a production problem occurs, a large number of finished glass panels may have to be destroyed because the problem was not detected early enough.

A suitable machine vision system, however, would be able to perform the above tasks much faster than manual analysis with more consistent results and at lower costs. The faster feedback would minimise production of unacceptable glass and require much less labour. Such a system is also capable of automating the report generation required by many countries regarding the specifications of the safety glass, as well as maintaining the required permanent records of tested samples using data compression techniques and optical storage technologies.

Algorithms for such a system are described in the remainder of the paper. In the next section, a brief overview of the basic approach is given. In ➲ Sect. 33.3, preprocessing techniques are presented, and the new boundary restoration algorithm is described in

➲ Sect. 33.4. ➲ Section 33.5 examines an alternative approach for boundary reconstruction using watershed transforms, and test results are given in ➲ Sect. 33.6.

33.2 Basic Approach for an Automated Glass Analysis System

The automated system under development utilises a linear camera with 64 grey levels positioned over a conveyer to produce a digital image of the shattered glass. Optionally, images can be acquired from a print, produced as explained above, using a scanner. With either approach, the image is then processed to obtain the desired statistical data.

A major difficulty is the acquisition of an image with distinct boundaries. A typical image is shown in ➲ *Fig. 33.1* in which a number of particle boundaries have poor contrast or missing segments. Due to intensity variations, many of the cracks are lost with simple thresholding, but this can be minimised with more effective image processing. A more severe problem occurs when a crack is perpendicular to the plane of the camera and light source. Such cracks are very small and do not refract sufficient amounts of light to be detected as dark regions by the camera. As a result, there are missing boundary segments that cause the merging of two or more pieces into one larger piece. This decreases the accuracy of the particle counts and distorts statistical information. Such regions must be reconstructed before accurate automated particle analysis can be performed.

Previous work in this area utilised a morphological process in which each piece was subjected to a series of erosion operations until it either was segmented into smaller pieces or was reduced to an insignificant size. If segmentation occurred, the resulting piece or pieces were individually dilated using the same number of iterations that were performed during erosion to approximate their original size.

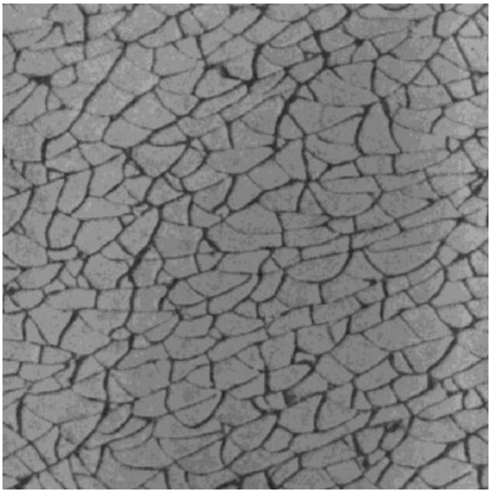

Fig. 33.1
Typical image of shattered glass

One of the underlying assumptions was that pieces were basically convex in shape which was true of some initial shattered panels. However, it was found that other samples contain long thin shards. If the shard had less thickness in the centre than at the ends, repeated erosion operations would incorrectly split the piece at its thinnest point.

Clearly, improvements were needed to obtain sufficient accuracy. Using a technique to restore missing boundary segments rather than a segmentation approach would provide significant improvement. In addition, careful preprocessing would provide a better starting point for boundary restoration. The next section describes a useful processing approach.

33.3 Image Processing

Since the image size of typical windshields scanned at a resolution greater than 100 dpi can be greater than 3 $\times 10^6$ pixels, processing time and hardware costs can become excessive. However, because only 5 × 5 cm regions of interest need to be evaluated fully, just corresponding pixels from the image need to be analized. A given region is extracted from the original image along with a 10 pixel border region which is required for later morphological filtering operations.

The first step in preparing the image for analysis is to perform a logarithmic transformation to remove the multiplicative effects of illumination between areas of high and low intensity. Each pixel in the image is assigned a new grey-scale value by the relationship

$$p[i,j] = \frac{255 log(p[i,j])}{log(255)} \tag{33.1}$$

where $p[i, j]$ denotes the grey-scale value of the pixel at (i, j).

Next, a background estimate is made on the logarithmically transformed image by performing a grey scale morphological closing operation with a structuring element large enough to span the cracks in the image. The resulting background estimate is then subtracted from the log-transformed image to create an inverted image with the particle boundaries bright against a dark background.

To remove any shading still present in the image, a 5 × 5 gradient operation is performed followed by clipping to remove negative pixel values. Since the gradient uses only local information and the image was previously log transformed, the resulting image contains only the particle boundaries and noise. To suppress the noise, a morphological closing operation is performed with a very small (two element) structuring element.

The resulting image is then binarised as illustrated in ➲ *Fig. 33.2*. Two methods have been successfully used. The first approach simply thresholds the entire image about a carefully selected threshold. A minor shortcoming here is that the threshold value was found to change as a function of the glass type which must be manually determined.

A second approach is to segment the image into approximately 25 subregions and threshold each subregion about its local average. Since most of the image is background in which the boundaries are bright, the resulting average will tend to favour the background, producing a suitable threshold. This procedure was found to provide similar results to that of a manually selected global threshold and has the advantage of being completely automated.

At this point the 10 pixel frame is removed from the image, and a single pixel border is placed around the resulting image to connect all boundary segments that have an endpoint at the boarder of the region of interest. Four connectivity is then applied, and remaining isolated

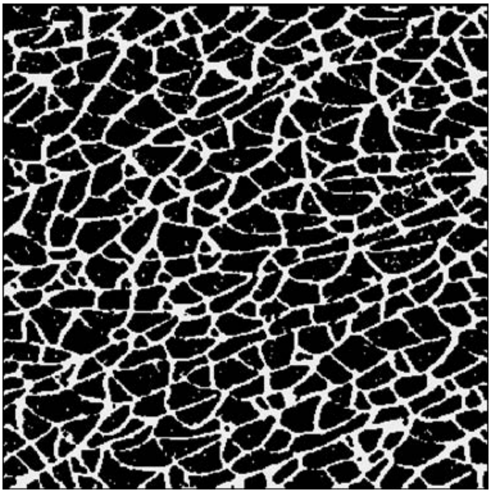

Fig. 33.2
Image after gradient and thresholding operations

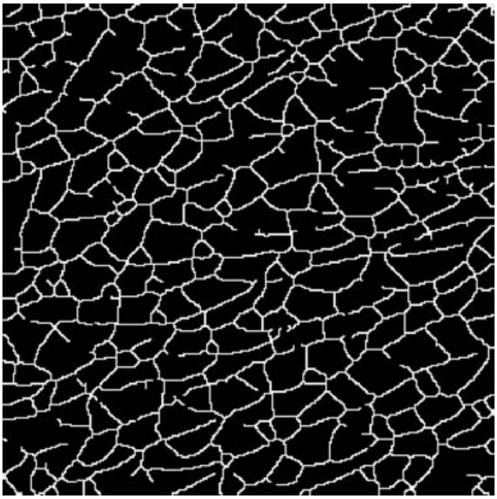

Fig. 33.3
Image after thinning

pixels are discarded. The cleaned, binary image is then thinned by repeated applications of a hit-or-miss transform as illustrated in *Fig. 33.3*.

After thinning, any "branches" which are only a few pixels in length are removed from the image by a simple pruning algorithm. This algorithm uses the same binary classifier as the reconstruction algorithm described in the next section to locate dead-end branches and their corresponding base points. With each branch identified, it is a simple matter to create an image without the small undesired branches caused by the thinning algorithm. The resulting pruned image is then ready for reconstruction.

33.4 Reconstruction Algorithm

Any branches remaining after pruning are assumed to belong to the border set and as such must be reconnected to the remainder of the border. Typically, two cases are encountered. In the first case, there is a section of a border missing from the middle of an edge. In this case, reconstruction involves connecting the resulting two branches to each other. In the second case, a section of border is missing from the 'corner' to somewhere in the middle of a piece. In this case, there is only one branch, and it must be extended in such a way as to complete the boundary pattern.

An algorithm to perform the reconstruction is outlined below and later described in more detail.

1. Apply binary spatial relationship classifier.
2. Identify points with only one neighbour.
3. Locate base point, the first point along a branch that has more than two neighbours.
4. Determine direction of segment.
5. Search for other points with only one neighbour in the direction of the segment, which are designated as candidates for connection.
6. Connect any branches which have only one candidate for connection.
7. Next consider branches with multiple candidates. First, reject any candidates that do not contain the current segment as candidates for their connection. Then, connect the current segment to the remaining candidate closest to the current segment's direction.
8. Connect remaining branches to the vertex (points with more than two neighbours) closest to their direction, or if no vertex was found, extend the branch in its direction until the extended branch connects with the crack pattern.

Since the image is four connected and thinned, every point has at most four neighbours. To identify points with only one neighbour, the pixel value (represented internally as an 8-bit character) is replaced with the results of the following binary classifier, where "$*$" represents the current pixel.

$$\begin{bmatrix} 0 & 4 & 0 \\ 1 & * & 0 \\ 0 & 8 & 0 \end{bmatrix}.$$

The resulting value for a pixel with an adjacent pixel to the north, and another to the west would be five, and so forth. The resulting pixel values now represent the connectivity and spatial relations of each point in the image. Identifying dead-end branches is simply a matter of finding pixels with only one neighbour, namely those with values of 1, 2, 4 or 8.

Once such points have been found and recorded as end points, their accompanying base point must be found. The base point is the point at which a branch either connects to the boundary pattern, or in the case of a totally isolated branch, simply ends. The algorithm makes use of the directional information produced by the classifier to follow the branch from its endpoint to the base point, which is then recorded for future use.

The equation of a line (l) from the base point passing through the endpoint of the segment is determined as illustrated in ➲ *Fig. 33.4*. Next, the point along the branch that is furthest from the line that maximises distance d is found which is designated as point A in ➲ *Fig. 33.4*. The point halfway from point A to the end point is then determined. The direction of the branch is then estimated by the line starting at point B and passing through the end point.

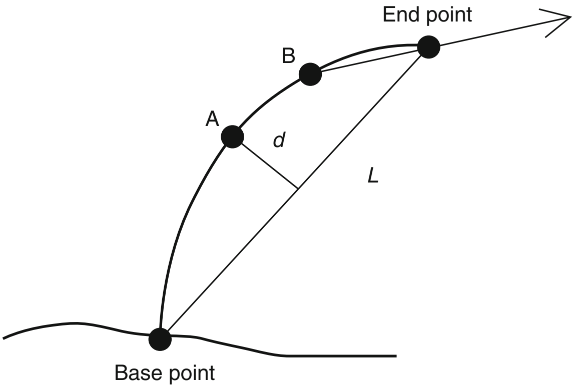

Fig. 33.4
Technique for measuring direction

It should be pointed out that simply using the last two points in the segment to determine direction would always result in directions of up, down, left or right due to the underlying four connectivity. Several other methods for obtaining the direction were tried, including fitting a spline to the points along the segment and taking the derivative near the end. It was found that the spline approach yielded inaccurate results due to the oscillations of the spline between the data points.

Note that the direction does not necessarily reflect the direction (derivative) at the end point. To improve the estimate further, the direction is modified by an amount proportional to the curvature of the segment. Note that the original estimate is correct if the segment is itself linear, and as the curvature increases, the estimate becomes worse.

First, a measure of the amount and direction of curvature is made. If the angle from the horizontal to line l is less than the angle from the horizontal to line BA, the segment is said to curve right as illustrated in ➔ *Fig. 33.5*. Similarly, as shown in ➔ *Fig. 33.6*, if the angle to line l is greater than the angle to line BA, the segment is said to curve left. An analogy can be made by considering how an automobile is steered to an endpoint along an arc.

The amount of curvature *C* to the left or right is assigned a value by the relationship

$$C = \frac{300d}{l} \tag{33.2}$$

This is a heuristic function that has been experimentally determined to yield satisfactory results. Note that only one direction of curvature can have meaning for any given segment. If the segment curves left the variable C_R (Curve Right) would be set to zero and C_L (Curve Left) would be found from (➔ 33.2). The direction μ of the segment is then updated to be:

$$\mu = \frac{\mu + (2\alpha\, C_L - 2\alpha\, C_R)}{2} \tag{33.3}$$

where α is a user specified constant, corresponding to the shift for the curvature associated with the given segment. Experimentation has shown values of α around 12 provide good results.

Once the direction of the segment is determined, a search is conducted along a linear path starting from the end point of the segment, about its direction, for connection to other candidate segments. All vectors starting at the end point and in directions from $(\mu - \delta\mu)$ to $(\mu + \delta\mu)$ are

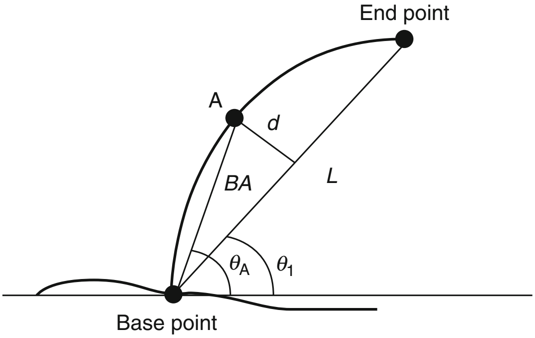

Fig. 33.5
Definition of "Curves Right"

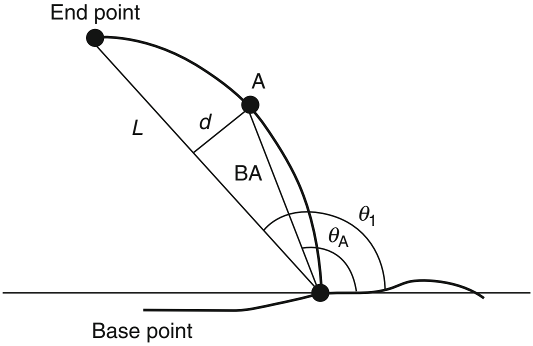

Fig. 33.6
Definition of "Curves Left"

examined to see if they contain any points with only one neighbour corresponding to the end point of another segment. The search along each vector is terminated when either a candidate is found or the vector reaches a boundary. Note that here a candidate means either an end point of another segment or a vertex. Typically, $\delta\mu$ should be between 30° and 45° for best results.

The algorithm identifies all regions where a particle boundary is incomplete and locates any possible end points which can be joined either to other end points or vertices. The next step is to examine this data and make the appropriate connections. This is accomplished by applying the following connection rules in sequence:

Rule 1: Connect all segments that are mutual candidates for each other where at least one of the segments has only one candidate, and mark both segments as connected. Such connections are typically made in regions where a short section of the boundary pattern is missing in a long shard.

Rule 2: Connect all remaining segments with only one candidate and mark both segments as connected. Typically, such connections are made when a short section of the boundary is missing, and one of the segments to be joined is a complex curve, usually having a "hook" at the very end.

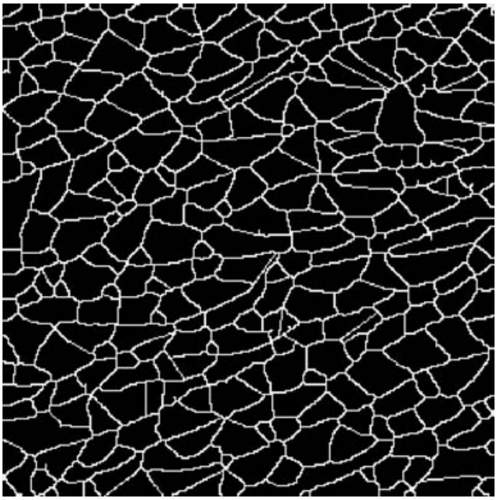

Fig. 33.7
Final image after boundary restoration

Rule 3: Connect all remaining segments which are mutual candidates for each other to the candidate closest to the direction of the current segment and mark both segments as connected.
Rule 4: Connect all remaining segments to the candidate closest to the direction of the current segment and mark both segments as connected if there are any candidates.
Rule 5: Connect all remaining segments to the vertex closest to the direction of the current segment and mark the segment as connected. Note that any connections made at this point are made to segments for which no other segments were found as candidates for connection.
Rule 6: Connect all remaining segments to the boundary pattern by extending them until they connect with the boundary.

At this point, every segment has been completely interconnected with the particle boundaries as shown in *Fig. 33.7*. It should be pointed out that the above rules only allow one connection to be made *from* each segment, but multiple connections *to* each segment are allowed. Hence, a segment can still be a candidate for another connection even if it has already been connected by a previous rule. It is this mechanism that provides reconstruction of missing vertices.

33.5 Segmentation by Watersheds

Segmentation by watersheds is a well-known morphological technique originally developed by Lantuéjol and has been used to analyse images that have many similarities to those obtained from shattered glass [1–3]. The watershed algorithm is quite different from the heuristic procedure described in the previous section and requires fewer assumptions about the nature of images being analysed. The watershed algorithm used here was developed by Luc Vincent and Pierre Soille [3]. Its relative speed and robustness is especially suited for purposes here.

Preprocessing issues are similar for the watershed transform in that a clean set of local minima must be attained prior to the application of the transform. This was accomplished by performing the background correction, noise filtering and positive gradient as before. Note that with the particle boundaries bright against a relatively dark background, the catchment basins correspond to the pieces of glass, while the watershed lines correspond to the particle boundaries. In this manner, the boundaries may be viewed as the watersheds of the gradient [3]. To create the marker set, a simple grey-scale stretch was performed on the gradient image, such that all grey-scale values from zero to three were set to zero, and the remaining values (4 to 255) were equally redistributed (from 1 to 255). This results in clear identification of the local minima. The watershed transform was then applied to this image.

It was found that great care must be taken when enhancing the local minima. Quite often, if the minima are not sufficiently enhanced, the watershed transform takes every impulse and local deviation and treats them as separate catchment basins. This causes too much segmentation which is an inherent difficulty with the watershed transform [3]. It may be possible to alleviate this problem with a more robust technique for detecting local minima.

However, if the preprocessing stage should inadvertently merge two or more real minima into one larger minimum, the resulting watershed lines will only reflect the single catchment basin, resulting in insufficient segmentation. While this methodology is quite powerful, it is very sensitive to noise and has the undesirable property of having poor repeatability when random noise is present in the image.

In general, segmentation was not satisfactory using the watershed approach. A comparison of the original and processed images indicated inconsistent segmentation with failure to reconstruct obviously missing boundaries and segmentation of particles that should not be split. The poor contrast of the boundaries and high noise caused significant problems. Better preprocessing may improve performance considerably given that this technique has been successfully applied in similar applications. The heuristic method's performance was much better for the given application.

33.6 Results and Conclusions

The heuristic reconstruction algorithm has been experimentally tested on a wide range on sample images, obtained both by camera and from scanning prints. Results are comparable with the two methods of image acquisition, although it is felt that scanning with a linear camera with more grey levels would provide better performance than scanning prints. In order to evaluate performance of the boundary restoration algorithm, 20 images of 5 × 5 cm regions were obtained and copies of these regions were given to three individuals for manual analysis. The particle counts obtained automatically compare favourably to those obtained manually with results most of the time falling between the three individuals. The average magnitude of the deviations from the mean of the three individuals was 2.53%, and in all cases the error was less than 6%. In general, automatic particle counting appears to be quite feasible using the technique described in ➲ Sect. 33.4.

After image acquisition, a region of interest is selected. Typically, this is a 5 × 5 cm square window. After background/illumination correction a positive-half gradient is used as a simple edge detector on the inverted image. Such an image is shown in ➲ *Fig. 33.2*. (See ➲ Sect. 33.3 for more details.) The resulting gradient image is then thresholded and thinned. See ➲ *Fig. 33.3*. There are obviously many branches of the crack pattern that simply dead end. Since the crack pattern is totally interconnected, such dead ends represent regions of image drop-out, or thinning anomalies. Any branch of only a few pixels is almost certainly due to effects associated with the thinning process and as such are removed from the image by a simple pruning algorithm. (See preprocessing issues for more information.)

Consider the image of shattered glass shown in ➋ *Fig. 33.1*. Notice that the crack pattern forms a completely interconnected web-like matrix, which forms the boundaries of each individual piece of glass. The objective is to identify each piece of glass in the image. Simply thresholding the image produces inadequate results due partially to the large amounts of noise in the image, but mostly due to local regions of image drop-out where the crack was simply not detected by the camera/scanner. These regions of drop-out usually occur when the crack is perfectly perpendicular to the plane of the camera, and thus refract insufficient light to be detected by the camera (or to prevent exposure of the print).

Abstract: The stability of glass substrates is an important concern for the flat panel display industry. High-resolution displays have very tight geometrical requirements and alignment of the various display components is critical if good performance is to be obtained. Prior to development of manufacturing processes for these displays, it was necessary to determine how glass substrates change during the various processing steps. This chapter describes a system to measure electrode patterns before and after critical processing steps for color plasma panels. The electrode patterns, which are made of thin-film gold, form a series of parallel electrodes. In order to measure electrode locations, a vision system consisting of an X-Y stage, a video camera, a frame grabber, and personal computer was used. Images captured with this setup were processed to minimize the effects of noise and improve accuracy. A gray-scale interpolation technique in which the centroids of the electrodes are calculated was used to enhance measurement resolution.

34.1 Introduction

Flat-panel displays represent one of the key technologies of the future. AC Plasma panels, one example of flat display, consist of two glass plates or substrates separated by a small and very uniform gap as shown in ➲ *Fig. 34.1*. Each plate has an array of parallel gold electrodes with a pitch of about 60 lines/in.. The electrodes are covered by a clear dielectric material and the two plates are oriented so that the electrode patterns are orthogonal to each other as illustrated in ➲ *Fig. 34.1*. The plates are sealed together to form a gap between the opposing dielectric surfaces. Each intersection of two electrodes defines a display pixel or cell that can be lit or extinguished under control of the driving electronics. Spacers are provided at regular intervals to maintain a uniform gap of approximately 4 mils over the panel area.

Traditional plasma panel displays use neon gas with trace amounts of argon and xenon. Since they are monochromatic, they are not suitable for television applications. The use of phosphors and a gas that emits large amounts of ultraviolet light is necessary to produce true-color images. Triads of red, green and blue phosphors must be deposited accurately to maintain the necessary alignment with the electrode intersections.

Maintaining this alignment, however, is quite difficult over large areas because the glass substrates tend to shrink during various high-temperature manufacturing processes, such as dielectric firing and sealing. An understanding of the exact manner in which substrates change during these processes is required in order to design phosphor deposition artwork that will be properly aligned with the electrode patterns. Dimensional changes in the glass substrate are less than the distance between electrodes, so measuring electrode positions before and after each processing step provides an accurate measure of substrate stability. The changes are typically on the order of parts/thousand so highly accurate measurements are needed. It was very desirable to use existing equipment in order to minimize cost. For this reason, an existing system for measuring spacers and dielectric thickness was modified to make the new measurements [1]. In the following sections, a description of the basic system will be provided along with the analysis techniques that were developed.

34.2 The Measurement System

The basic measurement system consists of an X-Y stage to move a given panel substrate for gauging and feature identification, a personal computer with image acquisition hardware and an illumination source. A light-section microscope with video camera and an

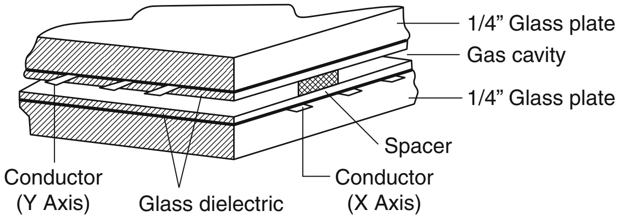

Fig. 34.1
Construction of an AC Plasma Panel

alignment camera are also present in the system but were not used for dimensional stability measurements. A third camera was added for the new measurements.

34.2.1 X-Y Stage

In order to perform measurements at various locations on a given substrate, an X-Y table with stepper motors was used to position it. With this arrangement, the substrate is mounted on the table using a fixture to secure and position the substrate in a consistent manner on the table. Since some variation in the electrode pattern relative to the substrate exists, X and Y offset adjustments are made using a fiducial reference point in the electrode pattern.

The stepper motors are driven by a pair of controllers that accept commands from the host computer via a serial port. The controllers provide the necessary velocity profile by controlling acceleration and deceleration to minimize the time required for movement without sacrificing accuracy.

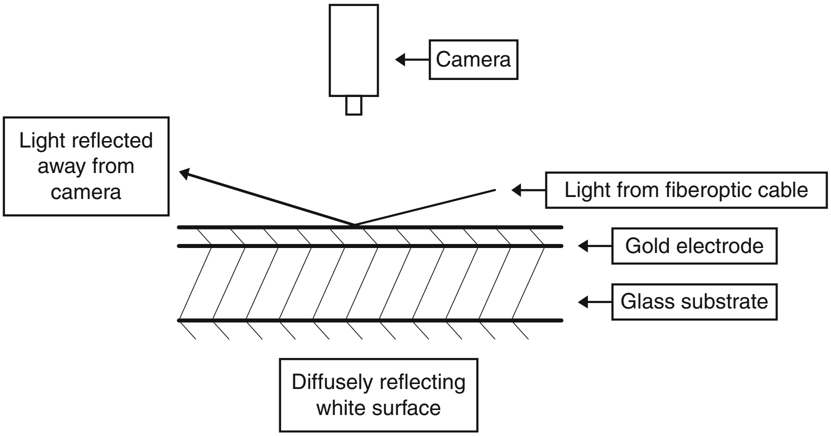
34.2.2 Image Capture Hardware

For image acquisition, a standard RS-170 camera is used to observe selected substrate areas. A field of view approximately 5 × 3.75 mm is obtained with a 75 mm camera lens and extension tube. A frame-grabber card digitizes and stores the video signal. A live video image can be shown on the monitor so that an additional monitor is not required for setup. Text or graphics can be combined with a recently captured image.

34.2.3 Lighting

Since the electrodes are opaque, the best illumination technique is back illumination. However, no provision was made originally for this type of illumination since the system only used a light-section microscope for measurement. A back-illumination source would be difficult to implement so an alternative technique was used that took advantage of the specular properties of the electrodes.

The panel electrodes have a mirror-like surface, so dark field illumination was used (➜ *Fig. 34.2*). Incident light nearly parallel to the electrodes strikes them at a low angle. This light is reflected away from the camera so the electrodes appear dark. The white surface under the substrate reflects light diffusely and appears bright relative to the electrodes.



Camera
Light reflected away from camera
Light from fiberoptic cable
Gold electrode
Glass substrate
Diffusely reflecting white surface

Fig. 34.2
Light striking the electrode pattern at a low angle is reflected away from the camera and appears dark

As will be noted later, this type of lighting causes a noticeable gradient across the image in which the side nearest to the light source is markedly brighter than the opposite side. As described in the next section, simple image processing can eliminate problems resulting from this nonuniformity.

34.3 Image Analysis Algorithms

The basic approach to determine the degree of change between different manufacturing steps takes advantage of the regular parallel electrode pattern on a substrate. Measuring the location of each electrode relative to some reference point provides a straightforward technique to determine how a substrate changes.

34.3.1 Image Acquisition and Processing

A matrix of 5 × 3.75 mm measurement regions was defined for a given type of panel substrate and each was moved under the camera and captured at a resolution of 640 pixels/line × 480 lines. A typical image, given in *Fig. 34.3*, shows the panel electrodes as dark horizontal lines against a brighter background. A light gradient is evident in the image and is caused by lighting the substrate from only one side. Simple image processing is able to minimize any errors caused by the nonuniform illumination. The PC provided sufficient processing speed for real-time measurements [2].

It may be noted that there is a great deal of redundancy in the image. The important information can be retained by reducing the image resolution in the horizontal direction by summing adjacent horizontal pixels. This will provide faster processing since the image size is much smaller and, more importantly, reduce image noise because of pixel summing. A reduction factor of 16 was used, so that the final image resolution was 40 pixels × 480 lines.

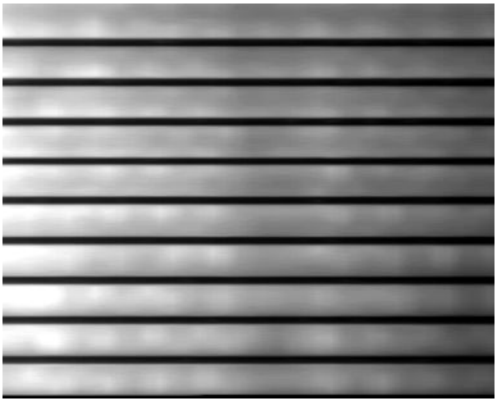


Fig. 34.3
Digitized image of electrode pattern with left-to-right light gradient

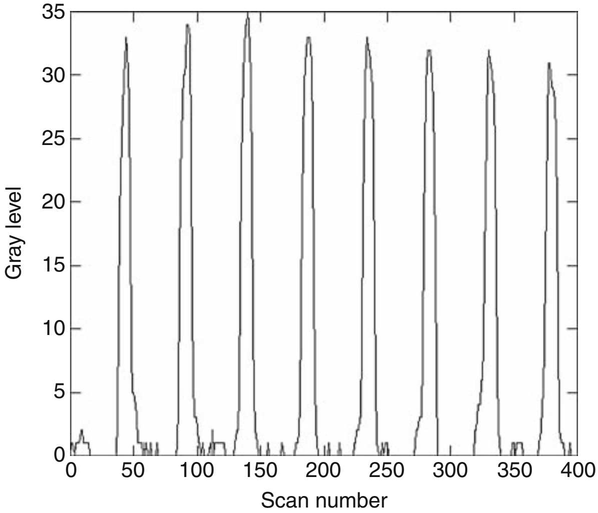

Fig. 34.4
Electrodes appear as bright peaks against a dark background after image processing

After reducing the horizontal resolution, a gray-scale logarithmic transformation is performed to minimize the effects of nonuniform illumination [3]. A gray-scale closing operation is used to estimate the background light level [3, 4]. Since the electrodes are less than 10 pixels wide, a vertical structuring element of this length or greater will remove them. Subtracting the original image from the closed image provides an illumination-corrected image in which the electrodes appear as bright horizontal lines against a dark background. A plot of light level versus scan number given in *Fig. 34.4* illustrates this.

To provide an accurate measurement of the electrode positions the centroid for each electrode at a given x (pixel) locations is calculated using

$$\mu_{xk} = \frac{\sum g(x,y) \cdot y}{\sum g(x,y)}$$

in which μ_{xk} is the centroid for the kth electrode and the column of pixels at x and $g(x,y)$ is the gray level of the pixel at (x,y). The pixels used for this calculation are those from the kth electrode that are above gray level 10 that was established heuristically. The location of each electrode was found by averaging all of the centroids associated with that electrode. An error estimate was calculated at the same time and in general was well under 0.1 mils which is better than the precision of the X-Y stage.

34.4 Results and Conclusions

Measurements were made before and after various processing steps and analyzed using statistical techniques. A model was constructed from these results which showed a linear correlation between distance from a reference point and the amount of compaction with a correlation of 98%. A plot of the results is given in ➲ *Fig. 34.5*.

From this model, artwork for phosphor deposition can be designed that will be properly aligned with the electrode pattern. Measuring electrode locations by calculating gray-scale centroids is an effective and accurate way to improve vision system resolution for this type of application.

Abstract: This paper discusses simple but effective one-dimensional morphological techniques for the identification of primary and secondary peak locations associated with light patterns reflected from glass surfaces. A common optical technique for measuring glass thickness and related properties is to observe light reflected from the front and rear surfaces of the glass. Two reflections can be observed when an appropriate structured light source is used to illuminate the glass: a bright primary reflection from the front surface will be observed, along with a much fainter secondary reflection from the back. The secondary reflection is difficult to detect reliably, due to the large difference in intensity compared to the first reflection, the presence of noise, and possibly overlap between them. The methods described in the paper have been implemented successfully for two separate applications, using standard matrix and linear cameras. In both cases, the signal is pre-processed using one-dimensional morphological and linear methods, to normalize the background and remove noise. Further morphological operations are performed, to identify the peaks associated with the primary and secondary reflections.

35.1 Introduction

Morphology has been a significant and useful technique for image analysis and processing. It was initially developed for binary image processing and has been developed further to process gray-scale images by treating them as three-dimensional surfaces. [1] In this chapter, elementary gray-scale morphological concepts are applied to one-dimensional signals to find distances between primary and secondary peaks using light reflections associated with a change in the index of refraction. This is useful for detecting boundaries between different transparent materials.

The morphological techniques that are used here are based on the basic properties of erosion and dilation [2] Gray-scale *erosion* is defined as

$$(X\Theta B)(x,y) = \min_{(j,i)\in B}\{X(y+j,x+i) - B(j,i)\} \tag{35.1}$$

where X represents a gray-scale image and B is a structuring element. When the structuring element is placed over the pixel at (x, y), the difference between the image pixels and corresponding structuring element values is calculated. The minimum value becomes the value at pixel (x, y) in the eroded image. Similarly, the expression for *dilation* is

$$(X \oplus B)(x,y) = \max_{(j,i)\in B}\{X(y-j,x-i) + B(j,i)\} \tag{35.2}$$

This is similar to *erosion*, except that the pixel and structuring element values are added and the maximum value is chosen. Note that, if the structuring element is not symmetrical, its reflection about its origin must be used for erosion.

Performing a gray-scale erosion on an image produces a new image that is in most places darker than the original image. If there are small bright regions in an image that are spanned by the structuring element, they will be removed by erosion. The opposite effect is observed with gray-scale dilation: most parts of a dilated image will be brighter than the original image, while dark regions that are smaller than the structuring element will disappear.

Morphological *opening* and *closing* are obtained by using both erosion and dilation. To perform an opening on an image, it is first eroded and the resulting image is then dilated using the same structuring element. To close to an image, the operators are used in the reverse order, again with a common structuring element. An important property of opening and closing is that they have no effect on those areas of an image that lack features smaller than the structuring element. The general principle is that openings remove small bright features, while closings eliminate small dark ones. The size, shape and gray-scale values of the structuring element determine the effect that a given operation will have on an image.

In this chapter, two separate applications using morphology to identify primary and secondary reflections are presented. In the first, the measurement of dielectric thickness in AC plasma display panels, employs a light-section microscope (LSM). ➊ *Figure 35.1* illustrates the basic construction of this type of device. Dielectric material is applied over a glass substrate with thin-film metal electrodes. When the device is assembled, two parallel substrates are held a fixed distance apart by spacers. Their electrode patterns (arrays of thin parallel lines) are orthogonal to each other. Prior to final assembly, the dielectric thickness is measured, using a video camera and frame grabber with the LSM. The image of the top surface of the dielectric (glass plate) appears as a very bright horizontal line. The secondary reflection, associated with the rear dielectric–glass interface, is much dimmer. A plot of the intensity profile given in ➊ *Fig. 35.2* illustrates this. The distance between the two peaks is proportional to the dielectric

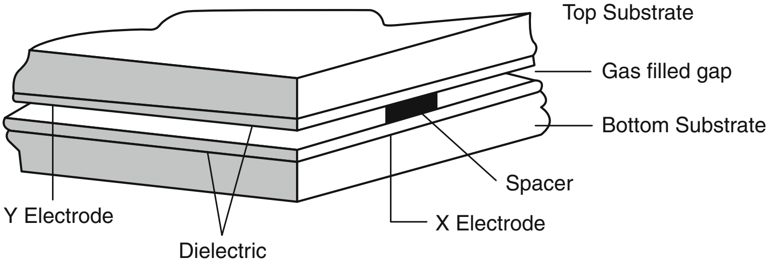

Fig. 35.1
Construction of AC plasma display panel

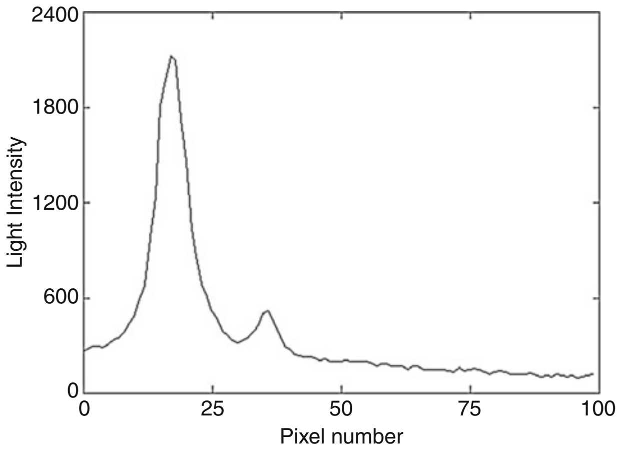

Fig. 35.2

thickness. It should be noted that the difference between the heights of the two peaks is actually much greater than the plot indicates, since the data was logarithmically transformed prior to plotting as shown in ➋ *Fig. 35.2*.

The second application is similar but the data are of poorer quality, due to the manner in which the data acquisition was performed. A linear camera was used here. For reasons of confidentiality, no specific information about the application can be disclosed, except for the details of the data preprocess and finding the distance between the primary and secondary peaks.

In both applications, data analysis is performed to measure the distance between the two peaks but important differences exist. For dielectric thickness measurements, obtaining accurate measurements with limited spatial resolution was the prime objective. Averaging was used extensively so noise was not a problem but the coarse spatial quantization imposed special processing requirements. In the second application, preprocessing reduced the effects of high noise levels.

35.2 Data Acquisition

In order to achieve accurate measurements, the LSM, video camera, frame grabber, and motion-control hardware were assembled and measurement software was developed. The LSM was a critical component, since it provides images that could be analyzed to extract three-dimensional information, including dielectric thickness. A general overview of the system is in ➋ *Fig. 35.3*, illustrates the various system components.

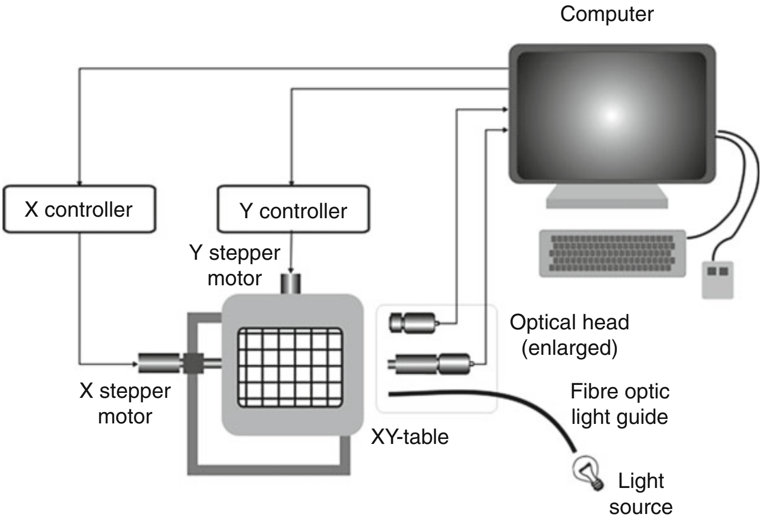

Fig. 35.3

Hardware used for dielectric thickness measurements. The box in the lower left corner provides additional information about the optical head

35.2.1 Surface Profile Measurements

The LSM produces a surface profile by making an optical "cut" using structured light. An incandescent lamp, masked by a slit is focused using an objective lens to produce a narrow band of light at 45° to the dielectric surface. The light stripe is reflected off this surface and is imaged by the microscope at 135°.

A cross-line reticule is provided in the eyepiece for manual measurements but is not used by the software. A camera port suitable for mounting a video camera is provided on the microscope. A moveable mirror is provided on the microscope to divert the image to the eyepiece or the camera.

35.2.2 Motion Control Hardware

In order to measure dielectric thickness at various locations on a glass substrate, either the substrate or microscope must be moved. Moving the substrate is easier, since it weighs less than the microscope with its video camera assembly and is unencumbered by cables. An *X*–*Y* table driven by stepper motors is used to position the substrate. The substrate is mounted on the table with a fixture that secures it in a fixed position. Given that there is some variation in the electrode pattern relative to the substrate, *X*- and *Y*-offset adjustments can be made using a fiducial reference point.

The stepper motors are driven by a pair of controllers that accept commands from the host computer via a serial port. The controllers provide the necessary velocity profile, by controlling acceleration and deceleration. This is necessary to minimize the time required for movement and avoid to positioning errors. A variety of commands may be presented to the stepper-motor controllers, including the option of making relative and absolute position adjustments. Status information is obtained by data returned from the controller after the appropriate command has been issued to it.

Since the panel substrates may not be perfectly flat, it is necessary to control the distance between the microscope objective lens and the surface being inspected. In this case, the microscope, not the substrate, is moved by small increments. As the *X*–*Y* stage moves to each new location, the microscope height is adjusted, so that the dielectric surface remains a fixed distance from it. After each new image has been acquired, the dielectric surface is identified and a correction applied to the microscope's vertical position. If the magnitude of the correction is above a defined value, a new image is acquired. However, a second image is normally only required when moving to a new spacer location.

35.2.3 Image Acquisition Hardware

A standard RS-170 camera was attached to the camera port of the LSM using a custom C-mount adapter. A combination VGA/frame-grabber card stores the digitised video signal. A "live" video image can be shown on the VGA monitor with this board so that an additional monitor is not required for setup. The VGA memory is also used for image capture and allows text and graphics to be combined with a digitised image.

35.3 General Approach for Identifying Primary and Secondary Peaks

As stated above, both applications provided measurements based on the distance between the primary and secondary peaks. The same basic technique for identifying peak values was employed in both applications although preprocessing differed considerably.

35.3.1 One-Dimensional Gray-Scale Morphology

The one-dimensional erosion and dilation operations are defined in Eqs. 35.1 and 35.2 respectively. However, in both applications, data can be analyzed using one-dimensional (signal) analysis techniques. Hence, erosion and dilation can be reduced to the following form:

$$(X\Theta B)(x) = \min_{(i)\in B}\{X(x+i)\} \tag{35.3}$$

$$(X\oplus B)(x) = \max_{(i)\in B}\{X(x-i)\} \tag{35.4}$$

Notice that the spatial extent of the structuring element is the only adjustable parameter.

As noted previously, these operations were combined to perform opening and closing operations. Using an opening operation with a structuring element wider than the base of the peaks provides an estimate of the sensor shading, or DC offset. Subtracting this from the original data generates a signal consisting only of the peak data. The results from each step in this procedure are illustrated in *Fig. 35.4*. The top curve (A) is the original data showing the primary and secondary peaks. The dashed horizontal line segments (B) below the peaks represent the processed data after an opening operation. In many locations the original and

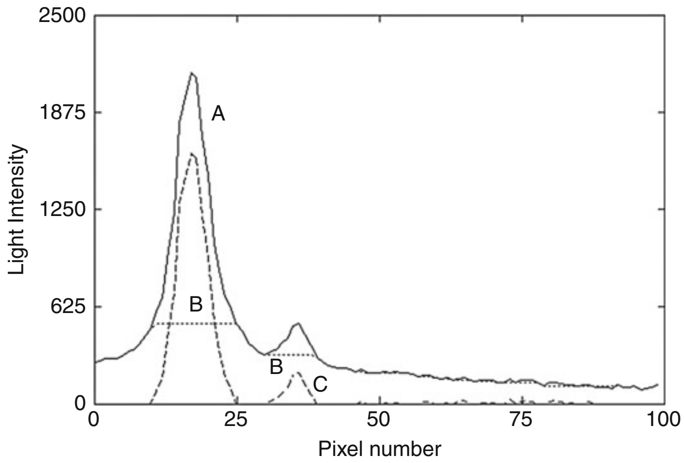

Fig. 35.4
Using morphological opening operation to remove undesired background information

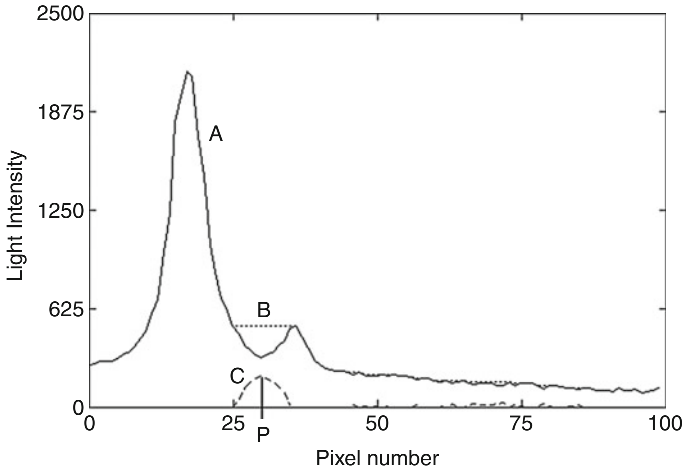

Fig. 35.5
Using morphological closing operation to identify the valley between two peaks

opened data coincide so they cannot be distinguished visually. Subtracting the opened data from the original data provides the third plot (C) in which all points are zero or nearly so except for the two peaks.

The next step is to find the location of the valley between the two peaks. The valley region is detected using a closing operation on the original data which fills in the valley as illustrated in *Fig. 35.5*. The horizontal dashed lines (B) in this figure correspond to the data from the closing. As with the opening, many of the closed data points are obscured by the original data (A). Subtracting the original data from the closed data produces the peak corresponding to the location of the valley. This is indicated by (C), which also contains some much small peaks due to noise.

The pixel number (P) corresponding to the maximum value of curve (C) in *Fig. 35.5* is used as the starting point of the search to locate the two peaks. Finding the maximum values to the left and right of P provides the locations of the two peaks.

This approach has proven to be very robust and will identify peaks correctly under a variety of conditions. The presence of noise can affect the results, so some preprocessing for noise suppression is very desirable. The next two sections describe the special processing unique to each application.

35.3.2 Dielectric Thickness Measurements

In order to measure the dielectric thickness of AC plasma panels with a light-section microscope, locations of reflections from both the dielectric surface and the dielectric/substrate interface need to be detected accurately and unambiguously. By finding the difference between the peak positions, the dielectric thickness can be estimated. Detection of the reflection from the dielectric is quite easy because the surface is highly reflective and produces a bright horizontal line in an LSM. However, the reflection from the dielectric/substrate interface is much fainter and requires processing to locate it accurately.

35.3.2.1 Noise Reduction Considerations

Video camera noise causes significant problems at low light levels, so steps must be taken to minimize it. Frame integration is one effective technique for reducing video noise; quadrupling the number of frames in a given integration sequence approximately doubles the SNR of the resulting image. The main drawback with this approach is the time penalty imposed when performing the frame integration.

A similar approach takes advantage of the nature of the image. Each column of pixels contains information degraded by noise about the two reflections. In principle, each column of the image could be summed, to provide a low-noise estimate of the light profile through the two reflections.

However, unless the camera is very carefully aligned with the horizontal reflections, the resulting estimate will be degraded and the peaks of the two reflections will be "broadened". This can be alleviated by summing over smaller vertical regions and obtaining a number of low-noise estimates of the light profile across the image.

35.3.2.2 Calculating Dielectric Thickness

Although an estimate of dielectric thickness can be obtained by finding the distance between the positions of the maxima of the two peaks, the results do not achieve the desired precision. Errors caused by quantization effects are large because the separation between peaks is only about 20 pixels, corresponding to 38 μm. The desired precision of the thickness measurement was ±0.25 μm. This level of precision was achieved by calculating the first order moment about each peak.

In order to estimate dielectric thickness, the procedures described previously are used in sequence. Frame integration reduces the effects of camera noise. To reduce noise further, the image is divided into a number of vertical strips and all columns of pixels in a given strip are added together. Morphological processing is then used to find the primary and secondary peaks for a given image strip and the first order moment is calculated about each peak to reduce quantization errors. In the last step, the dielectric thickness estimates for each image strip are averaged to obtain a better estimate.

35.3.3 Proprietary Application

It was not feasible to average a number of scan lines together to suppress noise for the proprietary application. In addition, the linear camera exhibited a significant amount of nonuniformity between odd and even pixels, which acted like a synchronous noise source. The top trace (A) in ❯ *Fig. 35.6* represents typical data with the odd/even pixel nonuniformity evident in low-gradient regions.

Opening and closing operations with five-element structuring elements were used to remove this noise. The procedure previously described was used to find the peaks. The lower trace (B) in ❯ *Fig. 35.6* illustrates the result. Once the valley between the two peaks was identified, the primary and secondary peaks could be separated. As before, the use of one-dimensional morphology provided a reliable and robust means for primary and secondary peak detection.

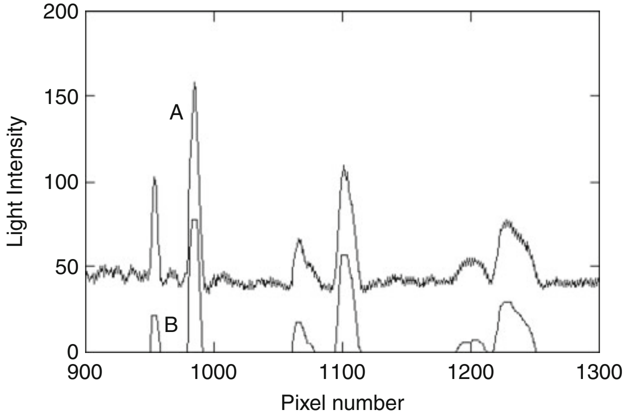

Fig. 35.6
Typical data from the proprietary applications. The original noisy signal (A) was processed to obtain the bottom trace (B)

Abstract: An important aspect of machine vision is the inspection of products during manufacture, in order to achieve control of quality. This is as necessary for food products as it is for metal or plastic parts, though there is a difference in that food products are highly variable: e.g., even two fairly ideal apples will have marked shape, colour and other differences, and this will have to be taken into account when devising inspection algorithms. Another important aspect of food inspection is the speed with which product location has to be carried out, as the process of location involves unconstrained search: contrariwise, product scrutiny often involves examining a relatively small area of an image, and can often be carried out much more quickly. To understand the process of algorithm design, this chapter takes a number of case studies relating to the location of objects in food and cereal images. These range from finding Jaffacakes, cream biscuits and cereal grains to identifying insects, rodent droppings, moulds and foreign seeds amongst the cereal grains. In the first three cases the objects had to be scrutinised for defects, whereas in the other cases the cereal grains had to be scrutinised for contaminants.

36.1 Introduction

It is many years since computers were first used for analysing digital images, and thousands of industrial, medical, space, forensic, surveillance, scientific and other applications have now been recorded. This huge subject area is called machine vision and is characterised by the use of artificial vision to achieve actions in the real world. Thus it is a rather separate subject from computer vision, which endeavours to understand visual processes by experiments which test algorithms to see how well they permit vision to be achieved, and to determine what principles are involved in the process. In a sense, computer vision is the science and machine vision is its engineering colleague. However, this does not mean that machine vision has to be unscientific. Far from it: machine vision necessarily takes on board all the methodology and conclusions of computer vision, but also aims to arrive at cost-effective solutions in real applications. As a result, there is some emphasis on producing more efficient solutions, which are not only effective but to some extent minimal, with viable but rigorous short cuts being taken to save computation and hardware cost, but without significant invasion of robustness, reliability, accuracy, and other relevant industrial parameters. The way in which this end can be achieved is by noting that many applications are constrained in particular ways, so the full panoply and power of the most comprehensive algorithms will not always be needed. Naturally, this implies that some loss of adaptability in the chosen algorithms may have to be accepted in any one case. However, this is by no means unusual in other types of application, and in everyday life we are used to selecting appropriate tools to handle any task we tackle. Thus machine vision is intimately concerned with the selection of software tools and algorithms, and furthermore it is concerned with the specification and production of such tools.

Unfortunately, although the subject has developed vastly and even impressively over the past decades, it cannot yet be regarded as a fully mature subject. Software specification and design are not yet possible to the extent that they are in other areas of engineering. The blame for this lies in the complexity and variability of the image data that machine vision systems are expected to handle. Not only are the image signals highly variable, but also the noise within the images is highly changeable. For instance, noise may be white or “coloured,” Gaussian or impulse, position or time dependent. In addition, it may arise in the form of clutter, i.e., it may take the form of other objects which partly occlude those being observed, or other objects forming a variegated or even a time-varying background. In fact, the variability of real imagery is more often due to the effects of irrelevant objects than it is to noise, though noise itself does play a significant part in complicating the overall situation. Lastly, the objects being observed can vary dramatically, not only in their intensity, colour or texture, but also in their shape (especially when the 3D viewpoint is variable) and in changes that are the result of defects or damage.

To develop the subject further, it is necessary to take account of all these factors, and to try to understand the specification–application problem in more detail. However, theory on its own is unlikely to permit this to be achieved. The way forward seems to be to take a careful record of what happens in particular applications and to draw lessons from this. As more such records become available, sound all-embracing theories and guidelines will gradually emerge. However, at the very least, such case studies will permit design by analogy and by example, so very little should be lost. The case study approach is a powerful one which is particularly relevant at this point in the development of the subject. Accordingly, this chapter describes a number of case studies from which lessons can be drawn.

In fact, the subject of machine vision is very wide indeed, and there is a limit to what a single chapter can achieve. Hence it will be useful to consider a restricted range of tasks: by focusing attention in this way, it should be possible to make more rapid progress. On the other hand, many tasks in different areas of vision bear significant similarity to each other – notice the ubiquity of techniques such as edge detection, Hough transforms, neural networks, and so on – so the possibility of transfer of knowledge from one part of the subject to another need not be substantially reduced. For these reasons, this chapter is targeted at automated visual inspection applications, and in particular some tasks which relate to food products. Foodstuffs have the reputation of being highly variable, and so the tasks described here cannot be considered trivial – especially, as we shall see, because quite high rates of inspection are required.

In the following section we first describe the inspection milieu in rather more detail, and then we proceed to a number of case studies relating to food and cereals. Selected theoretical results are also considered at relevant junctures. Finally, the concluding section of the chapter underlines the lessons learnt from both the case studies and the theory, and shows that both are relevant to the development of the subject.

36.2 The Inspection Milieu

Computer vision is widely considered to have three component levels: *low-level vision*, *intermediate-level vision*, and *high-level vision* [1, 2]. Low-level vision consists of primitive processes such as removal of noise and location of image features such as edges, spots, corners and line segments. Intermediate-level vision involves the grouping of local features into boundaries or regions, and also the identification of geometric shapes such as circles. High-level vision analyses the purely descriptive groupings resulting from low and intermediate-level vision and makes careful comparisons with objects in databases: relational analysis, inference, reasoning and statistical or structural pattern recognition techniques are used to help achieve viable matchings, and the image features are finally identified as actual objects – together with various attributes such as motion parameters and relative placements.

As mentioned in ➋ Sect. 36.1, machine vision aims to go further and identify actions which should be initiated as a result of visual interpretation. However, it is also able to limit the practical extent of the algorithms at a level below that represented by the computer vision ideal, so that efficiency and speed can be improved. This means that instead of focusing on low, intermediate and high-level vision, we should concentrate on achieving the task in hand. In the case of industrial inspection, this means attending first to object location and then to object scrutiny and measurement. However, the very first task is that of image acquisition. This is especially important for inspection, as (a) careful illumination can ensure that the image analysis task is much simplified, so fewer advanced algorithms are needed, thereby saving computation and speeding up implementation; and (b) careful illumination and acquisition can ensure that sufficient information is available in the input images to perform the task in hand [3]. Here it has to be borne in mind that object recognition is less problematic when only one type of object can appear on a specific product line: the natural restrictions of machine vision permit the whole process to be made more efficient.

Overall, we now have the following four-stage inspection process:

1. Image acquisition
2. Object location
3. Object scrutiny
4. Rejection, logging or other relevant actions

Here the "object" may be the entire product, or perhaps some feature of it, or even a possible contaminant: note that in the first of these cases the object may have to be measured carefully for defects, while in the last case, the contaminant may also have to be identified. The situation is explained more fully in the case studies.

Set out in this way, we can analyse the inspection process rather conveniently. In particular, it should be noticed that object location often involves unconstrained search over one or more images (especially tedious if object orientation is unknown or if object variability is unusually great), and can thus involve considerable computational load. In contrast, object scrutiny can be quite trivial – especially if a pixel by pixel differencing procedure can be adopted for locating defects. These considerations vary dramatically from one application to another, as the case studies will show. However, the speed problem often represents a significant fraction of the system design task, not least because products are likely to be manufactured at rates well in excess of 10/s, and in some cases such as cereal grain inspection, inspection rates of up to 300 items/s are involved [4].

36.3 Object Location

In the previous section the problem of limiting the computational load of any vision algorithm was mentioned, with the indication that the demands for meeting real-time processing rates could be quite serious in food processing applications. In fact, this difficulty is inherent in the object location phase of any inspection process. The reason is that unconstrained search through one or more images containing some millions of pixels may be required before any object is encountered. Furthermore, at each potential location, a substantial template may have to be applied with a large number of possible orientations. If objects of 10,000 pixels are being sought, and 360 orientations can be defined, some 10^{12} pixel operations may have to be performed – a process which will take a substantial time on any computer. This clearly rules out brute force template matching, but turns out not to eliminate template matching per se, as it can instead be applied to small object features. Often the template can be as small as 3 × 3 pixels in size, and there will be a correspondingly small number of definable orientations, so the computational load can immediately be reduced to around 10^7 pixel operations for a 256 × 256 pixel image – a much more realistic proposition. However, this leaves the problem of how to locate objects from their features – a process that involves inference rather than logical deduction: it should be noted that inference can itself lead to computational problems and to potential ambiguities, unless care is taken in the choice of the relevant algorithms. ➲ Chapter 18 considers the situation in depth, and arrives at several general approaches to the problem. These include the Hough transform, which is particularly appropriate when edge features are used to locate objects, and graph matching, which is appropriate mainly when point features are used for the purpose.

36.3.1 Feature Detection

Before proceeding to discuss inference procedures in detail, we briefly examine how feature detection can be achieved. The most commonly used approach involves the use of convolution masks. If a feature of a certain shape is to be detected, this is achieved by applying a mask of the same intensity profile – insofar as this is realisable within a digital (pixel) representation. The method is amply illustrated by the case of corner detection. If corners are to be detected, convolution masks such as the following may be used (To be rigorous, the convolution mask *enhances* the feature, and this then has to be *detected* by thresholding or related operations [1]. In this section we follow common practice by referring to feature detection without further qualification of this sort.):

$$\begin{bmatrix} -4 & -4 & -4 \\ -4 & 5 & 5 \\ -4 & 5 & 5 \end{bmatrix}$$

Clearly, such a mask will only be able to detect corners of this particular orientation, but application of eight similar masks whose coefficients have been "rotated" around the central pixel essentially solves the problem. Notice how such masks are given a zero sum so that they can achieve a modicum of invariance against variations in image illumination [5]. Interestingly, while corners and other general features require eight such masks within a 3 × 3 window – and rather more in larger windows – edge detection only requires four masks of the following general types:

$$\begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix}$$

This is because four of the eight masks that might have been used differ from the others only in sign. However, if we permit ourselves to change the strategy for edge detection from pure template matching by noting that edges are vectors with magnitude and direction, it becomes possible to employ just two masks: these then detect the horizontal and vertical components of intensity gradient. The pattern of ±1 coefficients employed in the above edge detection mask is not the best possible, since it leads to inaccurate estimates of edge orientation – a parameter that is of particular importance for Hough transform and related methods of object location. Within a 3 × 3 window the most appropriate edge detection masks are thus those of the well-known Sobel operator:

$$S_x = \begin{bmatrix} -1 & 0 & 1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{bmatrix} \quad S_y = \begin{bmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{bmatrix} \tag{36.1}$$

for which magnitude and direction can be estimated from the gradient components g_x, g_y using the equations:

$$g = (g_x^2 + g_y^2)^{1/2} \tag{36.2}$$

$$\theta = \arctan\left(g_y/g_x\right) \tag{36.3}$$

Next, we come to line segment detection. Line segments are not vectors as symmetry ensures that any vector that is associated with them will have zero magnitude. This suggests that we should employ an eight-mask set for line segment detection, though symmetry considerations reduce this set to just four masks. However, recent research has shown that if the following pair of masks is used [6]:

$$L_0 = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix} \quad L_{45} = \begin{bmatrix} -1 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & -1 \end{bmatrix} \tag{36.4}$$

line features can be detected by combining the two outputs in a vectorial manner. The situation is curious, but this operator acts within an abstract space where the normal 360° rotation is transformed to 180°, with the result that the operator predicts a line segment orientation ψ which is twice as large as expected. However, dividing ψ by 2 leads to sensible results as symmetry only permits line orientations to be defined in the range 0–180°.

Finally, note that hole and spot detection masks only require a single convolution mask to be applied:

$$\begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix}$$

36.3.2 Design of Template Masks

So far, we have seen that much of the weight of object location devolves onto the use of template masks for feature detection. While design of such masks can be dealt with intuitively and checked by experiment, design principles are hard to come by. The *zero mean rule* [5] is a generally useful one, but important questions remain – such as how large the masks should be and how the pixels should be divided between the foreground and background regions.

In fact, it is generally the case that greater sensitivity of detection results from the additional averaging achieved by larger masks. However, there is a limit to this which is determined by the probability of disruption introduced by impulse noise [7]. Specifically, if one pixel within a mask succumbs to impulse noise, this may well falsify the response from that mask, and (for example) cause a vote to be placed at a totally erroneous position in the Hough transform parameter space. Clearly, the probability P of this happening increases rapidly with the number of pixels within the mask. If the probability of a pixel intensity being corrupted in this way is p, and the area of the mask is A, we find [7]:

$$P = (1 - p)^A \tag{36.5}$$

If we set P at some reasonable limit of acceptability, such as 0.75, and if p is taken to have a value of about 0.01, we find that $A \approx 28.6$, and in that case the window size should not be larger than about 5×5.

Once the window size has been determined, the problem of disposition between background and foreground remains. A simple calculation can be used to solve this problem [8]. We first write the mask signal and noise power in the form:

$$S = w_\mathrm{f} A_\mathrm{f} S_\mathrm{f} + w_\mathrm{b} A_\mathrm{b} S_\mathrm{b} \tag{36.6}$$

$$N^2 = {w_\mathrm{f}}^2 A_\mathrm{f} {N_\mathrm{f}}^2 + {w_\mathrm{b}}^2 A_\mathrm{b} {N_\mathrm{b}}^2 \tag{36.7}$$

where A_f, A_b are the numbers of pixels allotted to the foreground and background regions, w_f, w_b are the respective mask weights, S_f, S_b are the respective signal levels, and N_f, N_b are the respective noise levels. Optimising the signal-to-noise ratio for a zero mean mask of fixed total area $A = A_\mathrm{f} + A_\mathrm{b}$ now leads to the equal area rule:

$$A_\mathrm{f} = A_\mathrm{b} = A/2 \tag{36.8}$$

though complications arise when $N_\mathrm{f} \neq N_\mathrm{b}$, a situation that becomes important when the foreground and background textures are different. Finally, when the equal area rule does apply, the mask weights must follow the rule:

$$w_\mathrm{f} = -w_\mathrm{b} \tag{36.9}$$

Thus theory can help substantially with the design of masks, once the design constraints are known reliably.

36.3.3 The Hough Transform

The Hough transform is a model-based inference technique which may be used for locating objects of known shape. It has been used in many applications for locating lines, circles, ellipses, and shapes composed of these basic structures. It is also known how to apply the Hough transform to locate arbitrary shapes [1]: however, these shapes must first be defined unambiguously, and this may be achieved using analytical formulae or with the aid of look-up tables. The basic principle of the Hough transform is described in detail in ➋ Chapter 18, together with its application to detect lines, circles, ellipses and general shapes. However, it will be useful to note here that the Hough transform is particularly suited to inferring the presence of objects from their edges. It is also useful to point to the particular advantage of the Hough transform, and indeed of more recent, related projection-based transforms [9]: this resides in its impressive robustness against noise, occlusion and object distortion – or even breakage. It is achieved because edge pixels arising from noise, occluding objects or distorted parts of the object boundary give rise to candidate centre locations that are spread out in parameter space: these are unlikely to focus on particular locations and to give rise to misleading solutions. In any case, quick tests will usually eliminate any false positives that may arise (see the detailed discussion in ➋ Chap. 18).

36.3.4 The Maximal Clique Graph Matching Technique

Graph matching provides another approach to model-based inference which may be used for object location. However, the graph matching approach is aimed at locating objects from point features such as corners and small holes rather than from edge or line segments which are only localised in a single dimension.

The concept of graph matching is to imagine the point features in the image as forming a graph, and those in the model as forming a separate graph. The matching problem then amounts to finding the isomorphism with the largest common subset in the two graphs, as this represents the greatest degree of agreement between the model and the image data. The solution is represented by a subset of the model graph because part of any object in the image may be occluded or broken away; likewise, it is represented by a subset of the image data as there will usually be features from other objects or from noise which have to be ignored.

One way of achieving graph matching is by the maximal clique technique. Because this and related graph matching techniques search for valid subsets of the input data, they are, like the Hough transform, robust against noise, occlusion and object distortion [1]. Unfortunately, graph matching per se can be computation intensive, and methods have been described for using the generalised Hough transform to achieve the same end, with far less computation. Details of this approach are presented in ➋ Chap. 18, and will be considered further below.

36.4 Case Study: Jaffacake Inspection

Jaffacakes are examples of food products with high added value, as a significant number of processes are required during their production [10]. In addition, they are enrobed with a substantial layer of chocolate – an expensive commodity. These factors mean that, ideally, each stage of manufacture should be monitored by an inspection system to ensure that further value is not wasted on any defective products. However, inspection systems themselves cost money, both in the necessary hardware and software, and also in the need for careful setting up, calibration, and continual re-validation. In such cases it is usual to employ a single inspection system: there is some advantage from placing this at the end of the line so that the product is given a full check before it finally goes off to the consumer. This was the situation for the Jaffacake inspection system described here. Note, however, that in other applications a different judgement may be made – as in the case of cereal grain inspection (see ➋ Sects. 36.6–36.8), where it is crucial to inspect the raw commodity.

Jaffacakes are round shallow cakes resembling biscuits which are topped by a small quantity of jam before they are enrobed with chocolate (➋ *Fig. 36.1*). Cooling is necessary before packing to ensure that the chocolate has solidified: this also helps the final inspection process as liquid chocolate gives rise to glints which could confuse the inspection software.

Many problems arise with such products. First, the spread of cake mixture depends on temperature and water content, and if this is not monitored carefully the products may turn out too large or too small. While 10% variation in diameter may be acceptable, larger variations could lead to packing machines becoming jammed. Second, the jam or the chocolate could cause products to stick together, again causing problems at the packing stage. These factors mean that a variety of parameters have to be monitored – roundness, product diameter, the

Jaffacake characteristics. (a) shows an idealised Jaffacake on which the boundary of the jam appears as a slanted, darker region. (b) shows its cross section, and (c) shows its radial intensity histogram to the same scale as in (b). (d) shows a less ideal Jaffacake in which some "show-through" of the cake appears, and the surface texture is more fuzzy. © M^{2}VIP 1995

diameter of the spot of jam, the presence of excess chocolate, and any "show-through" (gaps in the chocolate). In addition, the product has to be examined for general appearance, and in particular the textural pattern on the chocolate has to be attractive.

To achieve these aims, the products first have to be located and then suitable appearance matching algorithms have to be applied. In fact, the Hough transform provides an excellent means of locating these round products, and is sufficiently robust not to become confused if several products are stuck together, as all can be positively identified and located. To perform the matching several processes are applied: assessment of product area, assessment of degree of chocolate cover (area of dark chocolate region), computation of radial intensity histogram (This sums and averages the intensities of pixels within concentric rings around the centre of the product [1].) to assess the jam diameter and offset (determined from the region bounded by the very dark ring on the chocolate) and the overall appearance of the product (measured from the radial intensity histogram correlation function) (➲ *Fig. 36.1*).

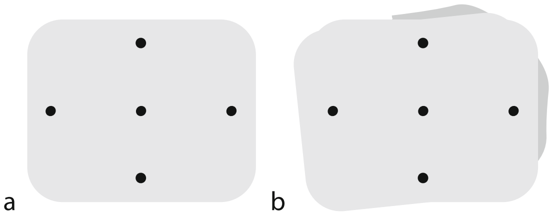
Considerable speed problems were encountered during this work, and special hardware accelerators had to be devised so that inspection could take place to perform 100% inspection at around 20 products/s. Hardware design was eased by making extensive use of summation processes, such as area measurements, computation of radial intensity histograms, and computation of the radial intensity histogram correlation function [10]. Finally, some care was required to obtain uniform lighting: this was achieved by using a set of four lights symmetrically placed around the camera. While lighting did not have to be set critically, because of the robustness of the algorithms used, reasonable uniformity in the lighting was useful to minimise the number of separate measurements that had to be made on each product.

36.5 Case Study: Inspection of Cream Biscuits

This case study describes the inspection of cream biscuits which consist of two wafers of biscuit with cream sandwiched between them (➋ *Fig. 36.2*). There are two particular reasons for inspecting these biscuits: one is to check on the alignment of the two biscuit wafers; the other is to check whether there is substantial leakage of cream from between the wafers. Clearly, both of these aspects have a distinct influence on the appearance of the product and its acceptability to the consumer. They also reflect the possibility of jamming the packing machine.

Conventional shape analysis techniques can be used to check the overall shape of the final product and thus detect these defects. However, the overall shape can be quite complex even if small amounts of misalignment or cream are evident (➋ *Fig. 36.2*). Hence considerable simplification of the overall algorithm results from adopting an alternative strategy – to locate the biscuits by the small "docker" holes on the upper wafer, and then to check the overall shape against a template [1]. In fact, a further simplification is to determine how much of the product lies outside the region of the upper wafer as computed from the positions of the docker holes (➋ *Fig. 36.2*).

To achieve this, it seemed appropriate to employ the maximal clique technique as it is suited to location of objects from point features. While this worked well with biscuits containing up to six docker holes, it was found to be far too slow for biscuits with many holes (in some cases biscuits are decorated with patterns of well over 100 holes) [4]. The reason for this is that the maximal clique computation is "NP-complete," and this results in its having a computational load which varies approximately exponentially with the number of features present. Because of this, other procedures were tried, and it was found that the Hough transform could be used for this purpose. To achieve this, a reference point G was selected on the biscuit pattern (the centre of the biscuit was a suitable point), and all pairs of features located in the image were used to estimate the position of G, the votes being placed in a separate parameter space. This permitted the positions of all biscuits to be found with much the same degree of effectiveness as for circle location. The only problem was that it was not known a priori which was which of the holes in each pair, so two votes had to be cast in parameter space in each case [11]. While this gave a considerable number of false votes, no difficulty was experienced in determining the centre of each biscuit by this method. For further details of the technique, see ➋ Chap. 18.



◘ Fig. 36.2

Problems encountered in inspecting cream biscuits. (a) shows the plan view of an ideal cream biscuit, and (b) shows a less ideal product with misaligned wafers and leakage of cream. The "docker" holes by which the upper wafer can be located are clearly indicated

36.5.1 Problems with Maximal Cliques

The computational problems with the maximal clique approach have been known for some time, though as noted above they were not a particular problem for biscuits with up to six features. However, in this application another problem with the technique was identified. This arose because in the end the technique only makes use of features that are part of the largest available maximal clique: features which are not compatible with all the other features in the maximal clique that is finally taken to represent the object are in the end ignored. Unfortunately, distortions can result in some features not being compatible with a limited number of other features on the same object, while still being compatible with the remainder. In that case some information which is available from these features and which would be useful for interpretation is ignored.

As the method is potentially highly robust, it may still result in the object being recognised. However, when only a small number of features are available on any object, there is little latitude for ignoring any of them and some loss of robustness then results. A further factor is the loss of location accuracy that results from the decrease in position data. In general, then, the maximal clique method does seem to lose out significantly relative to the Hough transform approach when locating distorted objects. Food products are quite variable and are often slightly distorted during manufacture, so they are especially affected by these problems. Specifically, changes in the fluidity of the biscuit mixture may lead to size and shape changes which can push a number of inter-feature distances outside accepted tolerance limits.

Naturally, many distortion problems can be overcome by permitting a certain tolerance in the inter-feature spacings. However, if too much tolerance is permitted, this ultimately results in a large increase in the number of false alarms (whether these are recorded as votes in parameter space or lines in the match graph). Hence in practical situations, with given tolerance levels, the maximal clique approach results in reduced levels of robustness and location accuracy.

36.6 Case Study: Location of Insects in Consignments of Grain

Automated visual inspection has now been applied to a good many food products, and as indicated in ➋ Sect. 36.4, it is often appropriate to apply it at the end of the production process as a final check on quality. Nevertheless, there is a distinct need to attend to the quality of the raw products, such as the grain from which flour, breakfast cereals and many other derived products are made. In the case of grain, attention has so far been concentrated on the determination of grain quality [12], the determination of varietal purity [13, 14] and the location of damaged grains [15]. Relatively little attention has been paid to the detection of contaminants. In fact, there is a need for an inexpensive commercial system which can detect insect infestations and other important contaminants in grain.

This case study describes research which has been orientated towards the design of such a system. Of especial interest is the location of insects amongst the grains, as these have the potential for ruining a large store of grain in relatively few weeks, because of the rather short breeding cycle. This means that a highly reliable method is needed for detecting the insects, involving a far larger sample than human inspectors can manage: in fact, a sample of some 3 kg (∼60,000 grains) for each 30 t lorry load of grain appears to be necessary. As lorries arrive at intervals ranging from 3 to 20 min, depending on the type of grain terminal, this represents a significant challenge from both the effectiveness and the computational speed points of view [16, 17].

Preliminary analysis of the situation suggested that insects would be detected highly efficiently by thresholding techniques, as they appear dark when compared with light brown wheat grains. However, careful tests showed that shadows between the grains and discolorations on them can produce confusing signals, and that further problems can arise with dark rapeseeds, fragments of chaff, and other artefacts (➋ *Fig. 36.3*). This meant that the thresholding approach was non-viable, though further analysis showed that line segment detector algorithms (➋ Sect. 36.3.1) were well adapted to this application because the insects approximated to short rectangular bars. It turned out that high orientation accuracy is not required in this instance, though it is attractive to use just two vectorial masks to save computation.

The next significant problem was to design larger versions of these masks so as to obtain good signal-to-noise ratio at higher resolution with insects about 3 pixels wide. This was achieved with 7 × 7 masks which approximated to rings of pixels, for which about half of each mask would be in the background and half within the insect region. Geometric arguments

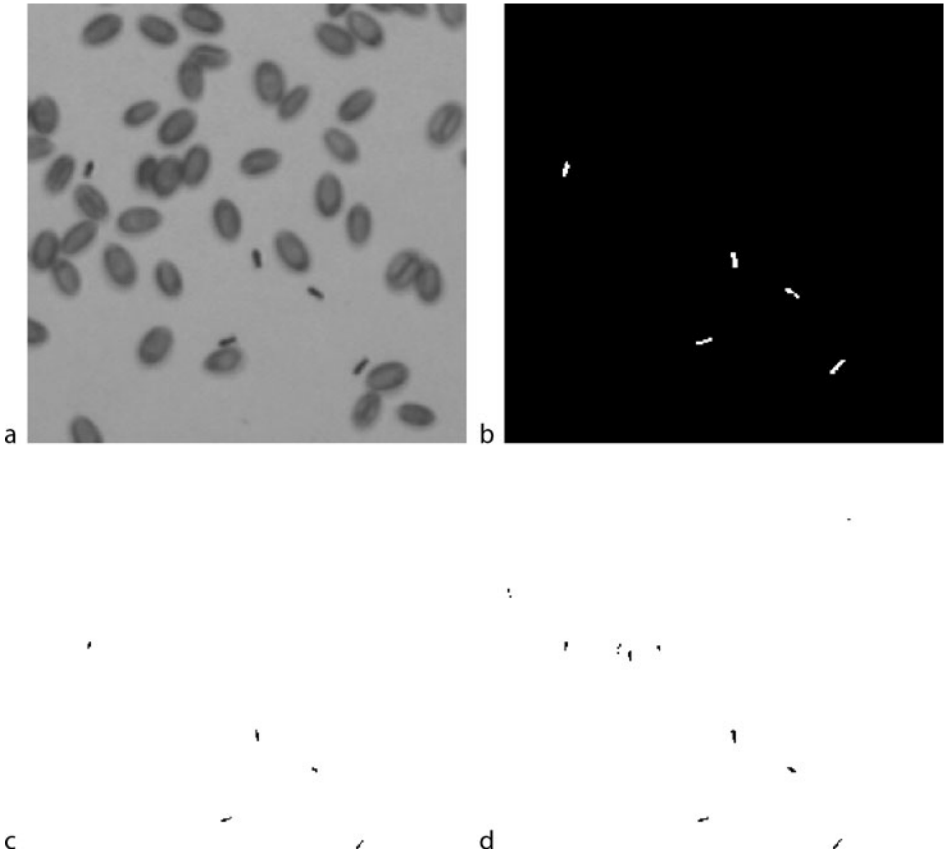


Fig. 36.3

Insects located by line segment detector. (a) Original image. (b) Result of applying line segment detection algorithm. (c) Result of selecting optimum (minimum error) threshold level on (a). (d) Effect of small increase in threshold. © EURASIP 1998

showed that this would be achieved when the mask radius was about $\frac{1}{\sqrt{2}}$ of the width of an insect (➋ *Fig. 36.4*).

Tests showed that the strategy was successful on images containing real grains and insects such as *Oryzaephilus surinamensis* (saw-toothed grain beetle). To perform the final detection, thresholding of the line segment operator signal was required; in addition, a test had to be applied to check that the signal resulted from a dark rather than a light patch in the image, as the line segment detector is sensitive to both. This procedure resulted in a false negative rate of around 1% against a total of 300 insects: minor detection problems arose from insects being viewed end-on or being partly obscured by grains. Another problem was a small false positive rate arising from the dark boundaries on some of the grains and particularly from "black-end-of-grain." Other problems occasionally arose from pieces of chaff resembling insects (➋ *Fig. 36.5*): one solution to this problem would be to increase resolution to improve recognition, though this would give rise to a drop in the processing rate and a faster, more expensive processor would be needed. Such issues are beyond the scope of this case study.

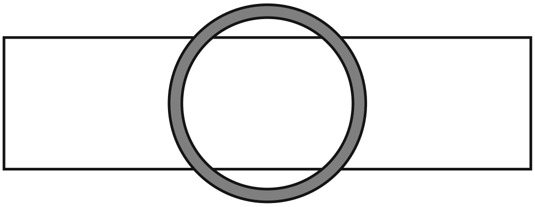

Fig. 36.4
Geometry for design of a line segment detector using ring masks. For optimum results the ring must be symmetrically placed and of such a size that it lies half within and half outside the rectangular object to be detected

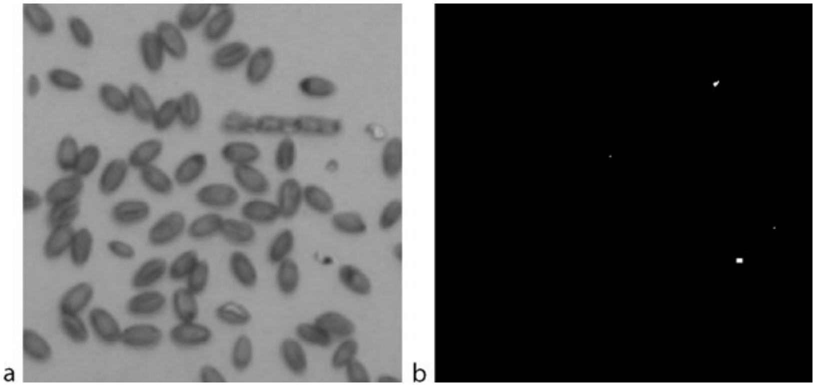

Fig. 36.5
Incidence of false alarms. (a) original image; (b) thresholded output from line segment detector. The false alarms are due to chaff and the darkened boundaries of grains: all are easily detected and eliminated via their shapes. For the specific type of line segment detector used here, see [17]. © IEE 1999

However, the line segment detector approach seems the right one to solve the problems of insect detection; and the vectorial strategy seems capable of limiting computation with the larger masks required in this application [16].

It would be interesting at this point to compare the work described above with that of Zayas and Flinn [18] who adopted a discriminant analysis approach to the insect detection problem. However, their work is targeted primarily at a different type of insect, *Rhyzopertha dominica* (the lesser grain borer beetle) and it would appear to be difficult to make a realistic comparison at present. More generally, the reader is referred to an interesting appraisal of different ways of finding pests in food [19].

36.6.1 Obtaining Improved Capability for Discriminating Insects

While the line segment detector type of approach worked very well, further improvements in any technique are always welcome, and in this case it seemed worth aiming for improvements in the discriminability of insects. In this regard, a template matching (TM) approach seemed to represent the ultimate in capability. However, the whole point of using the vectorial line segment detector approach had been its high efficiency, whereas the TM approach requires a large number of substantial masks for whole-object detection, thereby entailing excessive computation. However, it seemed that it might be possible to employ a two-stage system that would combine the speed of the line segment detector with the accuracy of TM. To achieve this, potential object points were identified using the line segment detector, and then the TM was applied to finally locate the object points. It was found to be important to keep the line segment detector threshold low so that no insect points were eliminated at that stage: the task of eliminating any false positives thus fell squarely on the TM operator. The final result was an error rate exactly matching that of the TM operator, but a considerably reduced overall execution time – composed of the line segment detector execution time plus the TM execution time for the set of regions of interest. One source of error was found to be fragmented insects, but it was found that employing a dilation operation within the line segment detector, before applying the final TM operator, could largely eliminate this problem.

The overall technique gave a welcome improvement in speed of operation – typically by a factor ∼10 – with no loss in accuracy, because a lower line segment detector threshold could be avoided. The technique was also found to be excellent at discriminating insects from dark regions on the grains and reducing the false alarm rate to a negligible level. In fact, it was able not only to detect the insects but also largely to maintain them at the correct size and shape. This was a crucial aspect of the overall inspection system, as the final stage of confirming the presence of insects and identifying artefacts such as chaff, foreign seeds and other items was via shape and size. Thus the overall insect detection scheme is a three-stage algorithm incorporating a binary shape analyser (➲ *Fig. 36.6*). It should perhaps be remarked that a further factor influencing the overall design is the need to be able to detect insects of a variety of sizes, and not just the main target, *O. surinamensis*. Details of how this was achieved will become clear in ➲ Sect. 36.7.

In this work [20, 21], a number of methods for the detection of insects in grain images were tested: their performance is summarised in ➲ *Table 36.1*. On the one hand there are methods based on template matching of whole bars, and variations that are designed to save computation. On the other hand there are methods based on edge detection (see [22]) that deduce or infer the presence of the whole object. In principle, these two approaches are merely different representations of the same underlying task and taken to their individual limits might be

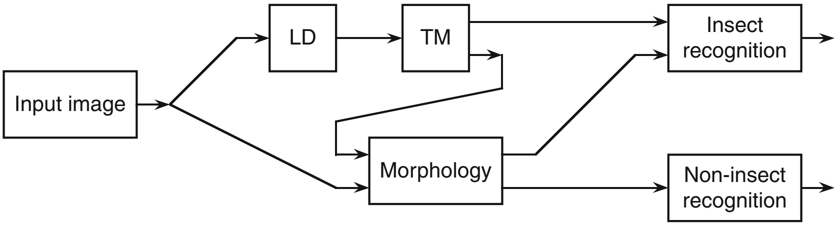

Fig. 36.6
Complete three-stage inspection system. This figure shows how morphology is used both as a component of the insect detection system and for non-insect detection. This aspect is also valuable in providing the capability for detecting larger types of insect. LD is the line segment detection module, and TM is the template matching module. © IMechE 2003

Table 36.1
Performance of the various operators on the grain images

Method	Sensitivity[a]	False alarm performance	Speed
Thresholding	Fair	Very poor: uncompetitive	Extremely high
Vector-based	Good	Good	High
Edge-based	Good	Good	High
TM	Very good	Very good	Very slow
2-stage TM	very good	Very good	Very high
Hough-based	Fair[b]	Poor[b]	Moderately high[b]

[a] Sensitivity means capability for detecting insects: for crucial false-alarm performance see next column

expected to yield the same results. In particular, both approaches in one way or another embody the spatial matched filter paradigm. However, if gross shape distortion or occlusion were to be a crucial factor, a Hough transform approach based on edge detection might prove more sensitive. Nevertheless, as a starting approximation, the Hough transform approach proved to be limited, because the insect profiles are fuzzy, distorted and noisy, and there is significant probability of interference from nearby grains. As a result, edge detectors of low support are needed, and it is difficult to use Hough transform or other methods when objects have fuzzy, ill-defined edges. (The reason for this is that it works on the basis of feature detection followed by inference, while whole-object TM performs all of this in a single integrated process.)

36.7 Case Study: Location of Non-insect Contaminants in Consignments of Grain

As noted above, there is a need for a commercial system for the inspection of consignments of grain. In fact, grain is subject to many contaminants other than insects. In particular, rat and mouse droppings have been reported, and moulds such as ergot are especially worrying as they are toxic to humans. There is also a need to keep a check on foreign seeds such as rape, though their presence is not especially worrying at low concentrations. It turns out that rodent droppings and ergot are dark and have characteristic elongated shapes, while rape seeds are dark and round: all these contaminants are readily detected by human operators. This again suggests that such contaminants could be detected automatically by thresholding. However, rodent droppings are often speckled (➔ *Fig. 36.7*), while ergot is shiny and tends to exhibit highlights, so again it has light patches – albeit for different reasons. There is also the possibility of confusion between the speckled regions and the grainy regions which are light but with a variety of dark patches caused by shadows and some dark patches on the grains themselves [23].

These considerations suggest that morphological techniques [24] should be used to help with detection of the dark contaminants mentioned above. More particularly, as human operators are able to recognise these contaminants from their characteristic shapes and spatial intensity distributions, a suitable combination of morphological operators should be sufficient to achieve the same end.

An obvious way forward is to apply erosion operations to eliminate the shadows around, and dark patches on the grains. These erosion operations should be followed by dilation operations to restore the shapes of the contaminants. While these actions are reasonably effective in eliminating the dark patches around and on the grains, they leave holes in some of the contaminants and thus make it difficult to identify them unambiguously (➔ *Fig. 36.7*).

An alternative approach is to consolidate the contaminants by performing dilation operations followed by erosion operations, but this has the predictable effect of giving significant numbers of false positives in the grain background. Eventually a totally different strategy was adopted – of consolidating the whole image using very large median filters. This procedure is able to virtually eliminate the speckle in the contaminants, and is also successful in not generating many false alarms in the grain regions. However, a certain number of false positives do remain, and it has been found that these can be eliminated by applying additional erosion operations (➔ *Fig. 36.7*).

Once good segmentation of the contaminants has been achieved in this way, with good preservation of their original shapes, recognition becomes relatively straightforward. Perhaps the main disadvantage of the method is the need to apply a large median filter. However, many methods are known for speeding up median operations, and this is not especially problematic. In addition, it could be argued that the methods described here constitute a form of texture analysis, and that there are many alternative ways of tackling this type of problem. However, texture analysis also tends to be computation intensive, and a considerably larger number of operations would be needed to segment the contaminants in this way. Overall, the approach adopted here seems to have the advantages of simplicity, effectiveness and also to be sufficiently rapid for the task. Perhaps the important lesson to be learnt from this case study is that the usual types of morphological operator are not as powerful as is commonly thought, so they have to be augmented by other techniques if optimal solutions are to be found [23].

Finally, an added bonus is that this final algorithm was found to be capable of locating large insects as well as non-insect contaminants. This is reflected in the overall system design (➔ *Fig. 36.6*).

36.7.1 Problems with Closing

The above case study was found to require the use of a median filter coupled with a final erosion operation to eliminate artefacts in the background. An earlier test similarly involved a closing

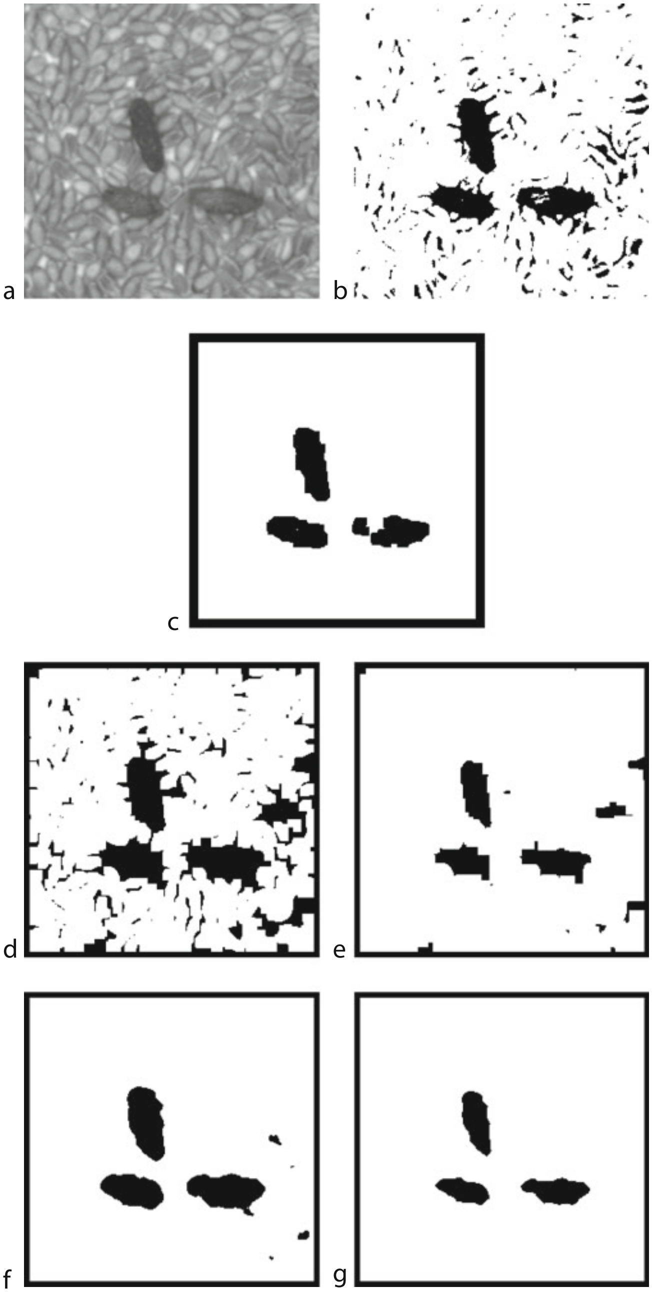

Fig. 36.7

Effects of various operations and filters on a grain image. (a) Grain image containing several contaminants (rodent droppings); (b) thresholded version of (a); (c) result of erosion and dilation on (b); (d) result of dilation and erosion on (b); (e) result of erosion on (d); (f) result of applying 11 × 11 median filter to (b); (g) result of erosion on (f). In all cases, ''erosion'' means three applications of the basic 3 × 3 erosion operator, and similarly for ''dilation.'' © IEE 1998

operation (a dilation followed by an erosion) followed by a final erosion. In other applications, grains or other small particles are often grouped by applying a closing operation to locate the regions where the particles are situated. It is interesting to speculate whether, in the latter type of approach, closing should sometimes be followed by erosion, and also whether the final erosions used in our tests on grain were no more than ad hoc procedures or whether they were vital to achieve the defined goal.

To analyse the situation, we consider two regions containing small particles with occurrence densities ρ_1, ρ_2, where $\rho_1 > \rho_2$ [25]. Clearly, the mean distances d_1, d_2 between particles will depend on the occurrence densities. Dilation will tend to group the particles, but the real aim is to dilate sufficiently to group the particles in region 1 but not those in region 2 (➋ *Fig. 36.8*). Assuming that this is possible, a subsequent erosion should give a good approximation to region 1. However, if any region 2 particles are near the boundary of region 1, they will be enveloped by region 1, which will then become too large, and a subsequent erosion will be needed to restore region 1 to its proper size and shape. The shift δ can be calculated on the basis that it is essentially a one-dimensional effect. However, corrections need to be applied as the particle density in the second dimension in region 2 is not unity and produces a reduction relative to the one-dimensional shift. The final result is:

$$\delta_{2D} = 2ab\rho_2(a + b) \qquad (36.10)$$

where a is the radius of the dilation kernel and b is the width of the particles in region 2. It is important to notice that if $b = 0$, no shift will occur, but for particles of measurable size this is not so. Clearly, if b is comparable to a or if a is much greater than 1, a substantial final erosion may be required. On the other hand, if b is small, it is possible that the two-dimensional shift will be less than 1 pixel. In that case it will not be correctable by a subsequent erosion, though it should be borne in mind that a shift has occurred, and any corrections relating to the size of

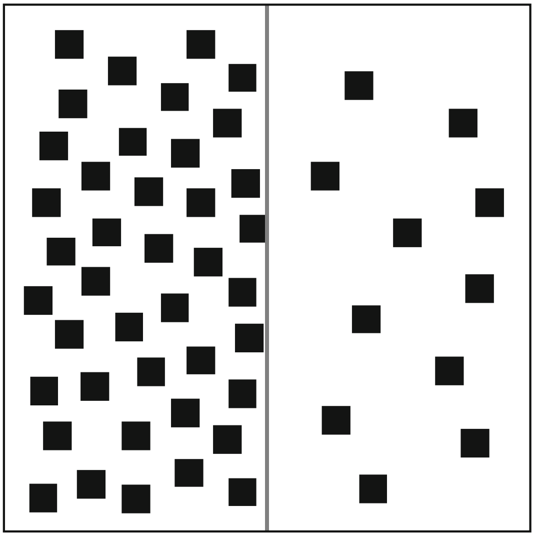

Fig. 36.8

Model of the incidence of particles in two regions. Region 2 has sufficiently low density that the dilated particles will not touch or overlap. © IEE 2000

region 1 can be made during subsequent analysis. While in our work the background artefacts were induced mainly by shadows around and between grains, in other cases impulse noise or light background texture could give similar effects, and care must be taken to select a morphological process which limits any overall shifts in region boundaries. In addition, it should be noticed that the whole process can be modelled and the extent of any necessary final erosion estimated accurately. More particularly, the final erosion is a necessary measure, and is not merely an ad hoc procedure [25].

36.8 Case Study: High Speed Grain Location

It has already been noted that object location can be significantly more computation intensive than the scrutiny phase of inspection, as it involves unconstrained search over the entire image area, and sometimes over several images. This means that careful attention to high speed object location procedures can be extremely useful. Of course, hardware accelerators can be designed to bring about any required improvement in speed, but if inspection systems are to be cost-effective, rapidly operating software is required.

In his earlier work on biscuit inspection (see the Jaffacake case study in ➋ Sect. 36.4 for the general milieu), the author solved this problem by scanning the image along a restricted number of horizontal lines in the image, and taking the mid-points of chords across objects [26]. Suitable averaging in the x and y-directions then permitted the centres of circular objects to be located highly efficiently, with speedup factors as high as 25. While some loss in robustness and accuracy occurred with this approach, performance degraded gracefully and predictably.

In the cereal grain inspection problem, even higher speedup factors were required, and an even faster type of algorithm was required. The only way of obtaining further substantial improvements in speed appeared to be to concentrate on the object regions rather than on their boundaries. Accordingly, a sampling technique was developed which sampled the whole image in a regular square lattice of spacing s pixels. This provided an intrinsic speedup of s^2 coupled with a loss in accuracy by the same factor [27].

Not surprisingly, the technique has significant limitations. In particular, the ideal saving in computation only occurs for square objects with their sides orientated parallel to the image axes. However, if a square object lies at 45° to the image axes it can miss all the sampling points, with the result that the latter must be placed $\sqrt{2}$ times closer together than the ideal to ensure intersecting the objects (➋ *Fig. 36.9*). Similarly, circular objects can miss the sampling points unless their spacing is $\sqrt{2}$ times the circle radius.

To properly understand the sampling process it is necessary to imagine the image space being tiled with shapes identical to those to be located. For simple shapes such as squares, the tiling can be perfect, but for other shapes such as circles, the image space will not be entirely covered without expanding the tiles so that they overlap – thus making the sampling procedure less efficient than the supposed ideal. In fact the situation is even worse when the varying orientations of real objects are taken into account: i.e., a greater number of tiles has to be used to cover the whole image space, and thus an increased number of sampling points is needed; a full explanation appears in [4, 28]. However, although the ideal is not achievable, the results can still be extremely useful, at least for convex objects, and impressive speedup factors can be obtained.

Another limitation of the technique is that accuracy of location is necessarily limited. However, this problem can be overcome once an object's approximate position has been found by sampling. At worst, a region of interest can be set up: within this region a conventional

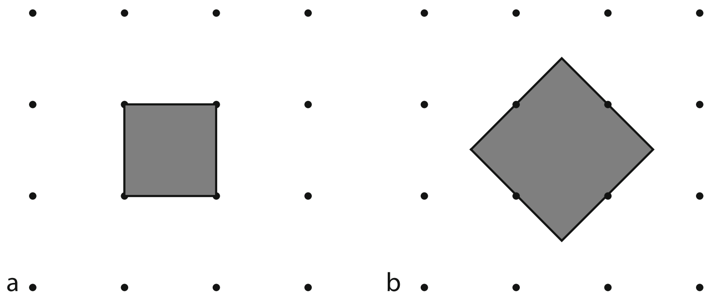

Fig. 36.9
Sampling points for location of *square objects*. (a) shows the spacing of sampling points for locating square objects aligned parallel to the image axes. (b) shows the reduced spacing required for square objects aligned at 45° to the image axes

object location method can be applied, and the object can be located with the usual accuracy. An overall gain in speed results because large tracts of image space are quickly by-passed by the sampling procedure. Interestingly, there is the possibility of finding an accurate location technique whose speed matches that of the sampling procedure. For circles and ellipses the *triple bisection* algorithm operates extremely rapidly: it has some resemblance to the earlier chord bisection strategy, but requires the location and bisection of only three chords of the object. For further details of the algorithm, see ➋ Chap. 18.

The technique has been applied to the location of peppercorns, which are approximately circular, and wheat grains, which are approximately elliptical with an aspect ratio of about 2:1. The method is highly efficient when used to detect circles, as is evidenced by the fact that ideally only one or two sampling points intersect with each object. For elliptical wheat grains, the method is rather less efficient and in the ideal case, up to three sampling points may appear in each object, though the average is close to two (➋ *Fig. 36.10*).

Overall, the technique works well, and saves considerable computation, but only if the objects are well separated. However, alternative procedures can be devised for accurately locating the centres of objects when these are in contact: the basic sampling procedure does not fail in such cases: it is merely more difficult to find accompanying procedures for accurate location whose speed matches that of the basic sampling technique.

36.9 Case Study: Detection of Insect Larvae Growing Within Grain Kernels

The previous three case studies on cereal grain inspection were fairly standard in using normal visible light. The next case study employed near-infrared (NIR) imaging to assess the possibility that insect larvae are growing inside grain kernels. This is important because a batch of grain may appear uninfested, yet after a few weeks insect offspring can emerge from the grain kernels. The strategy adopted to achieve this was aimed not at detecting the heat emitted by the insect larvae, but at observing the change in infrared emission from grains in which starch is becoming depleted, and in which the water content is changing as a result of feeding and

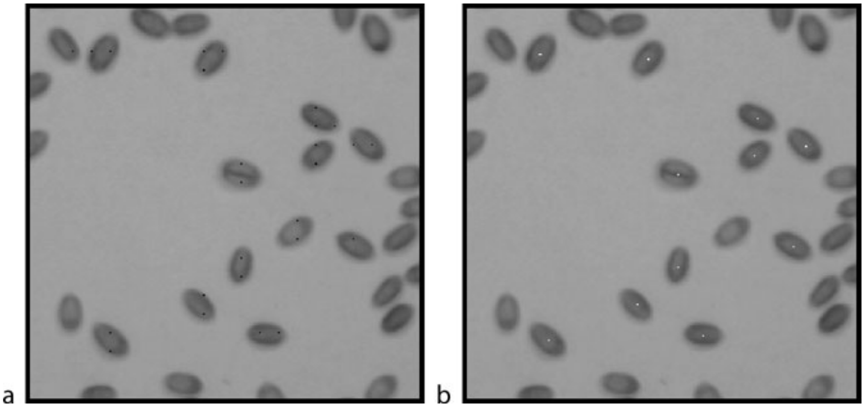

Fig. 36.10
Image showing grain location using the sampling technique. (a) sampling points; (b) final centre locations. © EURASIP 1998

excretion. The relevant spectroscopic lines are around 980 and 1,200 nm [29, 30], though the former offered a better prospect for application of machine vision, as CCD sensors have much greater sensitivity in this region of the spectrum. It should also be remarked that while X-rays offer the possibility of inspecting cereal grains for internal insect infestation, a machine vision system working in the NIR region of the spectrum would offer major advantages in terms of hardware cost, simplicity and safety [31]. In particular, the system would be far lighter and more convenient than an X-ray system, as the heavy shielding needed in the latter case could be dispensed with [4].

Preliminary tests using human inspectors indicated that infested kernels could sometimes be detected on the NIR images (➲ *Fig. 36.11*) by the presence of characteristic bright patches, which are generally absent from the uninfested grains. A variety of machine vision methods was used in attempts to detect the insects via these patches. Notably, initial trials of global and adaptive thresholding led to little success. Attempts were then made to normalise the grain images, to bring them to a standard shape and intensity profile, so that inter-grain variation would be cancelled out and detection would be facilitated. In that case each grain kernel would be compared with a normalised "average" grain kernel. However, all these procedures proved fruitless, ultimately because the inter-grain variation was far too large. Hence a novel approach was adopted – of comparing each grain with a normalised version of itself. This meant (1) filtering the grain images to eliminate any bright patches, and (2) subtracting any grain image from its self-normalised version to reveal the bright patches.

Many morphological erosion techniques were tried, with the aim of achieving the required grain normalisation, but most proved inadequate for this particular application. Perhaps oddly (considering that it had been presumed from the NIR images that only bright patches on the grains needed to be detected), it was found that the best type of filter was one using a centre-seeking statistic, such as the mean or median, which has no potential preference for either bright or dark patches on the grains. The reason this approach worked appeared to be because of the much superior noise suppression capabilities of these types of filter which proved capable of giving a robust well-defined level for comparison, thereby favouring bright patch

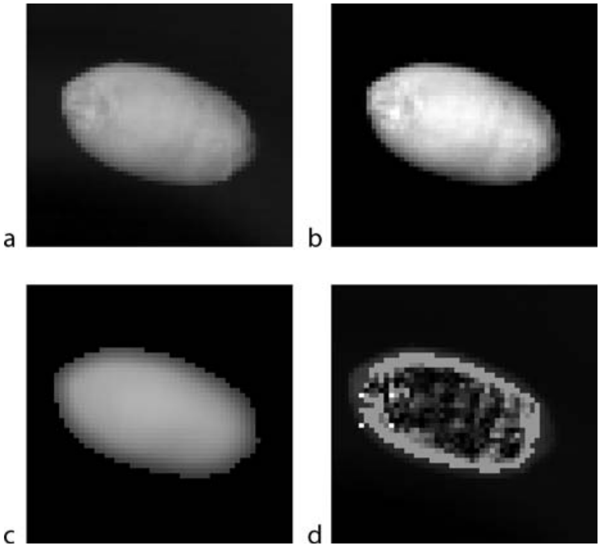

Fig. 36.11
Results for an infested kernel. (a) original NIR image; (b) enhanced version of (a); (c) model derived from (a); (d) difference image after masking: the brightest patch is highlighted with four dots. © IEE 2003

detection. Contrariwise, the reason that a minimum intensity filter did not work well was probably because it produced such an extreme reference that bright or other patches could not be compared with the reference with sufficient reliability. Overall, the median-based reference was distinctly better than the mean type of reference.

Following these strategic observations and decisions, more detailed experiments were undertaken to optimise the effectiveness of the bright patch detector. In particular, it was found that the grain kernels needed to be masked to exclude the outermost regions where there was little useful information for insect detection, and the optimum size and shape of the mask was determined (➲ *Fig. 36.11*). Other optimisations included (1) finding the most suitable size of the bright patch detection window; (2) determining the most appropriate thresholdable indicator of infestation; (3) estimating the optimum size and shape of the initial median filtering grain normalisation procedure; and (4) finding how to correct for the shape distortions produced by the median filtering procedure. The overall algorithm is shown in ➲ *Table 36.2*. ➲ *Figure 36.11* shows the difficulty of seeing anything by eye in the NIR images: note that the "bright patches" have to be enhanced to improve visibility.

In the majority of food inspection applications, it is normal to err on the side of rejection. However, this may not be the best way of dealing with large consignments of grain. In fact, it is better to err on the side of reducing the number of false positives (FPs), so that when the rejected grains are examined, they will be seen to be the ones containing insects. This could help to justify the rejection of any particular consignment (in general, consignments of grain are at least 30 t in weight).

These considerations make it necessary to examine the receiver operating characteristic (ROC). In many works the ROC curve is defined as the graph of true positives (TPs) against

Table 36.2
Stages of the basic insect detection scheme

1. Apply smoothing filter to model grain profile
2. Apply filter correction procedure
3. Apply subtraction procedure to reveal patches
4. Apply mask to locate relevant part of grain
5. Apply patch detection template
6. Apply threshold

Note: these stages ignore the need for setup, training and overall control of the system. In all, nine parameters had to be adjusted for optimal operation and the final threshold set by training on sample data. © IEE 2003

FPs, but here we define it as the graph of FPs against false negatives (FNs); the reason for this is to emphasise that we need to obtain an optimum balance between two undesirable quantities, which is often achieved by making them about equal. In this case, curve-fitting showed that both wings of the characteristic approximated closely to exponential form. As indicated above, the relevant wing is the one with low FP values, and this is shown on a logarithmic scale in *Fig. 36.12*. Notice that the errors increase towards the low FP end, but the fit is actually within one sample error throughout the whole range. Accurate modelling of the ROC characteristic is advantageous as it permits the curve to be scaled to cope with variations in the proportions of infested and uninfested grain kernels. Next, to achieve an optimum balance between FPs and FNs, the solution was taken to be given by the formula:

$$N_{\mathrm{FP}} = nN_{\mathrm{TP}} \tag{36.11}$$

in which we are aiming to minimise the parameter n. Noting that:

$$N_{\mathrm{TP}} + N_{\mathrm{FN}} = I \tag{36.12}$$

where I is the number of infested grains in the total number of grains T, we find:

$$N_{\mathrm{FP}}/n = I - N_{\mathrm{FN}} \tag{36.13}$$

To obtain a valid solution, this straight line has to intersect the ROC curve, and for an optimum solution (with minimum n) it has to be a tangent (*Fig. 36.13*): this follows as a tangent represents an extremum. Finding the tangent uniquely defines n in those cases where a solution exists.

In the experimental tests, the classification accuracy for individual grains was found to be around 80–85% for samples containing ~150 grains and 50% infestation: while this accuracy is not very much higher than the best achieved by human inspectors, the vision approach is naturally far more consistent and also is conducive to absolute measurement. The ROC-based analysis presented above was needed to estimate how to extrapolate the experimental results to situations where the infestation rate is far lower than 50%, e.g., 1% or less. Also, while the above classification accuracy applies to individual grains, analysis (based on the reduced probability of entirely missing infestation when there are a number of infested grains) indicated that batch infestation will be detectable with considerably greater accuracy – around 95% for a 1% infestation level. This is high enough to be practically useful, and also much less costly and more convenient than the obvious alternative of X-ray imaging, though further assessment is needed with larger numbers of images than were available in this study [32, 33].

Obtaining an optimal working point on the ROC curve. Valid solutions occur when the straight line (Eq. 36.13) intersects the ROC curve: for an optimum solution, the *straight line* has to be a tangent

36.10 Concluding Remarks

This chapter has described a number of case studies relating to the location of objects in images containing food and cereals. These have ranged from location of Jaffacakes, cream biscuits and cereal grains to location of insects, rodent droppings, moulds and foreign seeds amongst the cereal grains. In all cases the aim has been inspection, though in the first three of these cases the inspected objects had to be scrutinised for defects, whereas in the other cases the main commodity, cereal grains, had to be scrutinised for contaminants.

It is worth remarking that the reason for the emphasis on object location is that this is often, as in all these cases, the most computation-intensive part of the inspection task. Scrutiny itself takes a fraction of the computational effort taken by object location – even when this is carried out by feature detection followed by inference of the presence of the whole object. In fact, the problem of efficient object location for real-time implementation is so serious that in applications related to the Jaffacake inspection task it was necessary to develop an especially fast line-sampling technique. In the later cereal grain inspection problem an even faster technique had to be developed, based this time on a fast point-sampling method. Though sampling was not performed in the other case studies, very careful attention nevertheless had to be paid to achieving high speeds.

In the cases studied, the reasons for inspection ranged from ensuring that the products were the right size and shape – especially with reference to the need to ensure that packing machines are not jammed – and that the products were attractive in appearance. While this criterion obviously benefits the consumer, it also reflects the quantity of product that can be sold and the profit that can be made. However, there are other reasons for checking that products have a normal attractive appearance: specifically, there is then significantly reduced likelihood of foreign objects having alighted on or having been mixed into the product. With raw materials such as cereal grains, the possibility of contaminants is significantly higher. Indeed, cereal grains start their lives on the land, and are thus liable to be contaminated by mud, stones, twigs, insects, droppings, chaff, dust, and foreign grains. In addition, they are susceptible to moulds, sprouting and physical damage. Thus there are distinct health and safety aspects to the inspection task – the more so as certain moulds such as ergot are poisonous to humans. These factors make it all the more essential to inspect consignments of grain for insect infestations and excessive amounts of non-insect contaminants. This would seem to constitute sufficient reason for including these particular case studies in this chapter.

From the academic point of view, these case studies are mere vehicles for the exploration of the problems of inspection, and in the wider field, of machine vision. The similarities between the methods used to search for objects and their features vary very little from topic to topic in machine vision: there are distinct transferable skills and techniques between a good many of them. This point is illustrated by the theoretical sections of the chapter, which help to bridge the gaps between the case studies and to extend the area of application of the ideas they embody far more widely. In particular, it has been shown how speed can be optimised, how problems with matching algorithms (particularly the paradigm maximal clique technique) can arise and be by-passed, how an apparently ad hoc solution to a morphological technique (closing) can be rigorously solved, and how template matching masks can be designed to optimise signal-to-noise ratio and to prevent over-exposure to impulse noise or small amounts of occlusion.

In an ideal world it would be possible to design vision algorithms on paper, starting from careful specifications, but the present reality is that the situation is too complex and such specifications are seldom available, and in many application areas such as food the data images are too variegated and variable to permit us even to approach the ideal. In such circumstances case studies have to be the main route forward, though on occasion this route can be bolstered up and its elements bound more firmly together by theoretical analysis. It is hoped that this chapter will help show the way forward, and firmly demonstrate, with the other chapters in this volume, the enormous value of the case study approach. The reader will also find useful techniques and case studies in [1–3, 34–36].

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_37,

Abstract: The development of a machine vision system for automated high-speed produce grading is described. Image processing techniques were used to obtain an estimate of the volume of each item, which was then related to the weight through a closed-loop calibration. Accurate weight estimation led to more accurate and better control over the spread of package weights. This reduced the average package weight by approximately 20%, with a standard deviation of 2.5 g for a nominal 100 g package. Improved processing efficiencies doubled the throughput and significantly increased the profitability of the packinghouse.

37.1 Introduction

It is usual to sell produce (fruit and vegetables) by weight. When sold in a supermarket, the produce often is prepacked into fixed weight packages. This introduces three criteria on the packing process. First, all of the items within a package should be approximately the same size. A uniformity of size is not only aesthetically appealing, but when the produce is cooked it ensures that all of the items will have the same cooking time. A second, legal, requirement is that there should not be less than the stated weight within the package. There may be an allowance for a small percentage of packages to be slightly underweight, depending on the jurisdiction. The third criterion is that the grower or packinghouse will not want to significantly exceed the stated weight because this is effectively giving away produce.

When each item is a small fraction of the total package weight, and either the items or the packages can be weighed while packing, these criteria can be achieved readily, without giving away much produce. With small package sizes, where each package contains only a few items, the variability in package weight can be significant. The need for a uniform item size results in the weights being quantised. Unfortunately, most produce does not grow in discrete weights or sizes, but has a continuous distribution. The packing process therefore consists of weighing each item to assign it to a size grade, and then distributing the items within a size grade over several packages to achieve the weight criteria.

A packinghouse must maintain a high throughput to be profitable. Grading is usually a bottleneck in this process, so it is desirable to minimize the time spent on each individual item. Commonly, each item is weighed by passing it over a load cell. The load cell, which is effectively a very stiff spring, deflects slightly because of the weight of the item. A strain gauge converts this deflection into an electrical signal, which is then amplified and digitised to give the weight. The vibration and bouncing of the produce as it deflects the load cell combined with the intrinsic settling time of the load cell provide an upper bound to the throughput of the complete grading system.

Because a load cell is just a spring, when the load changes it will tend to oscillate. The time that it takes these oscillations to decay is the settling time of the load cell. A typical load cell has a settling time of 2–3 s, which is excessive in a high-speed grading application. The settling time can be reduced by damping the oscillations, either passively or actively. Commercially available damped load cells can reduce the settling time to about 100–200 ms, although such high-speed load cells are very expensive. When the target throughput exceeds ten items per second, physically weighing the individual items is very expensive and impractical.

To overcome these problems, size-based grading is often used as a substitute for weighing each item. An accurate estimate of the weight from the size requires the density to be constant, which is often the case. Any variations in the density will increase the uncertainty in the weight estimation, and the average package weight must increase to ensure that the minimum weight criterion is met.

For items that are approximately spherical, mechanical screens provide a fast and effective method of size grading. Each screen usually consists of a mesh with certain hole size. When the mesh is vibrated, any items that are smaller than the holes will fall through the mesh, while those larger than the mesh size remain on top. By having a series of meshes, the items can be sorted into several size categories. This approach is generally unsuitable for produce grading because it relies on mechanical jostling and this may bruise or damage some items. It is also unsuitable for items that are long and thin, because the size of each item then depends significantly on its orientation.

Machine vision can provide a viable alternative to mechanical weighing systems. One or more images are captured of each item (or part of each item). From each image, the object is segmented from the background to derive information on the object's shape. An image only provides a two-dimensional projection of the three-dimensional object so it is necessary to make assumptions about the shape of the object in the third dimension. These assumptions are usually embodied in a three-dimensional model, with the data derived from each image used to adjust the parameters of this model to match the view. The volume, hence the weight, can then be estimated from the model.

37.2 Application Details

We were approached by a packinghouse that was grading asparagus for export. They wanted to upgrade their existing grading line with a view to automating some of the packing process. Asparagus is quite perishable once harvested, with a storage life of less than 3 weeks [14], so it is necessary to have the produce on the shelves for sale as fast as possible. The steps within this process are as follows.

The asparagus is harvested manually in the field, often using migrant labour. They first select the spears that are sufficiently long and then cut these with a sharp knife just below ground level. Those that are too short are left to continue growing to be harvested later. Removing the spears stimulates the tuber to send out more shoots. This cannot continue indefinitely as the tuber only has limited energy reserves, so the harvesting season is usually quite short, typically 2–3 months. The harvested asparagus is placed in bins, which are regularly collected and taken to the packinghouse for packing. In the packinghouse, the bins are emptied into a water bath to wash any soil and sand from the harvested shoots. After the water bath, the produce is loaded onto a conveyor for grading. The conveyor consists of a chain of V-shaped cups which singulate the spears as shown in ➋ *Fig. 37.1*. The conveyor runs at a constant speed, which can be adjusted from 0 to 30 cups per second. A belt aligns the tips of the spears before a blade trims them to a uniform length, removing the field cut. The spear is then graded, with the result used to direct the spear down a particular chute. When the appropriate quantity has been collected by a chute it is released as a bundle to be packaged. Each bundle is banded and taped before being packed into small wooden crates (➋ *Fig. 37.1*). Wooden crates provide rigidity, protecting the produce during shipping. The produce is then heat-treated to prolong the shelf life by passing the crates through a tepid water bath for a predefined time, followed by rapid cooling using chilled air. Finally, the produce is exported to its destination by air-freight. The total time from harvesting to arriving in the country of destination is typically 24–36 h.

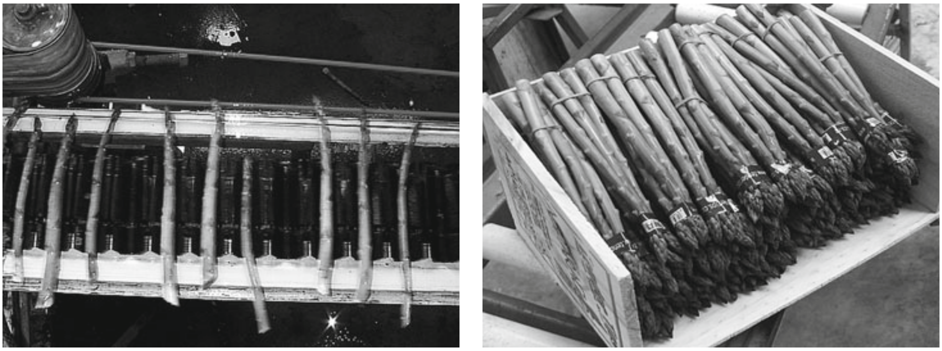

Fig. 37.1
***Left*: produce singulated onto the conveyor. *Right*: packaged produce in a wooden crate**

The throughput of the packinghouse is limited by the grading speed. The individual spears vary in weight between 5 and 50 g. These are to be packaged into 100 g bundles. Each bundle should contain between three and seven similarly sized items, with the very large and very small items rejected. Such a wide weight range per item, and a small item count per bundle, requires that each spear be weighed so that it may be allocated to an appropriate bundle.

37.2.1 Previous Grading System

When the grading line was first set up, size, resolution, and speed constraints meant that it was impractical to measure the whole spear. Each spear is approximately cylindrical, and the length is known (each item has been trimmed to the same length prior to grading) so a single diameter measurement was made at the base of each spear and used as a proxy for the weight. The camera was free-running with the aperture held open. As each cup passed the camera, it triggered a solid-state flash unit to effectively freeze the motion of the conveyer. The next frame after the flash was triggered contained the image of the cup and spear. Since each spear extended past the end of the cup, the produce was measured at the base where it appeared against a black background, enabling a simple global threshold to be used for segmentation. The diameter was estimated by measuring the area of the object within the field of view, which corresponded to a fixed length along the spear. Calibration then associated a range of diameters to each produce weight class.

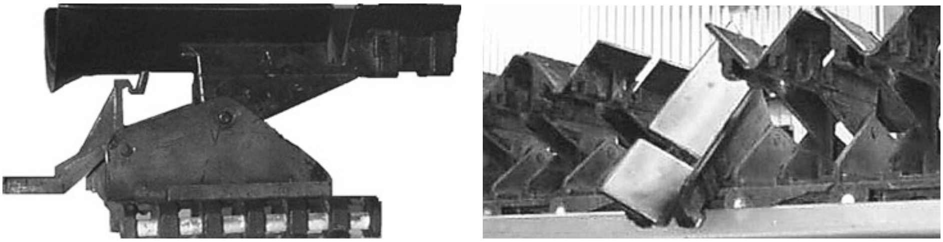
The system was calibrated in an ad hoc manner, through experience. Small adjustments were made to the diameter thresholds until there were fewer than the allowed number of underweight bundles. Unfortunately, the thresholds could not just be set once and left. Subtle changes in the shape and density of the produce during the season meant that the thresholds had to be adjusted slightly from day to day.

Unfortunately, there were several problems with the previous system. The biggest of these was the very wide spread of weight in each package. The primary cause of this was the fact that the whole spear was not imaged, and the single diameter measurement was not a very accurate predictor of the weight. The aspect ratio of a spear is such that to obtain an image across its complete length, the resolution in measuring the diameter is significantly reduced. This, combined with the greater processing power required to segment the spear from the conveyor system, led to unavoidable compromises being made in the original system design. The weight was not actually being estimated but instead the produce was separated into classes based on spear diameter at the butt. This resulted in a very wide spread in package weight. To avoid underselling, the packages had to be significantly overweight on average. This combination of factors meant that the packages assembled by the previous system were 20–30% overweight on average. Consequently, the packinghouse was effectively giving away 20–30% of the produce.

A second problem with the previous system was the limited throughput. The grading system was not only inaccurate, but it was also slow with a maximum processing speed of eight cups per second. The constraint here was the limited processing power available at the time that the system was developed.

A third problem was an actuation issue. The cups on the conveyor are mounted with an offset hinge (this is shown in ❯ *Fig. 37.2*). They are held in their normal position by a small latch with a protruding tag containing a soft iron armature. When a cup containing a spear reaches the desired chute, a solenoid is activated which pulls on the tag, releasing the latch. The cup then tips, dropping its contents down the chute. The solenoid must be activated precisely as the cup is travelling past. Since the conveyor speed can be adjusted, using a fixed time delay to account for the distance between the camera and the solenoid is not practical. The system counted cups as they passed the camera, and used the known constant spacing between the cups to determine the location of each cup. The distance (in cups) between the grading point to the release point for each chute is known enabling the solenoid to be activated at the correct time.

This worked fine, most of the time. Unfortunately, the cup spacing changed slightly as a result of both belt wear and temperature. The grading line was over 10 m long, and with a cup pitch of 5 cm a 0.5% change in belt length was sufficient to trigger the wrong cup at the end of the line. While this is a large change, the belt did stretch by this amount over the course of one or two seasons. A significantly smaller change was sufficient to give unreliable triggering. Consequently, as the packinghouse, and conveyor belt, warmed up during the day, the triggering mechanism began to fail. This necessitated stopping the grading line while the solenoid positions were manually adjusted so they would trigger reliably again. Such adjustment was needed once, and sometimes twice, on most days. While the adjustment only took about 10 min, grading was halted during this time.



■ Fig. 37.2
Cup showing release mechanism, and the cup in the released position (Reproduced from [10], used with permission)

37.2.2 Replacement Grading System

The goal of the project was to significantly improve the profitability of the packinghouse by reducing the average weight of each package and increasing the grading throughput. A secondary goal was to increase productivity by increasing the throughput, and reduce the amount of manual labour required as part of the grading process. This can result in a significant return on the investment in developing the grading system [5].

The legal requirement of maintaining the minimum weight implied that it was necessary to obtain a better estimate of the weight of each spear. This would be accomplished through more sophisticated image analysis techniques. A more accurate weight estimate would then allow more effective grading and package allocation strategies to be devised. The target was to reduce the spread in package weight such that the average package weight could be reduced to 105 g.

A target throughput of up to 15 spears per second was set. This speed makes standard weighing techniques prohibitively expensive, although a new measurement method based on the impact on load cells was investigated [7,8]. This technique used digital signal processing to cancel the resonant response of the load cell, and potentially enabled a standard load cell to make up to 20 measurements per second. However, the mechanical handling difficulties of bouncing spears off a load cell at this rate without collision made this technique impractical in this application.

This left image analysis methods to estimate the weight indirectly from the volume. The target throughput imposes a maximum processing time of 65 ms for each spear. This very tight time constraint limited the type of image processing operations that could be applied to the images. The initial design of the replacement system was documented in [4].

For practical reasons, the grading line had to maintain the same structure as the existing mechanical system. The produce was still loaded onto V-shaped cups and trimmed using the same mechanisms. The previous vision system was replaced with a new design based on imaging the complete spear. As the cup release mechanism was unchanged, it was necessary to develop a new approach to overcome the problems of belt stretching. Changes were made to the chute design to reduce the time between completing a bundle, and starting a new bundle. This was a first step within a larger project of automating the packaging of the produce. The redesign of the chutes and subsequent packaging technologies are beyond the scope of this chapter.

37.3 Modelling

Image processing techniques cannot directly measure the weight, or even volume of an object. Therefore, it is necessary to develop a model that relates data that can be measured to the weight. Some prior work has been carried out on 3D modelling of asparagus [11], although the focus there was estimating the surface area of the spears for calculating heat and mass transfer during post harvest processing. In contrast with this, the work in this chapter requires estimating the weight of each spear.

37.3.1 Verification of Constant Density

The closest that image processing can come to measuring weight is to estimate the volume of an object. This requires that the density of the produce is approximately uniform throughout the volume, and that the density varies little between items. Any variations at this stage will limit the accuracy with which the weight may be estimated, and consequently whether or not the target package rate could be practically achieved. Therefore, the first step before starting the project was to check that the project was not destined to failure.

A sample of about 100 spears was collected from over the full range of sizes to be graded. Each spear was weighed using precision scales. The volume was measured by immersing each spear in a measuring cylinder containing water, and the volume determined from the difference in water level before and after the spear was added. Although the density did vary slightly with spear size, it was possible to estimate the weight from the volume alone to within 1% accuracy.

This verified that estimating the volume of each item provided a viable alternative to actually weighing the items.

37.3.2 Volume Estimation

As each spear is approximately cylindrical, an obvious model is a generalised cylinder. An image of the spear provides a projection of the cylinder from which the volume is to be estimated. The volume of a generalised cylinder can be calculated by integrating the cross-sectional area as a function of the length

$$V = \int A(x)\mathrm{d}x \tag{37.1}$$

However, the cross-sectional area cannot be obtained from a projection. Referring to ➋ *Fig. 37.3*, the diameter, D, can be measured as a function of length, and assuming a circular cross-section the volume from ➋ Eq. 37.1 becomes

$$V = \frac{\pi}{4}\int D^2(x)\mathrm{d}x \tag{37.2}$$

When processing images, this calculation may be simplified by aligning the horizontal axis of the camera with the spear and ensuring that the camera line of sight is perpendicular to the spear. The diameter can then be measured by counting pixels within each column of the image within the spear, D_x. The discrete version of ➋ Eq. 37.2 is then

$$V \propto \sum_x D_x^2 \tag{37.3}$$

where the constant of proportionality depends on the size of each pixel and is determined through fitting the calculated result to the known volume. Estimating the volume from a single projection was only accurate to within 10%. Therefore, while such a model would enable more

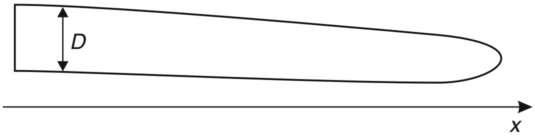


Fig. 37.3

The projection of a spear (Reproduced from [3], used with permission). Measuring the diameter as a function of length allows the volume to be estimated

accurate weight estimation than previous system, it is not sufficiently accurate to meet the target performance. Clearly, the assumption of circular cross-section is limiting the accuracy of this initial model.

To estimate the volume more accurately, it is necessary to take into consideration the eccentricity of the cross-section of each spear. A separate image was therefore captured of the end of each spear at the same resolution as the original image. From this the cross-section area, A_0, and diameter, D_0, at the base were measured. It was then assumed that this cross-section scaled in proportion to the visible diameter along the length of the spear:

$$V \propto \sum_x A_0 \frac{D_x^2}{D_0^2} = \frac{A_0}{D_0^2} \sum_x D_x^2 \tag{37.4}$$

This model improved the accuracy of the volume estimation to about 6%. The accuracy of this approach could not be increased any further because of the limited resolution in measuring both the spear cross-section and the diameter at each point along the spear. While an improvement, this was still outside the target accuracy requirements of the project.

The next approach was to measure projections from two perpendicular views. If an elliptical cross-section is assumed, this enables the cross-sectional area to be estimated from the projected diameters:

$$A = \frac{\pi}{4} D_{\text{minor}} D_{\text{major}} \tag{37.5}$$

In general, the perpendicular views will not be aligned with the major and minor ellipse axes. Therefore, the two measurements, D_1 and D_2, while perpendicular, will be randomly aligned with the ellipse axes. This situation is illustrated in ➋ *Fig. 37.4*. Substituting ➋ Eq. 37.5 into ➋ Eq. 37.1 gives

$$V \propto \sum_x D_1 D_2 \tag{37.6}$$

which results in significant error when the cross-section is more elliptical and is oriented close to 45°. However, it is known from moment invariants that

$$m_{02}^2 + m_{20}^2 = \text{constant} \tag{37.7}$$

where m_{02} and m_{20} are the second central moments in two perpendicular axes. For an elliptical shape, the second moment along an axis is proportional to the diameter in that direction. Therefore, inspired from these relationships the volume can be modelled as

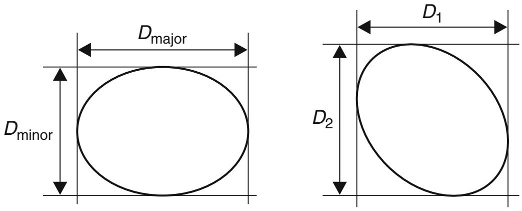

Fig. 37.4
The perpendicular projections of an elliptical cross-section (Reproduced from [3], used with permission). *Left*: ideal projections of the major and minor axes. *Right*: a more realistic set of measurements

$$V \propto \sum_x \left(D_1^2 + D_2^2\right) = \sum_x D_1^2 + \sum_x D_2^2 \tag{37.8}$$

Comparing ➋ Eqs. 37.8 and ➋ 37.3, it is clear that this is just the average of the volumes estimated from the two individual views. Initial measurements indicated that this model could estimate the volume of an individual spear to within about 3% accuracy. This was considered to be adequate for achieving the targeted goals.

37.4 Image Capture Setup

37.4.1 Optical Arrangement

The next stage was to obtain two perpendicular views of each spear as it moved along the conveyor at up to 15 cups per second. The first alternative was to have two cameras, each mounted at 45° to the conveyor. However, as each spear is significantly longer than its diameter, most of the image would be empty. There is sufficient space within a single image to capture multiple views of each spear. The two views can be obtained using a pair of mirrors [4], as shown in the left panel of➋ *Fig. 37.5*. Although two views can actually be obtained with a single mirror with one direct and one reflected view, the two-mirror arrangement has two advantages. First, the optical system is symmetric so that the two perpendicular views have the same path length, hence the same scaling. It also provides a third, direct, view that can be used for quality grading. The third view cannot be used to improve the volume estimation. Incorporating the central view destroys the moment invariant of ➋ Eq. 37.7, increasing the error.

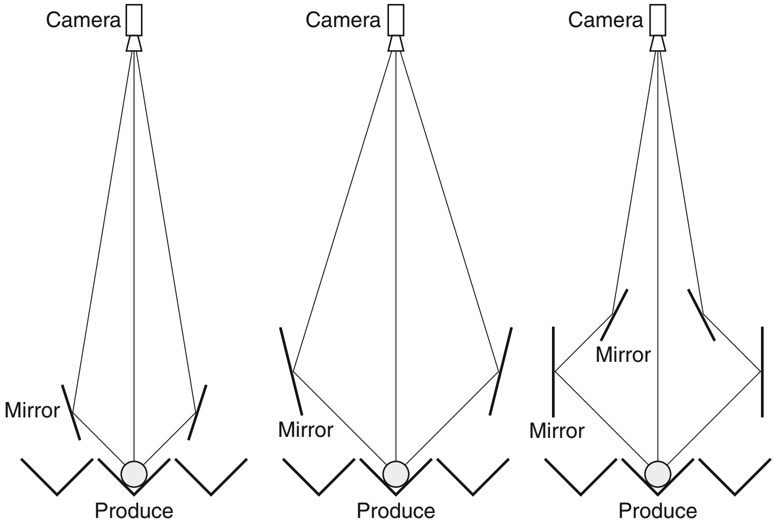

Fig. 37.5
Optical arrangements for capturing two perpendicular views using mirrors (not to scale). *Left*: initial arrangement (Reproduced from [3,4], used with permission). *Centre*: raising the mirrors. *Right*: final arrangement

To maintain adequate focus with the difference in path length between the central and side views, the camera has to be positioned as far as possible from the conveyor. This must be balanced by practical considerations, which limit the size of the grading system. A compromise was reached by placing the camera about 0.8 m above the conveyor and using a slightly telephoto lens.

To test the arrangement in the laboratory, two polished aluminium mirrors were mounted on a wooden substrate. While the aluminium mirrors were not imaging quality, they allowed several mirror configurations to be investigated, and to determine what adjustments would be needed when setting up the grading line.

The mirror system used for the actual grading line consisted of front-silvered optical glass mirrors. Normal mirrors are back-silvered, with the reflective coating behind the glass. While this protects the delicate, silvered, surface, it also results in a double image with reflections from both the front and back surfaces. This can be avoided by using front-silvered mirrors. The silvered surface is protected by a scratch resistant anti-reflective coating. The mirrors were mounted within an aluminium frame to facilitate assembly and removal for maintenance.

A packinghouse is quite a dusty environment. Any dust on the mirrors would reduce the quality of the image. To minimise dust on the mirrors, the complete imaging system was mounted within an enclosed box (apart from where the conveyor ran through). Filtered air was blown into the imaging box to create a downwards airflow to reduce the amount of dust rising from the conveyor. The box also blocked ambient light, giving more control over the lighting.

The arrangement worked fine in the laboratory, and also when first set up for testing in the factory. However, when the grading line was operated at full speed an occasional spear that was not quite sitting flat in the cup would catch on the bottom edge of the mirror and flick out. This would then catch other spears, and foul the system. When this occurred, the grading line had to be shut down and the conveyor cleared. Unfortunately, this happened sufficiently frequently to make the system impractical.

The problem is the relatively small clearance between the bottom of the mirror and the top of the cup. To achieve better clearance, the mirror needs to be lifted, and moved further from the centre-line, as shown in the central panel of ➲ *Fig. 37.5*. To fit all three views within a single image then required a significantly wider angle lens. Unfortunately, this also reduced the resolution by about a factor of two, with a consequent increase in the measurement error.

To retain the original field of view (and accuracy) but raise the mirrors, a second set of mirrors was introduced as shown in the right panel of ➲ *Fig. 37.5*. The disadvantage of this arrangement is that the path length of the side views is increased. This slightly reduced the resolution of the side views. It also required a longer depth of focus to obtain well focussed images in all three views. The depth of focus was increased by reducing the aperture, at the expense of requiring stronger illumination to maintain an adequate exposure.

Although the extra set of mirrors makes the optical arrangement more complex, it actually simplified setting the system up. The angle of all four mirrors was made adjustable, allowing control over both the angle of view and the position of the spear within the captured image.

This final arrangement doubled the clearance between the mirrors and the cups and overcame the initial problems with produce being caught on the bottom. Once the camera was focussed, the focus ring was locked with a grub screw to prevent unwanted changes as a result of vibration.

37.4.2 Lighting

The lighting must be such that the spear can be segmented from both the cup and the background. The cups are made of black plastic, which aids segmentation of the lighter spears. The ends of the spear extend past the ends of the cup so the background clutter was removed by mounting a matt black shroud between the conveyor and the cups.

With the cups moving continuously past the camera, it was important to freeze the motion in the images. With a throughput of 15 cups per second, the motion within the image is approximately 2,250 pixels per second. Therefore, to keep the motion blur to less than one pixel, an exposure time of 1/2,500 s or shorter was necessary. High intensity flash illumination was considered, but ruled out because flash frequencies of 10–15 Hz are known to trigger epileptic attacks in susceptible people. While the camera box is enclosed, some light would inevitably escape through the port where the conveyor runs through.

The exposure time was well within the range of electronic shutter speeds of solid-state cameras. Therefore, continuous illumination was used combined with electronic shuttering to freeze the motion. The short exposure time combined with the narrow aperture needed to give a broad depth of focus means that the camera receives very little light. This necessitated high intensity illumination, which was provided by a bank of quartz halogen lamps. Flicker was avoided by running the lamps from an independent DC power supply.

The initial lighting arrangement had the lights mounted adjacent to the camera. This gave good even illumination of the direct view, and provided additional light to the side views through reflection off the mirrors. This arrangement, however, was much less effective after changing to the optical system with four mirrors. Considerable time was spent, both in the laboratory and in the factory to find a new arrangement that gave even illumination for all three views. To facilitate this experimentation, the lamps were mounted on magnetic clamps that enabled both the position and angle of the lamps to be adjusted easily. In the final system, of course, the lamp brackets were firmly fixed to the frame.

The final lighting arrangement is illustrated schematically in ➋ *Fig. 37.6*. A pair of lamps was mounted above the cup, illuminating the spear from the ends. These are positioned at an angle to maximise the light between the sides of the spear and the cup. It was found that if these illuminated the near end of the spear, it was hard to obtain even illumination, and the centre of the spear was either significantly darker or lighter than the ends. This made segmentation from the cup more difficult. The presence of the imaging mirrors also restricted where the lamps could be positioned. The most even illumination was obtained by directing the light from narrow beam lamps to the far end of the spear, as shown in the left panel of ➋ *Fig. 37.6*. A polished aluminium reflector was placed at each end to direct light back along the spear. Sometimes the ends of the spear drooped slightly where they extended past the ends of the cup. An additional pair of wider beam lamps was mounted at each end of the cup to improve the illumination in this case. In total, eight 40 W lamps were used to provide the high intensity illumination needed for the short exposure. In the right panel of ➋ *Fig. 37.6*, the four lamps at the base of the spear can be seen. The central two are illuminating the length of the spear and the outer two providing additional illumination for the base. Only the two wide beam lamps are visible at the tip of the spear; the other two are just out of the field of view.

Once the lighting had been set up, the aperture ring on the camera lens was also locked with a grub screw. This precaution also prevents unwanted movement as a result of vibration.

To reduce any vibrations from the conveyor from affecting the images, both the camera and mirror arrangement were mounted on a separate frame from the imaging box, which was

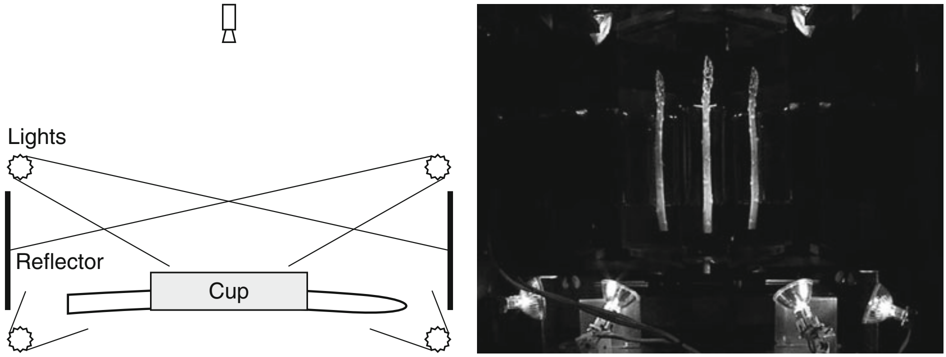

Fig. 37.6
Lighting arrangement to give even illumination. *Left*: relative light positions (Reproduced from [3], used with permission). *Right*: view from the camera

mounted directly on the conveyor frame. It is not known if this precaution was strictly necessary, but as a result, the camera and optical system experience very little vibration.

37.5 Image Processing

A sensor mounted beside the conveyor detected each cup as it passed. This was used to trigger the capture of an image and begin processing. Processing speed is critical because at 15 cups per second there is only approximately 60 ms to process each image. Several experiments were performed using both colour and infra-red imaging, but these gave very little additional information to that present in a monochrome image. A Sony XC-55 camera was chosen because it allowed the necessary asynchronous triggering to match the speed of the conveyor. It also provided a progressive scan output, enabling the full resolution image to be captured and output for each frame.

A typical image captured by the system is shown in ➜ *Fig. 37.7*. From this image, several difficulties are apparent from an image processing perspective. The two side views are slightly darker than the central view because of the slight attenuation from each reflection by the mirror. The limited illumination between the spear and the cup reduces the contrast making segmentation more difficult. The roughness of the surface of the spear results in significant variations in intensity, especially at the tip of the spear, and there are specular reflections from the bracks (the small triangular leaf-like growths) along the length of the spear. There are also specular reflections from end of the cup. This is because the tip end of the cup has a rounded profile to prevent the spear from catching on the cup as it is unloaded into a chute.

37.5.1 Object Detection

The first step was to determine whether or not the cup contains a spear. There was specular reflection from the bottom of an empty cup, which made it appear as if a spear was present. Since the spear extended past the ends of the cup and there was a dark background, this was the best place to detect the presence of a spear. The mean and variance were calculated of the pixel

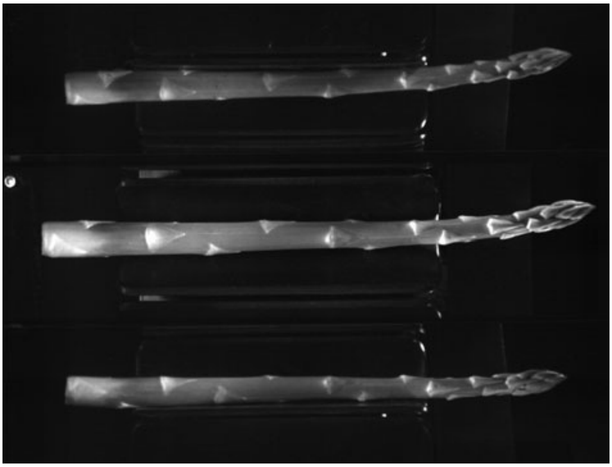

Fig. 37.7
A typical image captured by the system

values within a 96 × 1 window [3] at a predefined position between the end of the spear and the end of the cup from the central view. When no spear was present, only the background was within the window, so the mean and variance were both small. When both exceeded a threshold, the presence of a spear was indicated.

The image was also checked for the presence of the index LED, seen on the left side of *Fig. 37.7*. This was used to associate an image with the reference cup, as described in a later section. The index LED is in a fixed location enabling its state to be determined easily.

If no spear was detected, processing returned at this point until the next image.

The next step was to verify the exposure of the image. Since electronic shutter control was used, it is possible to compensate automatically for any variations in exposure resulting from aging of the lamps or variations in the average colour of the produce throughout the season. An intensity histogram was accumulated of the captured image, and the 99th percentile determined. This gave the highlight pixel value while ignoring the specular reflections from the cup. If the highlight value was greater than 250 there was a danger of losing important detail through the image saturating. The over-exposure was compensated by increasing the shutter speed for subsequent images. If the highlight value was less than 192 there was a danger of losing detail because the full dynamic range of the image was not being exploited. This under-exposure was compensated by decreasing the shutter speed for subsequent images. Such exposure adjustment was effectively using fixed step size integral feedback control. The feedback gain (step size) must be sufficiently small to prevent instability resulting from natural differences in colour from item to item. The large dead band allowed for the natural range of normal highlight pixel values and avoided changing the shutter speed with each image.

37.5.2 Segmentation

In the earlier images (before the mirrors and lights were changed) there was a stronger specular reflection from the sides of the cups. The initial approach to segmentation was to mask out the edges of the cup and threshold the image to obtain the shape of the spears [4]. This worked reasonably successfully in the laboratory, but did not work reliably when tried in the factory. First, the position of the cup varied slightly from one image to the next. This, combined with the fact that the spear is immediately adjacent to the cup in the side images, meant that either part of the cup would remain in the image or part of the spear would be clipped out. The second problem was that there was limited light on the spear between the cup and the spear. Therefore, the edge of the spear adjacent to the cup was not segmented reliably by a simple threshold.

Attempts to first detect the cup and then the edge of the spear gave improved results, but was still not sufficiently reliable for grading in the factory.

After modifying the mirrors and lighting, a new approach was tried. This used a simple 3 × 3 Prewitt filter to detect horizontal edges, as shown in the left panel of ➲ *Fig. 37.8*. Then the light and dark boundaries were traced using a boundary tracking algorithm. Such an approach only actually processes around the boundary points it tracks, making the processing is very efficient. Again, the basic principle worked most of the time, with the most common fault being the detection and tracking along the cup edge. More complex preprocessing (right panel of ➲ *Fig. 37.8*) gave better boundary definition, and more sophisticated boundary tracking rules improved the performance. However, it still failed to detect the boundary reliably once in about every 200 or 300 images. While a 99.6% success rate would be enviable in many applications, this corresponds to one error every 15–20 s when operating at full speed.

Since boundary tracking could not be made to work with sufficient reliability, it was necessary to revert to full object detection. The processing sequence [3] is illustrated in ➲ *Fig. 37.9* for a typical image. The first step was to enhance the contrast between the spear and the background, while suppressing irrelevant details within the spear. To keep the processing fast, the contrast was enhanced using a fixed lookup table at the same time as calculating the histogram for exposure adjustment.

The specular highlights were then removed by a greyscale closing operation with a 1 × 9 pixel window. Rather than using the usual sequence of an erosion followed by a dilation, the closing was performed in one pass by scanning to locate the local maxima and then back-filling to remove the peaks.

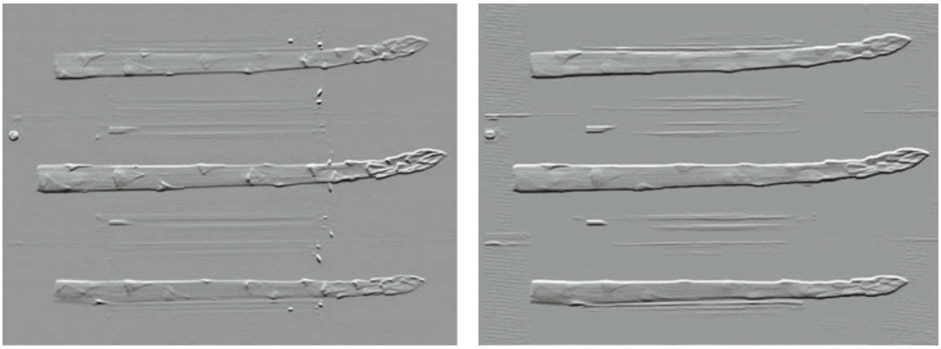

Fig. 37.8

Edge detected image used for boundary tracking. *Left*: original filtered image. *Right*: image with preprocessing prior to filtering

To remove much of the remaining background clutter, a background subtraction was performed. The image was split into three sections (one for each view) and the average pixel value, μ, calculated within each column for each section. Pixels with value smaller than the column average were considered background and were set to zero. The remaining pixel values were linearly expanded to maintain optimum contrast:

$$\hat{p}_i = \begin{cases} 0 & p_i \leq \mu \\ \frac{p_i - \mu}{255 - \mu} & p_i > \mu \end{cases} \tag{37.9}$$

This then enabled the image to be segmented using a fixed threshold level. Some of the cup edges were still classified as object; these were almost completely removed by a binary opening filter using a 9 × 1 element window. Again, an efficient implementation was used – if there were fewer than nine consecutive white pixels in a column, they were set to black. A similar opening and closing were performed using a horizontal 1 × 5 window to clean up the image. The final processed image is shown in the bottom right panel of *Fig. 37.9*. Note that some images still had a few pixels incorrectly segmented, although these represent a relatively minor error. This processing was sufficiently reliable that accurate weight estimates were provided for all spears correctly loaded into the cups.

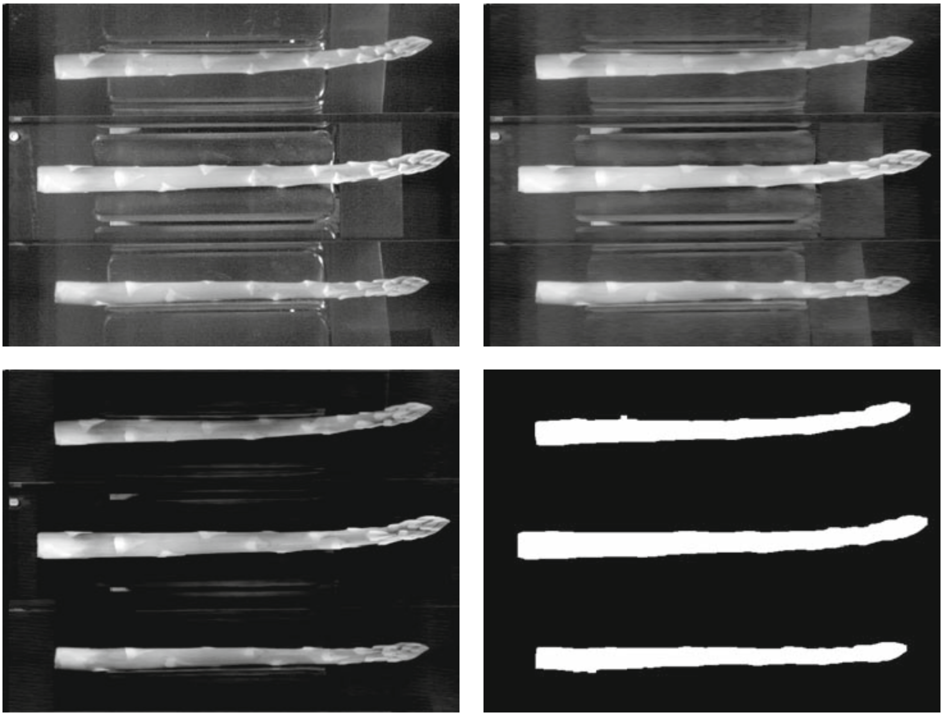

Fig. 37.9

Processing sequence. *Top left*: contrast enhancement. *Top right*: morphological filtering to remove specular highlights. *Bottom left*: background subtraction. *Bottom right*: thresholding and morphological filtering to clean the shape

37.5.3 Weight Estimation

The volume was calculated from the two side views using ➋ Eq. 37.8, where the diameter was determined by counting the pixels across the spear in each column. Since the edge of each spear was detected to the nearest pixel, at each position the measured diameter may be up to one pixel out. As a typical spear is 30–40 pixels diameter, this limited the accuracy to about 3%.

It would be possible to measure the diameter to sub-pixel accuracy by refining the detected edges using the gradient information from ➋ *Fig. 37.8*. The locations of the local minima and maxima gradient can be estimated to a fraction of a pixel [1] by fitting a parabola to the values of the extreme pixel value and the values immediately above and below it in the column. However, this was not needed, as the measured volume was already sufficiently accurate.

To convert the volume estimate in pixel units to a weight, two factors are required. The first is the size of each pixel, and the second is the density of the produce. These could be obtained through open loop calibration with a constant parameter for the proportionality constant in ➋ Eq. 37.8. A limitation of this approach is that there are small, but consistent, variations in density throughout the season and possibly throughout the day. The most accurate weight estimate may be obtained by dynamically determining the calibration as the density changes. A closed loop calibration is effective if the density is consistent between spears, and only changes slowly relative to the frequency of calibration.

Closed loop calibration was performed by actually weighing a random sample of spears as they were measured. Every 100th to 500th item (one spear every 10–30 s) was directed down a chute onto a set of electronic scales. This associated the digital volume with the known weight, providing a single point on the calibration curve. A least squares fit through the data from the last 100 calibration points provided a dynamic calibration curve. It also automatically compensated for any small variations in density with volume. The complete curve was replaced every 30–60 min, tracking small variations even during the day. After being weighed, the calibration items were redirected back to the input of the grading line where they were graded with the rest of the produce.

A further calibration issue is the difference in scale between the direct, central view and the two reflected side views. This is required to relate measurements between the three views for quality grading. To estimate the scale factor for a single spear, the length in pixels from the central view was divided by the average length in pixels from the two side views. Robust averaging (by eliminating outliers) over a large number of spears was used to provide an accurate estimate of the scale factor.

37.5.4 Quality Grading

One common application of machine vision is in quality grading, and this is particularly so in the case of produce. There is little prior work recorded in the literature of quality grading of asparagus. Rigney and Brusewitz [12] investigated 12 parameters derived from spear boundary data. They found error rates of up to 30% over manual classification. They also developed a machine vision system [13] for detecting spreading tips, broken tips, and scarred or cracked spears, with mixed results. Part of their context was mechanised harvesting; in the context here, with manual harvesting, many of these defects would be identified and culled in the field before grading.

In our system, in addition to estimating the weight, image processing was also used for a limited quality assessment of each spear. A complete inspection of each spear is not possible because only about 65% of each spear is visible to the camera. This is further reduced because the parts of the spear adjacent to the cup have limited lighting, making subtle defects all but impossible to detect in the side views.

The most important assessment is based on the ellipticity of the cross-section. While in principle it is possible to determine the ellipticity from three projections, the formula is quite complex. There is also little point in estimating the true ellipticity because the cross-section is seldom a true ellipse. However, a significant difference in the diameter of the three views (after correcting the central view for the difference in scale) indicates a significant deviation from circularity. If the ratio between the largest and smallest diameters at the base of the spear exceeded a threshold, the spear was rejected as being too flat.

It was also important to check that the field cut from harvesting had been completely removed when the spear was trimmed prior to grading. The angle of the butt end of the spear was measured in all three views. If any part of the base in any of the views deviated from perpendicular by more than a threshold angle then the field cut has not been completely removed. There was another trimming saw part way down the grading line that can further trim the spear. The known position of the saw was used to calculate the trimmed volume (and hence weight) for grading a spear into chutes beyond the second saw.

The field cut was usually made below the ground. The base of the spear from below soil level is lighter in colour than that from above the ground. The central view was examined for a change in contrast that indicated the position of ground level when the spear was harvested. If a contrast change was detected, as shown in ➲ *Fig. 37.10*, the spear was directed for trimming by the second trimming saw, and the volume (and weight) estimate adjusted accordingly. If this was insufficient to remove the base, then the spear was rejected.

The final quality assessment was to estimate the curvature of each spear from the three views. While there is no different in the taste between straight and bent spears, straight spears are significantly easier to package, especially by automated machinery. The deviation of the spear centreline from straight provided a simple measure of curvature. If the total deviation was greater than a preset threshold then the spear was rejected.

37.5.5 Measurement Summary

Speed required the image processing operations to be kept very simple. Standard operations used were histogramming, lookup tables, column averaging, and relatively simple morphological filters. Details of such operations may be found in any image processing text (see earlier

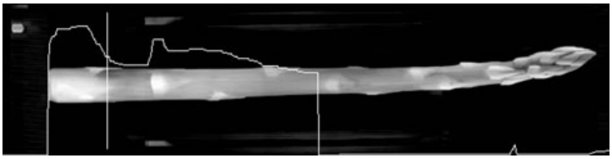

Fig. 37.10
Intensity profile of the base of the spear for detecting ground level

chapters in this handbook, or refer for example to [6,9,15]). The difference between what was used here, and a conventional implementation was that all of the code was optimised specifically for this processing task to minimise the computation. Successive operations were combined together where possible to reduce the overhead of unnecessary memory accesses.

The accuracy of the weight estimate of each spear is determined by a number of factors. These include variations in density from one spear to the next; errors in estimating the volume from the image; and the accuracy of the calibration from volume to weight. As described earlier, there is about a 1% variation in density, and the volume estimation has an uncertainty of about 3%. Since the calibration is determined by actually measuring the spears, each calibration point would have an expected uncertainty of about 4%. However, since the calibration results from fitting to 100 points, then the expected calibration error should reduce by a factor of 10. Therefore, the total error in measuring any one item is expected to be about 4.5%.

➋ *Table 37.1* summarises the results of weighing 2,500 items. For convenience, the spears have been divided into weight ranges based on the number of spears per 100 g bundle. Note that this might not be the actual grade that an individual spear is assigned, but it serves to provide a convenient reference. The RMS error is the difference between the true measured weight and the weight estimated by the system. The error is about the level expected, between 4.2% and 5.2%, with larger errors for the smaller spears. This is not unexpected, since the smaller spears have fewer pixels across the diameter, which will reduce the accuracy of the volume estimation. However, when the weight of a bundle is considered, the central limit theorem will reduce the relative error because the errors from measuring each spear are independent. The final column in ➋ *Table 37.1* therefore reflects the expected error in a 100 g bundle.

37.6 Grading Algorithm

Assigning a spear to a bundle based purely on a weight range results in a very broad spread of bundle weights, even if the weight of each spear is known exactly. This is illustrated in the left

Table 37.1
Summary of results from weighing 2,500 items

Bundle size	Weight range (g)	Count	Mean weight (g)	RMS error (g)	Error (%)	Bundle error (%)
Underweight	<13.3	159	11.7	0.70	6.04	
Seven per bundle	13.3–15.4	210	14.4	0.75	5.19	1.96
Six per bundle	15.4–18.2	430	16.8	0.78	4.67	1.91
Five per bundle	18.2–22.2	606	20.2	0.89	4.41	1.97
Four per bundle	22.2–28.6	649	25.0	1.13	4.51	2.26
Three per bundle	28.6–40.0	383	32.7	1.38	4.24	2.45
Overweight	>40.0	63	46.5	2.34	4.97	

panel of ➋ *Fig. 37.11* for an average bundle weight of 100 g. This was one of the problems with the previous grading scheme.

An accurate weight estimation allows a more complex grading scheme. It is now possible to allocate a spear to a particular bundle based on the weight accumulated so far [4]. For this, a target weight is calculated for each chute based on what it has already been allocated. For example, in a four items per bundle grade, the initial target weight would be 100 g/4 = 25 g. Suppose that a 22.6 g spear is assigned to that package. The new target weight would be (100–22.6)/3 = 25.8 g. This example is continued in ➋ *Table 37.2*. Each spear was allocated to the bundle with a target weight that most closely matches the estimated weight of the item. Underweight and overweight items were easily handled through the use of two-item (for the oversize) and ten-item (for the undersize) bundles.

To make effective use of the target weight scheme, it was necessary to be assembling several bundles within each grade, to allow more opportunity for finding the spear of the right size to complete the package. For bundles with small item counts, it is more difficult to achieve close

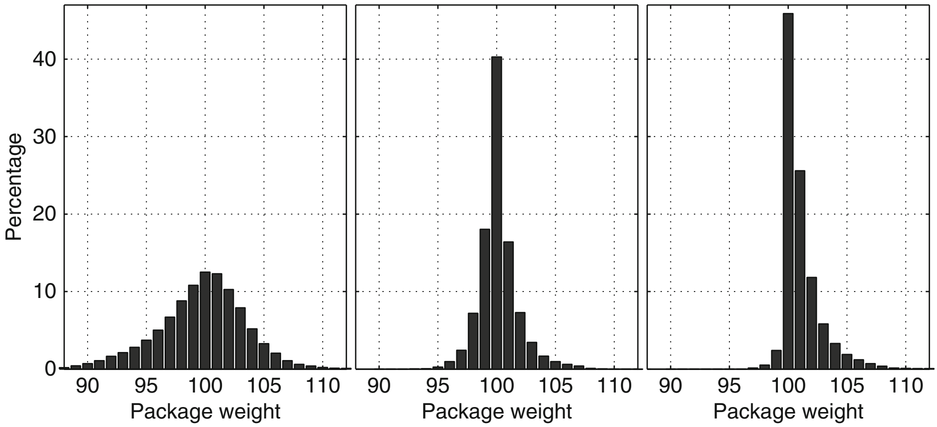

Fig. 37.11

Bundle size distributions with perfect weight measurement. *Left*: assignment based on weight range only. *Centre*: target-based assignment as described in the text. *Right*: target-based assignment with underweight penalty

Table 37.2

Example calculation of the target weight for a four per bundle grade as spears are assigned

Spear weight (g)	Total so far (g)	Remaining (g)	Spears remaining	Target weight (g)
	0	100	4	25.0
22.6	22.6	77.4	3	25.8
26.2	48.8	51.2	2	25.6
28.1	76.9	23.1	1	23.1
24.7	101.6			

to the target weight. A three-item bundle has an initial target weight per spear of 33.3 g. However, the next package size has an initial target weight of 25 g. So for a three-item bundle, items are selected from a relatively broad distribution, and there are few opportunities for selecting the best spear to complete the package. As the item count increases, the distribution becomes narrower, with the weights being added to a bundle with each spear being more similar. Consequently, the three-item bundles have a significantly larger spread in bundle size than the other counts. A balance was found by allocating four chutes for building three-item bundles and three chutes for each of the other grades. The effect of using a target weight for each spear is to give a much tighter bundle weight distribution, as shown in the centre panel of ➲ *Fig. 37.11*.

A problem remains with underweight packages. When a bundle requires only one more spear for completion, a severe penalty is applied to spears that are lighter than the target weight. The effect of such a penalty is to skew the distribution so that significantly fewer underweight bundles are produced. The resulting distribution of bundle weights is shown in the right panel of ➲ *Fig. 37.11*.

All of the distributions in ➲ *Fig. 37.11* are based on the assumption that the spear weights are known exactly. In practice, the measurement of each spear has a 4.5% error as described in the previous section. The effect of this error is to broaden the bundle weight distribution as shown in the left panel of ➲ *Fig. 37.12*. Note that the skew to overweight bundles is retained, but there is now a significant number of underweight bundles. The underweight tail cannot be eliminated completely, but can in part be compensated by increasing the target weight for each package. Setting the target weight to 104 g reduced the number of underweight bundles to an acceptable level. The resulting distribution is shown in ➲ *Fig. 37.12*.

➲ *Table 37.3* summarises the statistics for the different bundle counts. The average bundle weight was within the target of 105 g, with only about 2% of the packages being underweight. Most of these come from the smaller three-item and four-item bundles, which have a larger spread because of their small item counts.

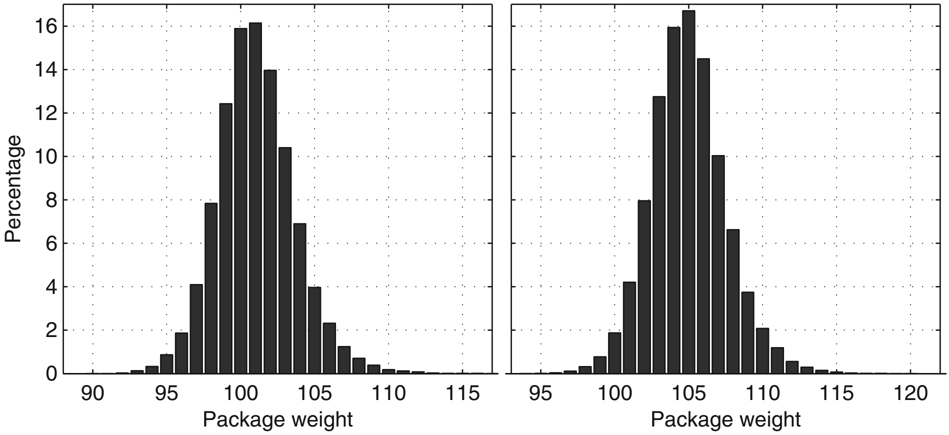

Fig. 37.12

Actual bundle weight distributions. *Left*: with a target weight of 100 g. *Right*: with a target weight of 104 g

Table 37.3
Statistics for the package weight distributions of the final system

Bundle size	Proportion (%)	Average (g)	Standard deviation (g)	% < 100 g	% > 110 g
seven per bundle	11.7	105.46	2.05	0.25	1.82
six per bundle	12.8	105.07	2.00	0.31	1.19
five per bundle	25.2	104.83	2.27	1.00	2.03
four per bundle	31.7	104.92	2.69	2.61	3.86
three per bundle	18.6	104.84	3.11	4.58	6.08
Overall	100	104.96	2.54	1.99	3.23

37.7 Software Implementation

LabVIEW for Windows was chosen as the platform for implementing the control and vision system because it readily enabled the different hardware components (image capture, chute control, and electronic scales) to be integrated within a single system. It also allowed different control and sorting algorithms to be simulated, and then used in the final production system without change. Tools were also available within LabVIEW for constructing a user interface that could be used as a control panel for the system.

Images were captured from the Sony XC-55 camera via a National Instruments frame grabber card. This also provided direct hardware triggering for image capture, which avoided problems with a variable software latency in responding to the trigger signal. Images were saved in multiple image buffers. This was necessary because Windows is not a real-time operating system, and can periodically switch to other tasks for periods of up to 200 ms. (All unnecessary functionality within Windows was disabled to reduce this. Networking in particular can induce some long delays, so all networking was switched off.) It is essential that no frames be missed or lost during this time, so a pool of 50 image capture buffers was pre-allocated.

All of the image processing routines were written as optimised C routines, and provided to LabVIEW using a DLL. These were then accessed through LabVIEW's DLL interface as custom operations. This approach was taken rather than use the image processing operations provided by the LabVIEW image acquisition module because it enabled the operations to be specifically tailored and optimised for this application. The use of custom image analysis software enabled several generic operations to be combined into a specific operation for this application. Algorithms for implementing standard operations were modified to significantly reduce the processing time required. The overheads of repeatedly allocating and freeing memory, and the associated memory fragmentation issues were avoided by pre-allocating sufficient scratchpad memory in LabVIEW, and passing this to the image processing routines with the image. Such optimisations enabled the final implementation to process each image in 35 ms on a 1.8 MHz Pentium P4 (a high end desktop PC when the system was developed). This corresponds to a maximum processing rate of 28 items per second, which was well within the target rate of 15 items per second. The image processing routines automatically measured and compensated for the scale difference between the side and central views and returned all of the measurement data as described above.

A LabVIEW module was developed to manage the dynamic calibration, which utilised a commercial electronic scale interfaced via an RS232 connection. The calibration curve was used to convert the measurements from pixel units to a weight. Based on the weight and quality measurements, another LabVIEW module graded the spear and allocated it to a chute. The number of the cup containing the spear was communicated to the actuator associated with a chute using an RS485 connection. Each spear was processed independently; once it had been allocated to a chute, and the data associated with the chute state updated, the spear was considered to have been processed.

The main control panel within LabVIEW contained stop and start buttons, the most recently captured image, and a summary of processing statistics. The latter two items were not strictly necessary, but were provided to enable the operator to see that the system was operating. In addition to the main panel, several setup screens enabled the target weight and grades for each chute to be specified. The settings of the trimming saws and the thresholds for the quality grading were also entered here. Several debugging screens were also developed, although they were disabled and inaccessible during normal operation.

37.8 Actuator System

To overcome problems with belt stretch, a distributed intelligent actuator system was introduced [10]. Each chute required an actuator, so sensing the cups at the point of actuation will be immune to variations in distance between the grading system and chute. Each actuator had to perform the following tasks: identify individual cups on the conveyor; communicate with the central grading system; buffer the list of cups containing spears destined for the associated chute; activate the solenoid for the specified cups; and release the completed bundles for packaging.

37.8.1 Actuator Controller

Several options were considered for implementing the actuator controller. Initial investigations considered using digital I/O cards mounted in the controlling PC. Typically, such cards have up to 32 I/O channels available so several would be needed to provide a sense input and two outputs for each of up to 60 chutes. Two problems were identified with this option. First, the operating system cannot time to the precision required. Second, the sensors and switching hardware would be mounted at some distance from the PC. The resulting long lines (up to 10 m) would be susceptible to noise interference. It would also be necessary to use individual solid-state relays to handle the current and voltage requirements of the solenoid and bundle release pneumatics.

A programmable logic controller (PLC) is designed to perform a function in response to attached sensors. Modern PLCs are networkable, so can be set up to receive instructions from the grading PC. Scan times can be as low as 1 ms, giving a 2 ms timing uncertainty which is satisfactory in this application. Again, to handle the current and voltage requirements it would be necessary to use external solid-state relays. To manage all of the chutes, several PLCs would be required, making this a relatively expensive option.

The relatively simple requirements for the actuator indicated that a small microcontroller would be a viable option. A Winbond W78E516B, an 8051 variant, was selected because it was flash programmable, and integrated all of the required features within a single chip: it is capable of accurate timing, includes serial communications, has ample I/O pins, and has a small amount of memory that can be used to buffer cup data. Power MOSFETs were used to provide the required actuation. The low cost of the microcontroller enabled one to be used for each chute, simplifying the software and making the system modular and flexible. The microcontrollers were powered from the 48V actuation system power supply using an integrated switch-mode regulator.

37.8.2 Communication

The intelligent actuators were connected to the grading system using an 115,200 bps multi-drop half-duplex RS485 network. The RS485 protocol uses two balanced lines, making it resistant to noise and DC offsets. This was important in this application as the momentary high currents when activating the solenoids could result in considerable movement of the ground voltage. MAX487 devices were used to interface the microcontrollers and the grading PC to the communication line.

Almost all communication was in packets of five bytes in the following format: address, command, two data bytes, and a checksum. A command/response protocol was used with all commands echoed back to the controlling PC to verify reception. This meant that the data direction on the bus was predictable, which was necessary with the half-duplex system. Failure to respond to a command indicated that the addressed actuator has encountered a fault, enabling the operator to be alerted.

Address zero was used to broadcast to all actuators; broadcast commands were obviously not echoed. Eighteen commands were defined. These included a number of query commands that were used primarily for debugging purposes; the echoed response contained the requested data.

Manual configuration of actuator addressing was avoided by using a self-addressing approach. The actuators were daisy chained using a select-in and select-out connection, with the select-out of one actuator connected to the select-in of the next. On power-up, all actuators started with an address of zero, and asserted their select-out low. Only the first actuator in the chain had a high select-in, so it would respond to a SET ADDRESS command and be assigned an address of 1. It then set its select-out high so that the next actuator in the chain would respond to the next SET ADDRESS command. In this way, successive actuators were assigned successive addresses. When no further replies were echoed, all actuators had been assigned addresses. If this differed from the expected number of actuators, the grading system could alert the operator which actuator had failed.

Automatic configuration in this way enabled all of the actuator controllers to be identical. This avoided the need to set jumpers to indicate the address, which is inevitably an error prone process. It also simplified maintenance, as all of the units were interchangeable.

With the large number of controllers, it was convenient to have in-circuit programming of the microcontrollers. A LOAD NEW PROGRAM command switched execution to a boot loader section of program memory, erased the main program flash, and waited to receive new code via the communication line. Either the whole chain could be reprogrammed at once, or an individual controller could have its code updated (for example if it was a replacement unit running an old version of the code).

There was considerable latency between when a spear was graded and when the solenoid needed to be activated to drop the spear into a chute. As soon as a spear was graded, a CUP ID command was sent to the actuator for the intended destination. The set of cup IDs for a chute were buffered by the actuator until the corresponding cups arrived and were triggered.

37.8.3 Cup Sensing and Identification

Several possible techniques were considered for cup identification. Since each cup must have a unique ID an obvious approach would be to install an RFID tag on each of the cups. Each chute would then require an RFID reader to sense the cup and its identity. However, at the time that the system was developed, none of the team had experience with RFID technology, and it was perceived to be overly complex for this application.

The initial approach was to mount a small neodium magnet on the cup trigger tags, and sense these using an Allegro 3121 Hall effect sensor, as shown in the left panel of ➲ *Fig. 37.13*. This enabled each cup to be detected as it passed the actuator. Individual cups were identified by counting the number of cups from a reference cup, which was assigned an ID of 0. The reference cup had two spatially separated magnets mounted on the trigger tag, which gave a double pulse when it passed the sensor, enabling it to be identified easily.

This approach appeared to work successfully, until after about a week it began behaving erratically, becoming increasingly unreliable. The cause was traced to the magnets mounted on the trigger tags. Each activation of the solenoid subjected a magnet to an electromagnetic pulse. The cumulative effect of these pulses was sufficient to partially or completely demagnetise some of the magnets depending on their polarity and their precise location relative to the solenoid. The net effect was that the signal from the Hall effect sensor became weaker, making cup detection unreliable.

The next approach was to use a reflective optical system based on a Sharp IS471. This is an integrated synchronous infrared modulator and detector, making it inherently immune to stray illumination. The modulator output directly drives an infrared LED, with the tag reflection detected and converted to a digital output indicating the presence of a tag. Both were positioned within the actuator enclosure, facing upwards through a thin window. The LED was inclined by 20° so that both the LED and detector were focussed on the same spot (see the right panel of ➲ *Fig. 37.13*). This gave a narrow detection range, with tags positioned between 5 and 10 mm above the sensor detected reliably. Objects further than 20 mm from the sensor were not detected.

The reference tag was made 50% wider than the other tags to enable it to be identified. The leading edge was the same, to enable reliable timing for solenoid activation, with the trailing edge extended. The length of the pulse produced by a tag depended on the speed of the conveyor, so the threshold was set at 125% of the normal tag transit time. To facilitate startup and shutdown when the conveyor speed was not constant, the tag transit times were filtered using a first order IIR filter.

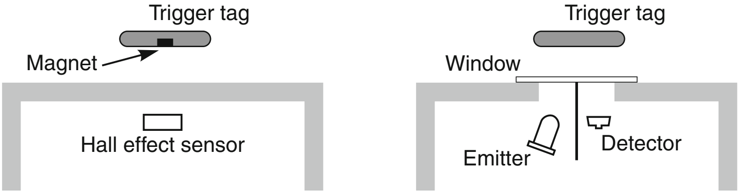

Fig. 37.13

Tag detection. *Left*: using magnetic sensing. *Right*: using synchronous optical sensing (Reproduced from [10], used with permission)

One limitation of the optical detection approach was that the viewing window became dusty from water droplets off the produce and general dust from within the packinghouse environment. This required cleaning approximately once every week as part of the regular maintenance cycle. The optical system was used within the packinghouse successfully for two seasons.

After this time, magnets with a higher coercivity were sourced that did not suffer from demagnetisation. The actuators were switched back to the Hall effect sensors because these did not have the same maintenance requirements as the optical system.

A cup sensor was also mounted at the camera to trigger image capture. When the reference cup was detected, the index LED was illuminated, enabling the image associated with cup 0 to be identified. This was important because with Windows there was a variable latency between capturing the image and the actual processing and subsequent grading.

37.8.4 Cup and Bundle Release

The actuators were required to trip the selected cups as they arrived at their destination chute. As the cup sensor was located ahead of the solenoid, when the required cup was detected, the signal to trigger the solenoid had to be delayed depending on the speed of the conveyor. Reliable triggering required the delay to be accurate to within about 5 ms. A cup was released by activating the solenoid via a power MOSFET for 20 ms. The solenoid was connected to the 48 V system power supply, drawing 4 A while activated.

When multiple solenoids were activated simultaneously, this injected considerable noise into the power supply. In the initial system, this voltage droop was sufficient on occasion to reset a microcontroller. This was overcome by providing each microcontroller with a 1,000 μF electrolytic capacitor to supply power during the short outages.

Off-the-shelf 24 V pneumatic valves were used to operate pneumatic cylinders that released completed bundles for packaging. The cylinder toggled with each bundle so on average each valve was energized half the time. If connected directly to the 48 V power supply, the valves would overheat. It was found that a 25% duty cycle was sufficient to reliably hold the valve closed. The microcontroller provided the required waveform via another power MOSFET.

A short delay was required between triggering the cup containing the last spear for a bundle and activating the pneumatic cylinder valve to allow time for the produce to fall from the cup into the chute. While a bundle was being released, spears from the next four or five cups could not be released at that chute. This was implemented by locking such a chute out of consideration during the grading process.

The actuator system worked reliably at up to 25 cups per second. Chute design and produce handling considerations limited the maximum practical speed to about 15 cups per second. Beyond this speed, the chutes needed to be repositioned or made wider to catch the spears being released from the conveyor.

37.9 Debugging

The initial system was installed on a test grading line within the laboratory. This enabled most of the obvious errors to be identified and corrected before installation in the packinghouse. Unfortunately, not everything scaled well between the installations. The conveyor within the test system had to be loaded manually, so it could not be operated fully loaded at full speed.

When installed within the packinghouse, the system operated fine when lightly loaded and running at low speed (conditions tested in the laboratory). However, when running under normal operating conditions, most of the produce went off the end of the conveyor, rather than into chutes. Debugging a system operating at 10–15 cups per second initially proved to be quite challenging, especially when the observed symptoms could result from many possible errors. Failure to detect a cup at the camera or chute would lead to miscounting and loss of synchronisation, resulting in the wrong cups being triggered. Image processing errors could lead to faulty weight estimates, or in severe cases result in the program terminating. Grading failure could result in a spear being allocated to the wrong bundle. Inaccurate timing of the solenoid could result in a cup failing to release. During the debugging phase, all of these errors occurred at various times. When there were so many possible sources of errors, finding the actual cause of a problem was difficult, especially when the system behaved correctly with low speed or throughput. As the system became more reliable, however, there were fewer errors and identifying the cause for a particular error became easier.

Debugging the image processing code was particularly challenging especially when an intermittent array bounds error caused the whole grading system to terminate. This was overcome by streaming each image to disk from LabVIEW before calling the image processing code. Then, when the programme failed, the image that caused the failure was available for analysis off-line. To facilitate debugging, the source code was also compiled within VIPS, a general purpose image processing algorithm development environment [2]. The image could then be analysed, the code edited and retested on the image until the bugs were removed. If necessary, the code could be single stepped in the debugger enabling the cause of the failure to be detected and remedied.

The other significant issue during the debugging stage was that the clients had the expectation that the system would work when first switched on. They took the debugging problems as evidence that the approach we had taken had failed. It took considerable persuasion to convince them that such problems were in fact expected when developing a complex system such as this. However, even with such reassurance, the visible delays in getting the system operational also led to pressure from the packinghouse, especially as the grading season approached. Even after the system was mostly working and in regular use, one or more members of the development team visited the packinghouse regularly to resolve the remaining problems.

After the system was working, it took some time for the results of the system to be accepted by the clients. During this period, they manually weighed every bundle produced by the system to verify that they were neither underweight nor significantly overweight. Eventually, however, they realised that this was unnecessary, and that the system was working as designed.

37.10 Summary

This chapter has described the process of developing a machine vision system for automated produce grading. It was a multi-disciplinary engineering effort, involving optics, lighting, modelling, image processing, statistics, software development, real-time systems, mechanics, electronics, and debugging skills.

Conventional weighing methods are very expensive for high speed grading and packing. Accurate, high-speed weight estimation of produce using machine vision has been demonstrated. Two perpendicular views were utilised to obtain an estimate of the volume of each item, which was then related to the weight through a closed-loop calibration. Processing speeds approaching 30 items per second on a desktop PC have been demonstrated, with an accuracy of 4–5% in measuring each individual item. This led to more accurate grading and better control over the spread of package weights. An average package weight of 105 g was achieved, with approximately 2% of the packages slightly underweight.

Attempts were made to automate as much of the system as possible, to reduce the opportunities for operator error. This led to automatic exposure adjustment, dynamic calibration, and automated configuration of the actuators. The system was also able to self-diagnose many of the faults that could occur.

Improved processing efficiencies resulted in a doubling of packing throughput. Better control over the bundling process enabled this higher throughput to be managed with fewer staff (the relatively short packing season made obtaining appropriate staff difficult), resulting in significant cost savings for the packinghouse. More accurate weight estimation reduced the average bundle weight by approximately 20%, increasing the sales and profitability for the grower by 20% for the same amount of produce. The reduced weight per package also decreased the air freight costs.

The success of the project is best demonstrated by the fact that the grading system is still in use in the packinghouse 6 years after it was developed.

Acknowledgements

A large project such as this is never a one-man effort. My role in the project related to the image and signal processing aspects. The other members of the development team were: Ralph Ball and Harvey Barraclough, who focussed on the mechanical engineering aspects of the project; Ken Mercer, who developed the intelligent actuators; Colin Plaw, who developed the LabVIEW based control system; Andrew Gilman, who investigated high-speed weighing using load cells; and Geoff Lewis from the packinghouse, who provided the test system and copious quantities of asparagus for testing.

We also acknowledge funding for this project from Technology New Zealand through a Technology for Business Growth Grant.

38 Analysing the Creasing Properties of Fabric

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_38,

Abstract: A large clothing retail store wishes to quantify the creasing properties of the fabrics used in shirts, blouses, dresses, etc. Hitherto, creasing has been judged subjectively and inaccurately, by comparing a sample with carefully designed models, photographs, etc. There is a need for a more objective measurement than this provides and a laboratory-based vision system to automate this task has been proposed. A sample of plain unprinted fabric is first creased in a standard way and then stretched gently as it is placed onto a table. Lighting at a low angle is then applied from one side. The image generated in this way has a low contrast but it is sufficient to allow the crease furrows to be seen. Results are presented for several non-linear filters that convert the grey-scale texture image to binary form. Measurements describing the resulting binary texture are defined. A multi-element vector created by combining several such measurements is then presented to a Pattern Recognition system. This is then trained to identify the creasing coefficient defined by the existing human inspector.

38.1 Background

In this short chapter, several methods are presented for analysing texture. These are discussed in relation to measuring the susceptibility of plain white fabric to creasing. No single method is identified as being superior to all others, as our aim is to demonstrate that there may be many *reasonable* solutions for a given application. It is important to be able to evaluate these easily and an interactive image processor (QT ➲ Chap. 21) has proved to be invaluable. Using QT in this role requires a slightly different approach from that needed for discrete machine parts. As usual, a single image is studied to find tentative ideas for filtering the texture. However, these must then be tested on many different samples of texture, to verify that the measurements and pictorial results that the program is robust. Texture often requires the derivation and analysis of several different measurements and this suggests the use of Pattern Recognition and/or regular statistical techniques. It would not be meaningful to present a complete solution to the task of characterising the creasing properties of fabrics, without including a lot of unnecessary detail about the application requirements and other background information. The author worked on the assumption that the texture analysis procedure would consist of three parts:

- *Stage 1*: Converting the texture in the original grey-scale image to binary form.
- *Stage 2*: Characterising the binary texture. (It is axiomatic that this is easier than characterising the original grey-scale image directly.)
- *Stage 3*: Relating the measurements obtained in Stage 2 to the subjectively defined texture classification currently used by the customer. The details are specific to each application and so will not be discussed further. Let it suffice to say that, to do this properly, requires experiments properly designed in accordance with the established experimental practice of psychology and formal statistical analysis.

38.1.1 Inspection Tasks

A certain UK clothing retailer wishes to improve the quality of the products it offers for sale. To do this, the company will impose strict in-house testing and inspection of the garments it receives from its suppliers. Among the important features that are to be measured is the resistance of fabric to creasing. At the moment, creasing is measured subjectively, by comparing the test sample with a set of standard images. The test sample is a piece of plain fabric that is crumpled manually and then flattened by hand. It is then viewed in a specially designed cabinet which provides low-angle (grazing illumination) Lighting is provided by a linear fluorescent tubes and the cabinet limits the effects of any variation in the ambient lighting. Since any form of physical contact with the fabric will distort the undulations due to creasing, optics and Machine Vision are the obvious technologies and are probably the only ones that offer any realistic hope of automating the measurement function. The task, then, is to design a vision system that can quantify the creasing characteristics of plain fabric. The garment supplier will also be required to install the same test equipment.

38.1.2 Related Tasks

Inspection tasks that provide similar requirements are to be found in industries involving:

1. Machined (i.e., milled, turned and ground) metal surfaces
2. Paper
3. Plastic film
4. Cork floor tiles

38.1.3 Image Formation

From the long experience gained by the clothing retailer with the traditional method of assessing creasing, it is known that grazing illumination is optimal, or very nearly so. ➋ *Figure 38.1* shows a sample image, obtained from a plain white linen handkerchief. To obtain this image, a non-collimated beam was projected from the left. Notice that the "back-ground" intensity varies across the picture, although this can be eliminated effectively, using spatially invariant lighting. Local intensity variations, due to creasing, indicate the varying angle of incidence. Shadows within the "valleys" were avoided by making sure that the light source was not too low.

38.2 Inspection Algorithms

The inspection algorithm consists of three parts:

1. Filtering and thresholding to generate a textured binary image
2. Generating a multi-variate description of that binary image
3. Associating that description with the creasing factor

38.2.1 Stage 1: Filtering

Six methods of processing this image to generate a textured binary image are illustrated below. Any of these might reasonably be expected to form the basis of an effective solution and could be combined with any of the binary texture analysis functions, Stage 2. Asterisks (*) indicate lines

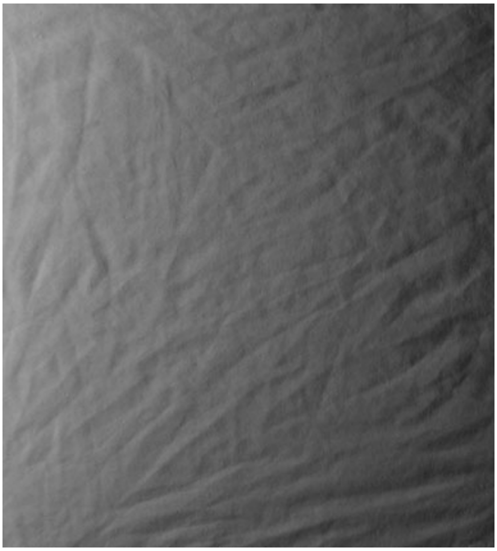

Fig. 38.1
Sample image, creased fabric. No attempt was made to optimise the image quality; better lighting would make the "back-ground" more nearly constant. This was done deliberately, so that the effectiveness of the image filtering algorithms could be demonstrated better

where parameter values might be adjusted to optimise results for different levels of magnification. This is best performed experimentally, which is a role for which QT is well suited.

It is not possible to explain, how each of the scripts listed below evolved while using QT. Human intelligence plays a key part in identifying branches on the search tree that will lead eventually to a good solution. How such decisions are made is a mystery!

38.2.1.1 Method 1: Difference of Low-Pass Filters

The following QT command sequence runs moderately fast and produced the image in *Fig. 38.2*.

```
enc             % Enhance contrast
mdf(7)          % Median filter noise removal*

sub             % Subtract results
heq             % Histogram equalise
thr             % Threshold at mid grey. This command following heq
                  produces an image in
                % which approximately 50% of the pixels are white
maj             % Majority voting filter
edg(8,0)        % Mask edge effects
```

38.2.1.2 Method 2: Local-Area Histogram Equalisation

The following is a rather slow QT command sequence and produced the image in *Fig. 38.3*.

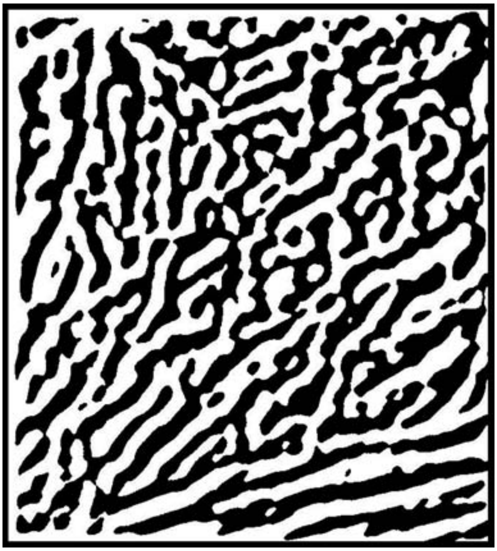

Fig. 38.2
Filtering and thresholding, Method 1

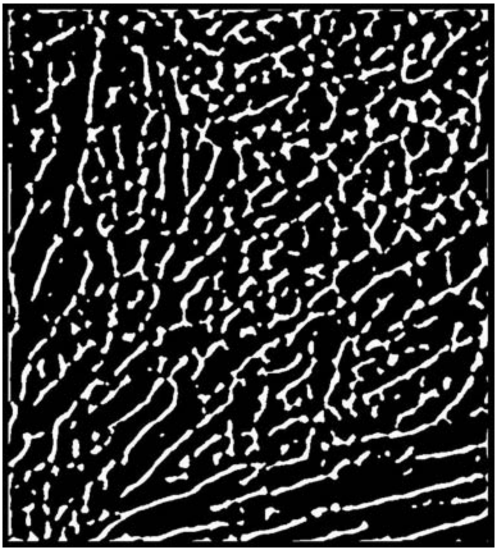

Fig. 38.3
Filtering and thresholding, Method 2

```
enc               % Enhance contrast
mdf(7)            % Median filter noise removal*
caf(7)            % Low-pass filter (averaging over a circular region)*
lhq(15,15)        % Local-area histogram equalisation (This is the slow part.)
thr(128)          % Threshold*
maj               % Majority voting filter
edg(8,0)          % Mask edge effects
```

38.2.1.3 Method 3: Direction of Brightest Neighbour

The following is a moderately fast QT command sequence and produced the image in *Fig. 38.4*.

```
enc                                 % Enhance contrast
mdf(7)                              % Noise removal*
caf(7)                              % Low-pass filter*
dbn                                 % Brightest neighbour
thr(4,4)                            % Select level 4 only*
maj                                 % Majority voting filter
edg(8,0)                            % Mask edge effects
```

38.2.1.4 Method 4: Unsharp Masking

The following is a relatively fast script and produced the image in *Fig. 38.5*. It is akin to Method 1.

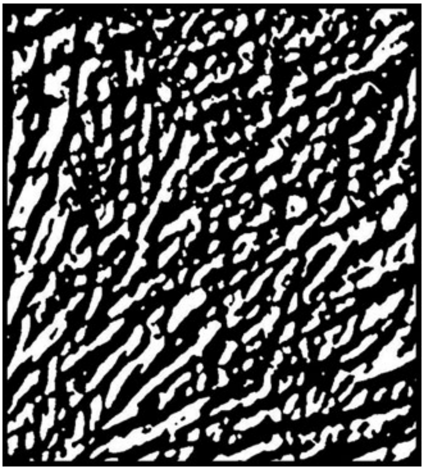

Fig. 38.4
Filtering and thresholding, Method 3

```
enc          % Enhance contrast
mdf(7)       % Noise removal*
caf(15)      % Low-pass filter*
sub          % Subtract
heq          % Histogram equalisation
thr          % Majority voting filter
edg(8,0)     % Mask edge effects
```

38.2.1.5 Method 5: Grey-Scale Opening

The following is a relatively fast script and produced the image in ➋ *Fig. 38.6*.

```
enc          % Enhance contrast
mdf(7)       % Noise removal
opn(15)      % Opening*
sub          % Subtract
heq          % Histogram equalisation
thr          % Threshold
maj          % Majority voting filter
edg(8,0)     % Mask edge effects
```

38.2.1.6 Method 6: Subtracting a Reference Image Created with *rox*

The following is a relatively fast script and produced the image in ➋ *Fig. 38.7*

```
enc          % Enhance contrast
mdf(7)       % Noise removal*
wri          % Save preprocessed image
neg          % Negate
rox          % Row maximum
neg          % Negate. This and two previous commands perform row minimum
wri(1)       % Intermediate result

lrt          % Invert horizontal axis
rox          % Row maximum (runs from left to right)
lrt          % Invert horizontal axis. This and two previous commands
               perform row maximum
             % running from right to left
rei(1)       % Intermediate result
adi          % Add images
rei          % Read pre-processed image
sub          % Subtract
heq          % Histogram equalisation
thr          % Threshold
```

```
maj          % Majority voting filter
edg(8,0)     % Mask edge effects
```

38.2.2 Stage 2: Analysing Binary Texture

Several methods are available for analysing binary texture; again, just a few of the many possibilities are described below. The illustrations are based on the image generated by Method 6.

(a) Count "zero crossings" (black–white or white–black transitions) in preferred directions: horizontal, vertical, ±45°.

Example: count all zero crossings:

```
bed          % Binary edge
cwp          % Count white points
```

Another example, count zero crossings along the horizontal axis

```
con([0,0,0; −1,1,0; 0,0,0])    % Intensity difference between horizontal
                                 neighbours
thr(200)                       % Keep black-white transitions
x = cwp                        % Count white points
```

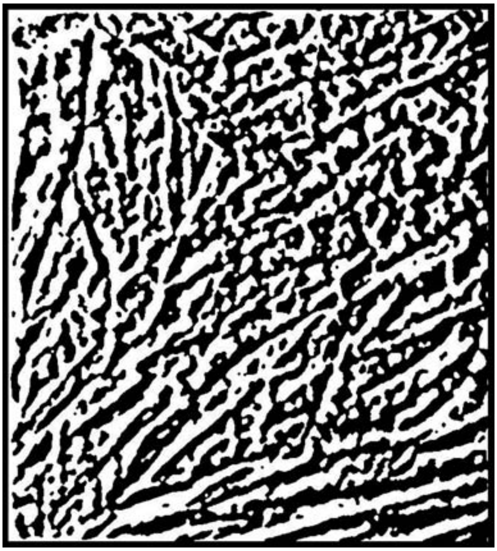

Fig. 38.5
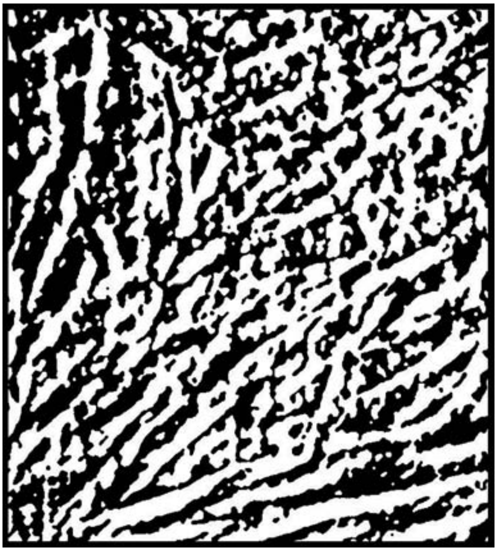
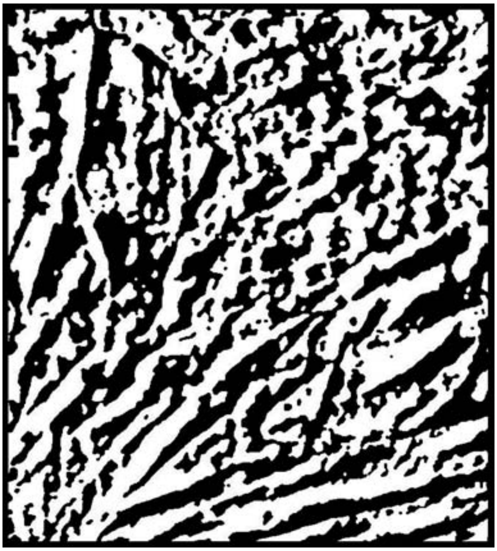
Filtering and thresholding, Method 4



■ **Fig. 38.6**
Filtering and thresholding, Method 5



■ **Fig. 38.7**
Filtering and thresholding, Method 6

(b) Size distribution of the blobs and spaces between blobs using *gft*:

```
gft          % Grass-fire transform measures sizes of
               white objects
wri          % Save image
swi          % Switch images
neg          % Negate
gft          % Grass-fire transform
rei          % Read image saved earlier
sub          % Subtract
hpi          % Display graph plotted in Fig. 38.8
x = dev      % Standard dev. sensitive to blob size
```

The graph shown in *Fig. 38.8* was obtained by applying this QT command sequence to the image in *Fig. 38.7* (*Method 6*)

(c) Horizontal run-lengths of the blobs and spaces between blobs using *rlr*. (Use *rlc* for measuring vertical run-lengths.)

```
rlr          % Run-length along each row
wri          % Save image
swi          % Switch images
neg          % Negate
rlr          % Run-length along each row
rei          % Read image saved earlier
sub          % Subtract
hpi          % Display graph – similar to that above
x = dev      % Standard dev. sensitive to blob size
```

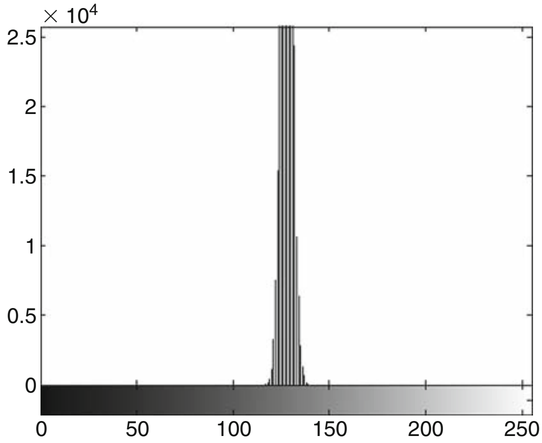


Fig. 38.8

Texture analysis. The width of the peak is sensitive to the sizes of the blobs and the spaces between them, which are dependent on the amount of creasing

This produces a graph similar to that shown in *Fig. 38.8*. Again, by measuring the width of the peak, it is possible to estimate the creasing factor.

(d) Morphology with directional structuring elements. The following table shows the effect of applying the erosion operator, with linear structuring elements inclined at ±45°, to the image shown for Method 6. In this case, the area (number of white pixels, function cwp) is more stable than the blob count (cbl). Further measurements can be obtained by using structuring elements at other angles (e.g., 0° and 90°) and by using dilation. A combination of erosion in one direction and erosion in the orthogonal direction could also be used to good effect.

Length of structuring element	Structuring element angle = + 45°		Structuring element angle = −45°	
	No. of blobs	Area	No. of blobs	Area
11	149	141,914	207	95,129
21	186	79,936	207	25,400
31	153	45,437	83	6,267
41	117	26,994	27	1,607
51	76	16,958	10	300

(e) Morphology with variable-size structuring elements. This is a variant of the method of analysing binary texture just described. It uses cross-correlation to measure the effects of (morphological) opening, with variable-size structuring elements. Several values are computed and are then used to derive a polynomial equation. In this way a statistical measure, estimating blob size and inter-blob spacing in the binary image, is calculated. Here is a function to do this:

```
function p1 = analyse_binary_texture(n,r)
% analyse texture in a binary image by applying opening with variable-size
structuring elements (1/2)
global current
global alternate
original = current;                    % Keep image
for i = 1:n                            % n is size of biggest. structur-
                                         ing element
current = original;                    % Recover original image
opn(i),                                % Opening – see notes below
alternate = original;
a(i) = icc;                            % Correlation coefficient
end
figure(2)                              % Will plot graph in figure no. 2
plot(a,‘xk’)                           % Plot points just found
title(‘‘Correlation coefficient’’)     % Title for graph
hold on                                % Keep what we have plotted
p1 = polyfit(1:n,a,r)                  % r-th order polynomial fits a(1:n)
```

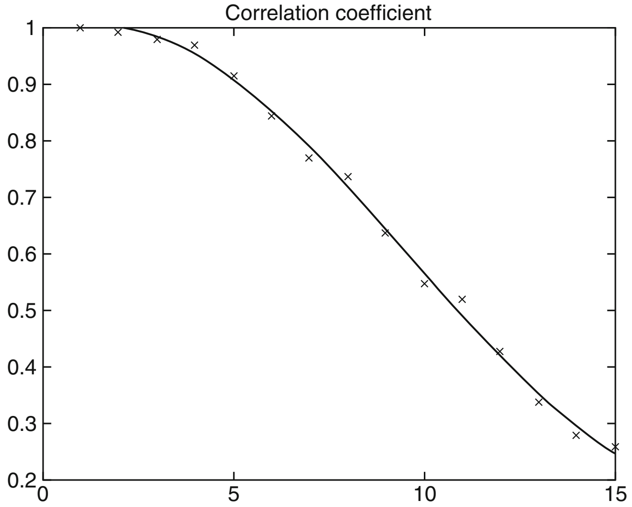

Fig. 38.9
Creasing is measured by finding the position along the abscissa where the correlation coefficient is equal to 0.5

```
q1 = polyval(p1,1:0.1:n);               % Evaluate polynomial
plot(1:0.1:n,q1,'-k')                   % Plotting polynomial
hold off                                % Finished plotting in figure no. 2
figure(1)                               % Revert to figure no. 1
swi                                     % Switch images
current = original;                     % Recover original image yet again
subplot(1,2,1), imshow(current)         % Draw current image
subplot(1,2,2), imshow(alternate)       % Draw alternate image
```

By evaluating the function

$$p = \text{analyse\_binary\_texture}(15, 3)$$

the coefficients (contained in the output vector p) of the following third order polynomial were obtained

$$y = 0.0004x^3 - 0.0118x^2 + 0.0361x + 0.9705.$$

A graph was then plotted (Fig. 38.9). To estimate the creasing factor, we might conveniently solve this equation, either numerically or by inspecting the graph, to find x (i.e., structuring element size) such that $y(x) = 0.5$.

38.3 Concluding Remarks

Naturally occurring texture cannot be defined precisely in mathematical terms. In any project involving texture analysis, human judgement must be the final arbiter, so the idea that there exists a unique *optimal* solution is non-sensical. For this reason, it is necessary to resort to experimental methods for designing heuristics for recognising textures. In this chapter, we have presented results for several ideas, in order to demonstrate that many *reasonable* solutions exist. While it is easy to suggest new texture filtering methods, it is not obvious, which if any of the six heuristics illustrated for Stage 1 could for the basis for a satisfactory solution. Evaluating them in combination with an appropriate Stage 2 method requires a considerable amount of further experimental work. This is problem specific and no amount of theoretical analysis can replace it! Several additional points should be noted:

- Low-angle (grazing) illumination was used to emphasise the texture of plain white fabric, creased simply by hand. In practice, a carefully controlled creasing protocol should be used. Printed fabric and material that has a patterned weave have not been considered and would almost certainly complicate matters.
- Several methods for Stages 1 and 2 are presented without making recommendations. To so would prejudge the experimental design needed for Stage 3. The large number of possible combinations of methods for Stages 1 and 2 makes it imperative that an appropriate set of computational tools is available.
- A primary aim of this chapter is to demonstrate that it is easy to suggest a multitude of "reasonable" solutions but these can only be judged subjectively. By using an interactive image processing system, like QT, a vision engineer can test and evaluate ideas quickly and easily. Many of these may simply be guesses, inspired by prior experience. The strength of systems like QT lies in the ease with which new ideas can be either dismissed as wild fantasy, or accepted as valuable new knowledge. An interactive image processor is well suited to "fine tuning" Stage 1 procedures, by adjusting their control parameters and seeing the results displayed almost immediately.
- The QT command *esr* facilitates the batch processing of a large number of images. So,

  $$[A, B, C] = esr(X, Y, Z)$$

  performs the operation X on all JPEG/TIFF image files in folder Y and leaves the processed images in folder Z. (Defaults are defined for Y and Z.) Any non-image files in folder Y are ignored. The output variable C is an array of A rows, each containing B measurement values.

39 Environmental, Social and Ethical Issues

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_39,

39.1 Introduction

J. H. Lemelson anticipated the subject now known as Machine Vision as early as 1954 [1]. (He filed 76 relevant patents but their lien on major Machine Vision manufacturers was released by a land-mark ruling in the U.S. Court of Appeals for the Federal Circuit in 2005. The judgement was made on legal, not technical, grounds.) However, it was not until the 1970s that serious work began. The 1980s began optimistically but growth slowed later in the decade, triggered by a lack of trust in the technology among US automobile manufacturers. The 1990s witnessed a great acceleration in technical progress and the rate of installation of new systems. Growth continued erratically in the first decade of the new century; world-wide sales of Machine Vision hardware are expected to reach $2,100 million by 2012 [2]. Major market sectors at the time of writing include automobile, aerospace, electronics, glass and plastic containers, printing and food. Non-industrial applications using similar technology include reading automobile number plates, recognition of faces, eyes (iris) and fingerprints. The latter enjoy the widest public awareness, being mentioned occasionally in televison news bulletins and popular drama productions.

It is an auspicious time to take stock of the situation and to raise awareness of both the dangers and potential benefits of Machine Vision technology. It has been said that the purpose of history is to avoid making the same mistakes again. What then are the lessons that we can learn from this relatively short period of development of our subject? The main one is that the expectations and hyperbole of the mid-1980s lead to a rapid growth of interest and the subsequent demise of a large number of companies involved in developing and selling Machine Vision products. The situation was very serious in Europe but in the United States the effect was catastrophic. Even now, we cannot build a Machine Vision system that can work properly in uncontrolled lighting, as some vendors have allowed their customers to believe. However, the market has recovered. The events of the mid-1980s should have been anticipated, since exactly the same effect had happened in the early 1970s to Pattern Recognition research, which the author witnessed at first hand. Many younger researchers in Pattern Recognition are unaware of the real reasons for the decline in research funding and interest then. Contrary to popular belief it was not the discovery of the limitations of multi-layer perceptrons but the realisation that the subject had been oversold. The technical achievements in both Machine Vision, in the 1980s, and Pattern recognition a decade and a half earlier, were judged by funding agencies as being not commensurate with the investment of time and money that had been made. It is important to understand why this happens. It is, in the author's opinion, an almost certain consequence of the process of obtaining research funds. Even young and innately enthusiastic researchers are encouraged to "oversell" their particular branch of technology, in order to convince the guardians of the research funds that their work should be sponsored. The author has observed that many people in the latter category expect "good" results in a far shorter period of time than is realistic. It is imperative that older, more experienced workers, who witnessed the events of earlier years, should tell their younger colleagues what really happened. As we shall see, "overselling" is one of the most pernicious errors to have afflicted Machine Vision and Pattern Recognition research. Older colleagues will recall that this happened to Cybernetics as well. It is interesting to note that subject labels, such as "Pattern Recognition" and "Cybernetics" have a period of popularity and then fade, to be replaced later by other "more modern" terms. The name "Automated Visual Inspection" has been replaced to a large extent by the more general term "Machine Vision", but this is due in part to the broadening scope of the subject, which now includes inspection, grading, sorting, counting, measuring, process monitoring, locating, and guiding robots.

An industrial Machine Vision system is usually purchased with one or more of the following claims by the vendor in mind:

(a) It will reduce product cost
(b) It will improve product reliability and/or safety
(c) It will improve process efficiency
(d) It will improve operator safety

The author suspects that (a) and (b) usually influence the decision to buy (or not buy) a Machine Vision system most heavily. Their justification for this is based on personal observation and anecdotal evidence received from his colleagues.

Appendix C presents a set of points in the form of "proverbs", intended to guide designers of Machine Vision systems. In the same manner, we shall summarise our main conclusions here in the form of "bullet points". The major topics to be considered in this chapter are:

(a) The impact of Machine Visions Systems on the environment.
(b) The implications of Machine Vision for product and factory safety, the health and well-being of employees.
(c) The importance of intellectual integrity in a field requiring a careful balance of advanced ideas and technologies.
(d) Commercial and managerial integrity.
(e) The impact of Machine Visions technology on employment prospects, particularly for people with low skill levels.

There are, of course, many general ethical, legal and moral issues which relate to all aspects of selling and procuring high-technology equipment. In this chapter, we shall concentrate upon those that refer specifically to Machine Vision.

39.2 Environment

Machine Vision systems are not particularly demanding in the level of resources they require. Of course, they are never likely to form a very high volume product. They include electronic circuits but, apart from that, do not require the use of particularly unpleasant materials in their construction. The real impact of Machine Vision systems on the environment is likely to be very positive. Certainly, the potential exists for this to happen. There several ways in which Machine Vision systems could provide very beneficial effects upon the environment.

- Machine Vision can reduce scrap by sorting "good" and "defective" items

  In 1979, the author was involved in a project which attempted to reduce scrap by sorting a "polluted" batch of fasteners into "good" ones, which could be re-used, and a much smaller number of "defective" items, which were truly worthless, except as scrap metal. At that time, the company involved estimated that, at a single factory, they were discarding about £700–£800 of *good* fasteners in polluted batches, *every week*. (This figure should be increased by multiplying by a factor of about ten, to estimate the value in present-day US dollars.) The implication is that, by sorting the polluted batches, the company would be able to meet the same production levels with a reduced demand on both raw materials and energy.

- Machine Vision can reduce the need for high quality raw materials

  On a more general level, we note that it should be possible to employ Machine Vision systems more effectively than at present by reducing, or at least limiting the demand for high-quality raw materials. For example, vegetables and fruit might be sorted/cut under the control of a vision system. This should allow a food-processing system to make good use of raw materials which have localised defects, such as bird pecks, insect holes, bruising, etc. Automatic cutting of leather (for shoes, bags, car seats, etc.) has been studied using an intelligent vision system to identify point and small-area defects. Similarly, more efficient use of timber might be possible using a cutter guided by a vision system. Since a vision system is potentially able to increase the efficiency of sorting, grading, packing, identifying and locating defects, on a wide range of materials and products, there is the potential for a significant benefit to the environment.

- Machine Vision can sort waste for recycling

  Automatic sorting of waste, prior to recycling, is one direct way in which Machine Vision could benefit the environment. There is considerable scope in this general area, particularly if we know what to expect the vision system to see. Until the 1970s, it was common practice to recycle milk, beer and soft-drink bottles, etc., by returning them to the supplier for washing and refilling. (In the past, many a young person has raised a handsome sum of money by returning empty bottles and collecting the deposit.) This practice has, of course, fallen out of favour. This is due, in part, to the difficulty of guaranteeing the quality of the recycled material. Vision systems should be able to help, for example, by sorting small spent batteries from consumer electronics.

- Packaging could be coded to aid identification of scrap by a vision system

  The task of sorting/verifying that the correct type of recycled container is present during refilling would probably be made much easier if scrap-identification codes were to be placed on all such products. Consider for example, the potential benefits that might be obtained if the major suppliers of soft drinks were to use vision systems to assist in the re-use of their bottles and cans. An effective Machine Vision system is likely to be necessary if we are ever to achieve efficient sorting of bottles rather than regarding them merely as cullet. It is folly to throw good glass-ware into a bottle-bank, since the energy cost of reheating cullet is the same as the cost of heating the raw materials used in making glass. (Heating is a major component in the cost of making a bottle.) By "rescuing" certain popular types of bottle, before they are smashed in the bottle-bank the energy savings could be significant. There are certain types of container for which recycling would not be safe but for many non-consumable products the dangers would be minimal. A vision system could, for example, inspect returned bottles of toiletries, after washing, to check for residual contaminants and structural integrity.

- Autonomous machines could clear litter in factories and streets

  We are all aware of the growing problem of litter in our streets and other public. Research into autonomous vehicles is progressing apace. The author suggests that developing self-guiding machines that hunt and gather litter would be an ideal application of Machine Vision. Of course, such a system would need to use vision to search for paper, plastics, cans, bottles, etc., Some common types of litter, e.g., soft drinks cans, fast-food wrapping could perhaps be made more be clearly identifiable by making it fluorescent. Industry needs similar systems that are able to perform tasks such as cleaning toxic, carcinogenic, biologically active and radio-active waste from factory sites and plant. An autonomous vacuum cleaner, guided by vision, would be very useful and would readily find application in a wide variety of industrial applications.

39.3 Product and Factory Safety

In many hazardous, or simply unpleasant, situations in which people are currently employed, there exists the possibility of using a machine to improve safety and/or avoid health hazards.

- Vision systems can protect workers from dangerous machines.

  Vision systems can be used to provide a "safety curtain" to protect workers who venture too near dangerous machines with fast moving parts, such as robots, power presses, stamping machines, metal-cutting machines, etc.
- Cost is no longer a barrier to installing a vision system to improve safety.

  Vision systems are able to perform well in a variety of relatively undemanding tasks that hitherto would have been regarded as insufficiently important to justify their use. For example, simple and inexpensive vision systems might be used to perform the following:
  - Monitor stacking of cartons
  - Monitor leaks, spills, etc.
  - Ensure machine safety guards are in place
  - Make sure that oven doors are closed
  - Check the floor for spills, obstructions in gangways, etc.
  - Warn workers of approaching fork-lift trucks, etc.
  - Look for oil/chemical leaks
  - Monitor coolant flow in metal cutting machines

  It should be remembered that it is possible to buy quite versatile, low-cost, stand-alone vision units ("smart cameras") and more sophisticated multi-camera systems. In both cases, the *incremental cost* of adding an extra camera can be quite small. The additional hardware needed comprises only low-cost items such as: lamps, fixing brackets, cables, lens, image sensor and its power supply unit. The incremental cost of the software is also small. (Designing and testing a new algorithm with a system such as QT or NeatVision usually takes just a few hours.)
- A person should not do hazardous work if a visually guided machine can do it.

  Given appropriate protection for the equipment and regular maintenance, a Machine Vision system can often reduce, or even eliminate, the need for people to work in conditions that expose them to hazards such as:
  - Very hot air
  - High levels of radiation: laser, strobed lighting, infra-red , ultra-violet, x-ray, and gamma radiation
  - Dust, fumes, smoke
  - Chemicals. These might be in liquid, aerosol or gaseous form. The hazard may be direct, caused by handling dangerous materials, or simply present as a pollutant in the broader working environment
  - Audible noise, ultra-sound and infra-sound

- Vibration
- Heavy or repeated lifting/manipulation

  Robots are already in use for cleaning and repair work inside nuclear reactors. Robots are also used to handle suspected bombs. A robot for ladling molten metal was developed some years ago but did not then use visual guidance. A robot has been developed for shearing sheep. When a human being performs this task, he adopts a poor posture and is therefore susceptible to back injury.

- Operator well-being should be a primary factor when commissioning a vision system.

  An example of an *indirect* benefit to operator well-being was encountered by the author some years ago, in a factory where forged ferrous automobile components were being made. At that time, the forged parts were being inspected for cracks using a magnetic-particle indicator method, which required a person to sit in a very small darkened cubicle, illuminated only by an ultra-violet lamp. The working conditions for the inspector were very unpleasant: the operator was in a tiny, dark depressing enclosure, exposed to the kerosene-based magnetic-fluorescent "ink" which is used to highlight the cracks. This environment is also very noisy. The prime motivation for the project, to build a vision system to inspect these forged components, was partly economic and partly motivated by the need to ensure higher product reliability. The benefit to the factory workers was viewed as being incidental but welcome.

- Legislators, employers and labour unions should all be made aware of the potential advantages of machine vision in avoiding exposing workers to unhealthy/unpleasant working conditions.

  The concept of "reasonable means" to define the limits of what is required of an employer in protecting his workers is enshrined in law. Engineers need to educate legislators, employers and labour unions that this includes the use of vision systems for inspection, process monitoring and control. Of course, the legal expectation of what is "reasonable" in terms of factory safety changes as technology advances. The education of thes groups is therefore ongoing.

- Legislators, employers and labour unions should all be made aware of the possibility of using machine vision to improve product safety.

  Again, the limit of what is regarded as "taking reasonable care" should be redefined in the light of recent advances in Machine Vision. It is only a few years since one of the author encountered several dangerous defects in everyday items of glassware. All of these could have been detected in the factory by a vision system. Techniques for inspecting bottles, jars and tumblers had been published 10 years prior to that. The author does not accept that it is a valid defence to say that no machine was available commercially, since the techniques for detecting these particular types of defects had been validated many years before.

39.4 Intellectual Integrity

It is clear to anyone who has worked in Machine Vision system development or research that the devices are complex, because they combine many different types of technology, and the algorithmic/heuristic procedures they use rely upon subtleties that are not obvious to the casual observer. It is especially important to approach working in Machine Vision with an appreciation that the real difficulties lie in the systems integration.

- Generalisation without proper experimental evidence is always dangerous

  Unfortunately, it is a common experience to find that a vision systems engineer, working for a manager who does not fully appreciate the technical nuances, experiences a lot of pressure to compromise on design principles. For example, a non-technical manager might well fail to appreciate that a vision system designed to inspect *clear* glass bottles might not work properly on clear glass jars, green or brown glass bottles, or on clear plastic bottles. (The side walls of the last mentioned are usually thinner and the refractive indices of glass and plastic are different.)
- What may seem like similar tasks to us may be quite different to a machine

  For sound commercial reasons, some vision companies focus on niche markets. For example, a company might produce a machine for inspecting bare printed circuit boards. It is all too easy to assume that the same machine can be modified slightly to inspect populated PCBs. In fact, it may be much easier to adapt that machine to inspect some completely different product, such as cloth, CDs, printing, etc. A would-be customer should not therefore expect the supplier of a machine vision system, capable of tackling one task, to be able to develop reliable and robust techniques for use in the same general market area.
- Do not assume that you are an expert on vision, simply because you can see

  One of the most common errors which causes significant problems is that a very experienced practitioner in Machine Vision is told by non-experts how to solve a problem. (The author has suffered this many times!) However confident or well educated the speaker, when a non-expert says "Of course, I can see at a glance how to solve this problem", a vision engineer is about to be told *erroneously* how to do his job. This mistake is particularly awkward if the speaker is the supervisor of the hapless vision engineer. Undue pressure from a non-expert manager can result in two undesirable events:

  1. The engineer is expected to achieve things that are physically impossible, or simply very difficult to achieve and will render the final solution unreliable.
  2. The technology is oversold to the would-be customer, who is not sufficiently well versed in the technology to be discriminating enough to sense its dangers.

  Customers do this as well! Indeed, one wonders sometimes why they bother to consult the vision company at all. The problem is caused by one commonly held fallacy: that introspection is able to reveal how the inner mind works. Quite simply it does not and no self-respecting vision engineer should ever listen to such foolish ideas.
- It may be impossible to collect a representative set of test samples

  The reason is that a manufacturing system is expensive to build and operate, so that it is only ever allowed to make "good" products for any significant length of time. ➔ *Figure 39.1* As soon as a cluster of defective products is detected, the operating parameters of the manufacturing system are adjusted, so that it quickly reverts to making "good" products again. The result is that very large numbers of "good" products are made but very few "defective" ones. Hence, it is possible that insufficient numbers of the latter group will be available to satisfy the requirements of traditional Neural Network training methods, which need large numbers of samples from two (or more) classes. Learning procedures that are able to use a single class of patterns are required in this situation. Even then, there are difficulties in evaluating the learning process and demonstrating to the customer that it has been successful. It is simple intellectual dishonesty to disregard the difficulties just described and to persist in using techniques which are manifestly unsuitable for the

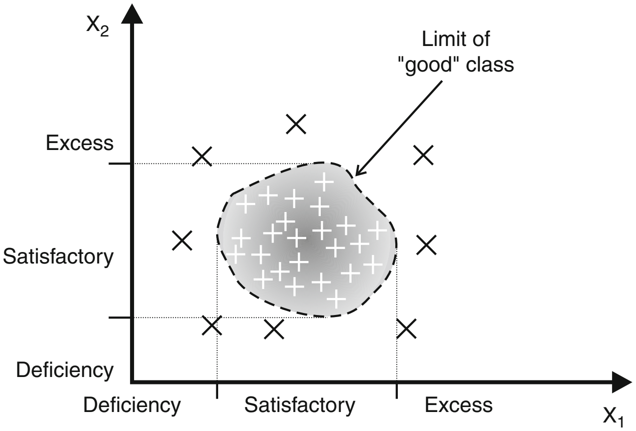

Fig. 39.1

Collecting enough representative data can be difficult. It is possible to collect very large numbers of "good" widgets (*vertical crosses*). However, manufacturers do not like making "faulty" widgets (*diagonal crosses*), because they cannot sell them. Except in the simplest cases, it is impractical to collect a representative sample of all types of "faulty" widget. When there are two parameters measuring the "quality" of an object, we need at least 8 (= $2 \times 2 + 2^2$) samples of the "faulty" class to defines the surface separating them from the "good" class. (This is the absolute minimum; in practice many times this number is required.) When there are N parameters, this number rises exponentially, as ($2N + 2^N$). Notice that it is probably impossible to adjust the manufacturing plant to make all types of defect

particular task in hand. A similar problem arises when trying to evaluate rule-based decision-making processes.

- Do not be economical with test samples

  It is very easy to misrepresent the truth about the performance of a vision system by presenting it with a few carefully chosen examples, during a demonstration. Machine Vision is particularly prone to this, since the factors affecting system performance are very subtle. For example, an inspection algorithm may work very well if the products are clean and dry. However, any appreciable amount of oil, dirt or moisture on them may confuse a vision system so badly that the system will be useless in the factory.

- Machines do not generalise as well as humans do

  A particular colour on a printed package may change in quite a subtle way, when the ink is supplied by a different company, or the carton is interchanged with one of a slightly different shade. A colour recognition system will not necessarily be able to cope with such changes, even though they are quite insignificant and unimportant to a human being.

- Exaggerated claims discredit the whole industry

  It is widely accepted that hyperbole is an integral part of selling. However, there is an important distinction to be made between extolling the virtues of one machine relative to another and knowingly making claims that are factually incorrect. As we have already emphasised, Machine Vision is characterised by having a large number of very subtle features that can seriously affect the performance of a given system. This makes the subject particularly sensitive to unrealistic claims. Moreover, customers do not always have the ability to discriminate between hyperbole and untruth. Eventually, of course, the untruths and exaggerated claims bring discredit to reputable manufacturers and equipment suppliers. We cannot emphasise enough that danger lurks in the subtle nuances. Every systems engineer knows this. The problem for vision engineers is, perhaps, as acute as it is in any other technology.

- For a vision system, appearance is everything

  The distinction between *composition* (e.g., made of brass) and *finish* (e.g., painted bright blue) is one classic point in Machine Vision circles. It is tempting to say that objects (of a given shape) made from any metal may be inspected by a certain system, However this is unlikely to be true unless, they have all been coated in the same way. Dull lead, polished brass or copper, oxidised steel or galvanised tinplate are so different that it is very unlikely that a single machine vision system will be able to cope with them all -unless, of course, they have all been painted bright blue!

- We must be seen to be up to date with technology!

  There is a seemingly natural desire, among some people, to employ automation, even in those situations where a simpler, more reliable technology might work just as well, possibly even better *and* be cheaper. Straightforward solutions exist for an enormous range of industrial inspection and measurement tasks. It is good practice, therefore, to question whether vision is really appropriate *in every application*. Employing an overcomplicated and inordinately expensive technology, when a simpler one will suffice, is simply poor engineering practice. This must be balanced against the enormous versatility of vision-based sensors.

- The machine may not be able to see a feature even though a person can

  Place a freshly laundered white handkerchief on a piece of white paper. Can you see it? In most cases a person can see it quite easily but it is doubtful whether a vision system will be able to do so, accurately and reliably. Human beings are extremely clever at discerning very fine differences in shade, colour and texture. Present-day vision systems are not nearly so adept. This is partly due to the fact that they use sensors that cannot match the performance of the eye, and partly because existing vision algorithms are very clumsy, compared to human beings. Since a machine may not be able to discern fine differences, we have to begin our design exercise with an open mind about what a machine will be able to see. Neither the vision engineer's manager, nor the customer, should try to exercise undue pressure to achieve what they erroneously "know to be possible". Expressed in simple terms, the maxim is "Trust the vision system, not your own eyes".

- All results should be reproducible but is the data?

  One well known supplier of vision systems produces a wall chart containing the following maxim:

  ► The results of all system performance demonstrations should be reproducible, statistically characterised as to be repeatable and be statistically verifiable.

  When inspecting "hard" engineering products, such as spark plugs, electrical switch contacts, carburetor components, etc., the advice given above is undoubtedly very well worth following. In practice, however, the situation is often far too complicated for this to be useful. To understand why, consider a bakery. Loaves and cakes cannot be preserved indefinitely, even by freezing, so any results we obtain with them are not reproducible. We cannot make replicas of cakes that are totally realistic. (Replicas of food items are made for the film and television industries and, for this purpose, they are perfectly adequate. However, they do not fool a human being upon close inspection.) The concept of "statistically verifiable" is not valid either, particularly when applied to a complex manufacturing plant, such as a bakery, where there are numerous independent variables. Even if all of the plant parameters and measurable material quantities (e.g., oven temperature, dough moisture content, etc.), could be measured, there remains an enormous number of unmeasurable and uncontrollable variables (e.g., bran and gluten content of the flour, sugar grain size, etc.), which render the concept of statistical stability invalid. Any operation such as baking, which relies upon natural materials is prone to variations of material characteristics which makes this piece of "good advice" unworkable.

- Vested interests often influence judgement

  A well-known and well respected journal once refused to publish an article written by the author. One of the referees, who was described by the editor of the journal as a "venerable and very well-respected figure", referred to certain results quoted in the article as "having been faked". (Another journal subsequently accepted that article. Similar work has also been published several times elsewhere. To prove his professional integrity in this matter, the author even offered to stage a public demonstration of his work. That offer was declined!) Why should an eminent person with a fine reputation make such an accusation? One possible explanation is that the referee had a certain predisposition in the matter and did not wish his/her academic standing to be diminished. Perhaps the problem was caused simply by an error of judgment but the fact remains that an idea, which has since gained respectability by independent refereeing, was nearly denied to the waiting world! In a subject with as many subtleties as Machine Vision possesses, there is no room for blinkered thinking. There exists a set of guidelines outlining the rôle of editors, referees and authors, who all have a responsibility to each other and to the wider technical community. There is much anecdotal evidence about prejudice within funding review committees and much could be written on this vexed question. However, these broader issues are not our main concern here, where are concentrating on question of integrity relating specifically to Machine Vision.

39.5 Commercial and Managerial Integrity

It is often claimed that Machine Vision is a very flexible technology. While there is no doubt that this is technically true, there is a practical difficulty which has, so far, made this an empty claim: there are simply not enough properly trained vision engineers to realise the full potential.

- We must not claim versatility for Machine Vision when there is not enough engineering effort available to realise its technical potential.

  There is no truly general-purpose industrial vision system on the market today. To explain the importance of this fact, let us consider just one well-known company, which has over 50,000 products. The company operates a policy for innovation and invention which ensures that, at least, 25% of sales are based on products that are less than 5 years old. Simple analysis shows that ten new products are being introduced by that single company each working day. We simply do not have sufficient skilled labour to be able to design vision systems to inspect or control the manufacture of all of them. Of course, this situation is repeated many times over, in every industrialised country. If Machine Vision is truly a versatile technology, we ought to be able to build equipment that can inspect a significant proportion of new products. Due to man-power limitations, we cannot do this for more than a tiny proportion of all potential applications. Hence the claim that Machine Vision is a versatile technology is an empty one.

The purpose of this book is, of course, to make more people aware of the potential and subtleties of Machine Vision technology. In this way, the contributors to this book hope to train more vision engineers, so that the bottleneck can be relieved and more successful applications achieved.

- Do not use vision when a simpler technology will suffice

  Since it is potentially very versatile, it is all too easy to rely upon Machine Vision technology, when a simpler one will suffice. In its usual modern English translation, Occam's Razor states

  ► It is vain to do with more what can be done with less.

  Many alternatives exist to Machine Vision, which for many people is beguiling, simply because it is perceived as an advanced technology. Less sophisticated technologies are often more appropriate on both technical and commercial grounds. In this situation, it is regrettable that many vision systems suppliers still persist in trying to sell their products. Unfortunately, this brings discredit on the whole vision industry.

- A vision engineer should be present when demonstrating the system.

  As we indicated earlier, Machine Vision contains many subtleties that are not obvious to a person with normal sight but who lacks comprehensive training in the technology. It is all too easy to provide a misleading answer to a seemingly straightforward question from a customer. Many questions relate to the ability of the vision system to generalise as the following question shows:

  ► You have successfully shown that the system can inspect brown widgets. Can it inspect green ones as well?

  It is absolutely essential that the answers to such questions are only given after appropriate and detailed experimentation. Offering a bland affirmative answer, without proper experimental evidence is totally unjustified and constitutes improper professional behaviour. Experienced vision engineers would not dare to answer without experimental evidence!

- False impressions may be given on purpose, accidentally or by neglect.

  An example of this was evident some years ago in a series of presentations by a well known vision equipment manufacturer, which persistently showed unprotected cameras hanging from a gantry in a steel-works. Since no verbal reference was made to this, there was a subtle implication that camera protection is unimportant and can safely be ignored. Every professional engineer sees the misleading impressions that glossy demonstrations at exhibitions and sales literature can bring. References to terms such as *real time*, *user friendly*, *industry standard*, etc., are technically meaningless, since they have no formal definition. The first of these, for example, implies quite a different time scale in relation to an automated baking plant (minutes) and power press (milliseconds). "Ambient light" is another ill-defined and often confusing term. Operating a vision system within a factory is quite a different matter from doing so in an open field, where the variations in light level are very much greater.

- Prove the system before selling it

  We have repeatedly emphasised that it is impossible to design a vision system while sitting at a desk, or drawing board. For the same reason, it is impossible to build a general-purpose system that is not programmed or adapted in some way to the specific task in hand. It is therefore very unwise to purchase a system that is claimed to be "general purpose", without testing it on the specific application.
- Training and post-sales support both form an integral part of supplying a vision system

  A proper appreciation of the factors that influence a vision system is essential, if the maximum benefit is to be obtained. Prior to installation of the system, the user should be alerted to the importance of such issues as following a regular maintenance procedure, surface finish of the product, stray light entering the camera, and local atmospheric pollution, due to fumes, spray, smoke and dust. After commissioning the system, there will often be occasions when the system is not working properly because some such lesson has been forgotten. The equipment supplier should anticipate this and budget accordingly.
- Avoid built-in dependency upon one supplier

  Contrary to what has just been said about the need for providing good after-sales support, there is a danger that the customer will become dependent upon that one company and therefore be unable to make the mental switch necessary to refer to a new company, or a consultant. Customer dependence on one supplier has obvious dangers for the long-term development of the subject.
- The terminology and concepts of Machine Vision are not unique to any one company

  It does a company no credit to obscure the operation of a machine by using words and phrases that are not well understood in the academic community. The supplier of Machine Vision equipment should avoid the use of jargon of his own invention; standard, well-understood engineering and scientific terms should be used, so that an independent consultant can evaluate the machine.
- Finance is not the only justification for installing a vision system

  All too often, economic considerations are assumed to form the only significant factor influencing the decision to purchase a vision system. Product and factory safety should be given a comparable weighting to that of finance. A professional person must not be "one dimensional" in his thinking. The equipment supplier should emphasise all of the potential benefits of installing a Machine Vision system. The customer should attempt to quantify all of the advantages, bearing in mind that finance is only one of them.
- Design new products with inspection in mind

  The benefits of retrofitting a vision system to an existing manufacturing plant may not be realized. On the other hand, by designing new products with automated visual inspection in mind may be very beneficial. Low-cost fluorescent materials can easily be added to a variety of plastic goods, packaging materials, food-stuffs, toiletries, pharmaceutical products, paints, inks and lacquers, to improve image contrast. This will often make visual inspection easier and more reliable than it might otherwise be. Injection mouldings can often be provided with a tiny protuberance, or an array of dots to enhance vision system performance to identify, locate, or orientate the product. The cost of such modifications may be very small but the effects, in terms of improved system performance may be enormous. Modifying the product slightly may make automated visual inspection both cheaper and more reliable.

39.6 Employment

- Do not attempt to automate jobs done by people with learning difficulties

  A few years ago, the author visited a bakery on a very hot summer day. One employee was working very close to one of the ovens, which, of course, made the poor man even hotter. His task was one which could easily been automated using a visually guided robot. However, he was described by the line manager as being "one of their best workers, who loves his job", even though he has learning difficulties. This was a man who, despite the working conditions, greatly valued his work. Automating that job would have made that man unemployed and possibly even unemployable. Vision gives us the opportunity to automate a lot of low-skill jobs but we should consider seriously the social and humanitarian consequences of doing that.
- Be careful when using vision to monitor staff activity

  A vision system is available for monitoring the movements of people in a shop or factory. One of its main uses is to observe what causes people to stop and look at the products in a supermarket. The appeal of supposedly eye-catching displays can be assessed. The same machine could be used in a factory for watching people as they are working (or supposed to be). Many people will be happy to accept this use of technology but others will, no doubt, liken its use to the excesses of Orwell's nightmare world of "1984". Watching people talking, when their employer thinks they should be working may eventually be judged to be a legitimate use of Machine Vision technology but we do need to debate such issues before it is too late to halt them.
- Automation causes unemployment - but only a little!

  Here, at last, is the one issue which nearly every reader will expect to see in this chapter. The author, like many other engineers concerned with automation and information technology has been taken to task on this topic, by many well-meaning individuals who are concerned about and, in many cases, fear the spread of computer technology. Many times they have been forced to defend their rôle in this development. We are all aware of the pernicious problem of unemployment in Western society. Most people seem to believe that automation is a major factor in creating unemployment. In fact, this is not so, as [3] suggests. This came as a complete surprise to the author, who began writing this essay with a different attitude from the one with which he completed it. While we must not be complacent about the rôle of Machine Vision technology in causing unemployment, this surprising fact does give some encouragement for us to develop our technology further, without undue fear of causing major social problems.

40 Lighting-Viewing Methods

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_40,

Guide: This chapter provides qualitative descriptions of a variety of lighting and viewing methods (LVMs). These are presented in alphabetical order, since there is no natural structure for such a list (➲ *Table 40.1*). There are usually five elements within an image acquisition sub-system: light source, illumination optics, image-enhancement optics, main lens and sensor. The positions of these relative to each other and the object being observed must be carefully selected, to obtain a digital image that is easy to process electronically. The physical layout of the optical sub-system and the choice of appropriate components are of equal importance. ➲ Chapter 7 describes the light sources available, while optical components are discussed in ➲ Chaps. 5 and ➲ 6. Scanners and cameras and are described in ➲ Chaps. 9 and ➲ 10 respectively. ➲ Chapter 8 explains some of the concepts necessary to appreciate the methods described here. Of particular note is that of an illumination diagram. This explains, in graphical form, the shape and position and of the light source in relation to the widget and camera. Notice that the diagrams included in this chapter are not drawn to scale; they merely suggest a design for the lighting-viewing sub-system in broad conceptual terms. A multitude of combinations of the methods described below is possible.

Throughout this chapter, the word "*widget*" is used to denote the object that is to be examined.

When designing the image acquisition sub-system, a vision engineer should normally follows the following steps:

(i) Look at the widget
  (a) In a darkened room, move a "point" light source round the widget. Rotate the widget as well. Watch the way that its appearance changes
  (b) Repeat (a) using a broad light source (e.g., stand in front of a window). Ensure that no light falls on the widget from any other direction
(ii) Bearing in mind the observations in step (1), consult the LVM Catalogue. Choose one or a few possible lighting-viewing methods
(iii) Build a prototype lighting-viewing sub-system based on the idea(s) suggested by the catalogue
(iv) Acquire some sample images
(v) Process these images using an interactive image processing system, such as QT (➲ Chaps. 21 and ➲ 41) or Neat Vision (➲ Chap. 22)
(vi) Adjust the lighting-viewing sub-system and repeat steps (4) to (5), until satisfactory results are obtained
(vii) Design and build the target system based on the prototype

Step (1) is very simple, yet it is always in danger of being omitted. The phrase that summarises this design process is "*Experiment, look and observe*". Over a period of many years, involving numerous applications, the author has found this procedure to be very effective indeed. *Never attempt to design an image acquisition system without moving from the desk!*.

Table 40.1
Alphabetical list of lighting-viewing methods

Title	Method number
3D shape analysis by projecting Moiré patterns	1
All round view of a cylindrical object	2
Anamorphic optics	3
Arbitrary lighting pattern	4
Automatic gain control and auto-iris lens	5
Back illumination of shiny objects (array camera)	6
Back lighting of matt opaque objects (array camera)	7
Back lighting of matt opaque objects (line-scan camera)	8
Calculate the field of view – I	9
Calculate the field of view – II	10
Calibration: calculating spatial resolution	11
Circle of light projecting radially outwards	12
Circular features	13
Circularly polarising filter suppresses glinting	14
Coaxial diffuse illumination	15
Coherent flexible fibre optic bundle	16
Collapse image into line	17
Collecting natural light/sun light	18
Colour filtering	19
Combined back and front illumination	20
Combining several views	21
Conical mirrors view an annulus	22
Continuously moving web	23
Crack detection (ferrous and non-ferrous)	24
Crossed linear polarisers reduce glinting	25
Dark field illumination (array camera)	26
Dark field illumination (line-scan Camera)	27
Detect pimples, pits and changes of refractive index	28
Detecting particles in a swirling liquid	29
Diffuse coaxial illumination	30
Diffuse front illumination	31
Dual orthogonal-beam X-ray imaging	32
Dual-wavelength height measurement	33
Endoscope for inspecting holes	34
Estimating range during image capture	35
Examine the inside of a pipe	36
Fast electronic shutter	37
Fibre optic image conduit/converter	38

Focussed annulus of light	42
Forced thermal emission	43
Generating light with arbitrary spectrum	44
Granular material (pellets) in free flight	45
Grazing illumination	46
Hand-held sensor for fixed-range close-up view	47
Hardness testing	48
Height analysis by projecting patterns	49
High resolution view of web	50
Highly variable ambient lighting	51
Homogenising illumination	52
Hypercentric (pericentric) lens	53
Illuminate top surface only	54
Illuminating a wide moving web	55
Illumination within a hollow cylinder	56
Injecting light into glassware	57
Inspecting a flat moving web using a laser scanner	58
Inspecting a rotating object	59
Internal analysis of an aerosol spray or dust cloud	60
Internal features on transparent objects	61
Laser bore scanner	62
Laser pattern projector	63
Locate object with zero contrast	64
Long focus optical system using mirrors	65
Low-definition range information	66
Magnify one image axis	67
Mapping by projecting multiple stripes	68
Mapping range with polychromatic light	69
Measuring range by projecting patterns	70
Measuring thickness of a thin film	71
Measuring thickness of a thin film	72
Micro-louvres suppress ambient light	73
Microscopic fourier analysis of transparent film	74
Motorised filter wheel	75
Multi-arm image conduit	76
Multi-camera specular and near specular illumination	77

Table 40.1 (Continued)

Title	Method number
Multi-camera structured lighting	78
Multiple views of a widget	79
Multi-spectral image sensing	80
Multi-view stereo imaging	81
Normal viewing of spherical surface	82
Objects on a conveyor	83
Observing bubbles in clear liquid	84
Omni-directional illumination	85
Optically tooled bowl feeder	86
Passive de-speckling of laser	87
Pipe or hollow cone of light	88
Polar-coordinate scan of annulus	89
Projected array of spots	90
Protecting the camera using a periscope	91
Protecting the camera with fibre optics	92
Protecting the camera	93
Range measurement using talbot fringes	94
Reading printing in photo-chromic ink	95
Real-time optical filtering (high-pass)	96
Ring of light projecting inwards	97
Rotate image using a dove prism	98
Silhouette from multiple shadows	99
Silhouette in restricted space	100
Size measurement in free fall	101
Split field viewing	102
Stabilised lighting	103
Steerable image sensor	104
Steering a laser beam in two directions	105
Stroboscopic illumination	106
Structured lighting	107
Switched-colour light source	108
Telecentric lens	109
Using mirrors to view front and back	110
Very large membrane mirror	111
Vibration analysis: speckle pattern interferometry	112
View annulus, ignoring central disc	113
View flat surface without glinting	114
View orthogonally polarised images	115
Viewing a bore	116

Table 40.1 (Continued)

Title	Method number
Viewing aerosol spray	117
Viewing inside an irregular transparent object	118
Viewing small objects (short focus lens attachment)	119
Viewing small objects/features	120
Viewing small objects	121
Viewing stress in a transparent sheet	122
Viewing through a small aperture	123
Visual sensor mounted on robot	124
Visualise changes in refractive index	125
Visualising heat distribution	126
Wireless image acquisition	127
X-ray imaging	128
Zooming by movement	129

40.1 Method 1: 3D Shape Analysis by Projecting Moiré Patterns

OBJECTIVE To obtain low-precision height information quickly about a smooth surface.
TYPICAL APPLICATIONS Measuring machined components, castings, forgings, mouldings, extrusions, etc.
EQUIPMENT Ruggedised projector, fitted with a fine grating. The camera views the object through a similar grating. The gratings may have patterns consisting of a set of parallel lines, arrays of spots, circles, or other curves.
CAMERA Array.
MOTION Static.
GEOMETRY The widget should not possess any step-like features, since they produce "broken" Moiré-pattern curves that are difficult to interpret (This requirement can be relaxed if verification, not measurement is to be performed).
MATERIALS The surface should be of nearly uniform reflectivity.
REMARKS Moiré patterns are created by overlaying one set of parallel lines/arcs, or a grid, onto another similar, but slightly different set. ➋ *Figure 40.1a* shows the optical layout, while ➋ *Fig. 40.1b–j* demonstrate the sensitivity of this method. Moiré patterns do not provide absolute measurements of surface height, since they do not indicate the direction of its slope. If the surface has a known shape, it may be advantageous to project a set of curves, instead of lines. If a set of projected lines/curves has a resolution similar to that of the camera's photo-detector array (taking the lens magnification into account), additional moiré stripes can be created (➋ *Fig. 40.1e–g*). Hence, care has to be taken, to avoid adding a secondary moiré pattern, due to the camera's finite resolution. Alternatively, it is possible to exploit this effect, by modifying the optical arrangement: we simply remove the grating near the camera. The projected line spacing should be equal to that of the camera's photo-detector array, which acts as the second sampling grid. Care must always be taken to avoid creating diffraction effects, due to the use of very narrow lines on the grating.
LAYOUT DIAGRAM AND EXAMPLES ➋ *Figure 40.1*

Moiré patterns. (a) Optical layout. (b) Parallel lines, inclined at 4°. (c) Superimposing the previous image onto an identical set of lines, inclined at 0°. (d) Grid, representing a video camera's photo-detector array. (e) Superimposition of image (b) and the same image rotated by a small angle. (f) Intersection of the binary images in (b) and (d). (The outputs from the camera's photo-detector array are proportional to the spot sizes here.) (g) Applying a severe blurring (low-pass) filter eliminates the fine detail. (h) Set of parallel arcs. (i) Moiré pattern, produced by the previous image and a set of vertical parallel lines. (j) Superimposing image (h) onto a similar set of arcs that have been rescaled slightly along the horizontal axis

40.2 Method 2: All Round View of a Cylindrical Object

OBJECTIVE To obtain an all-round view of cylindrical objects: 360° in the horizontal plane (The top and bottom of the cylinder are not viewed).
TYPICAL APPLICATIONS Inspecting corks, helical springs, various electrical and mechanical components.
EQUIPMENT Two ring lights.
CAMERA Three or more array cameras.
MOTION Static.
GEOMETRY Cylindrical.
MATERIALS The objects must not scratch, score or stain the feed tube.
REMARKS The widgets are fed and viewed while they are held in position within a glass tube. A wire cage might be used instead, although this might obstruct the view of the widget surface. Care must be taken to design the feed channel in such a way that the widgets do not jam. Three, four or more cameras can be used and would normally be spaced evenly around the widget. The feed mechanism can be modified to examine extruded products, such as confectionary bars and other food products), With the arrangement show in ➲ *Fig. 40.2*, lighting is uniform all the way round the widget but can vary in the vertical direction. By placing light sources above and below the viewing cameras, it is possible to minimise these variations.

LAYOUT DIAGRAM ➔ *Figure 40.2*

40.3 Method 3: Anamorphic Optics

OBJECTIVE To obtain controlled geometric warping of an image, to simplify, or speed up, the image processing operations.

EQUIPMENT Mirror or lens, specially made to achieve the desired effect. Anamorphic mirrors may be concave, convex, or both. Surfaces are often non-spherical.

MAJOR TYPES AND THEIR USES

Mirror form	Function/application
Convex cone	(a) Examine inside surface of a pipe/tube
	(b) Inspect female screw threads
Convex sphere:	(a) Inspect inside surface of a pipe/tube
	(b) Increase the resolution in the central part of an image compared to its periphery
Concave ellipsoid	Normal view of part of a spherical surface. Camera with a wide-angle lens and widget are placed at the two foci
Cylindrical lens	(a) Adjust image aspect ratio
	(b) Pair provides parallelogram warping of image
Concave toroidal lens	Magnify annular region radially
Double wedge	Image splitter
Axicon (conical lens)	Remove central portion of field of view
Parabolic mirror (used with fish-eye lens)	Provides infinite depth of field
Fish-eye lens	Provides field of view in excess of 2π steradians

REMARKS Many of the lighting-viewing methods described elsewhere in this collection are based on anamorphic optics.

Anamorphic optics, producing image distortion, are abundant in our everyday lives, since polished curved surfaces, (e.g., car body, chrome kettle, bowl of a silver spoon, Christmas-tree bauble, reflective "silver" wrapping paper, etc.) produce warping. The "Hall of Mirrors" at an amusement fair creates comical distortions of the human body, using mirrors that are not quite flat. Reflections in large windows are similarly distorted. After the 1745 rebellion in Scotland, images showing the likeness of the Young Pretender (Bonnie Prince Charlie) were outlawed. To overcome this restriction, his supporters often kept paintings of him that could only be viewed properly by observing the reflection in a brightly polished metal cylinder. The human brain quickly learns how to correct the anamorphic warping produced by variable-focus spectacle lenses. Fish-eye lenses produce anamorphic distortion, while providing an all-round view. Using this principle, certain CCTV lenses, intended for surveillance applications, are deliberately made to enlarge the central portion of the scene, while providing low-resolution peripheral vision. *Cinemascope* lenses are used to “stretch” a nearly square image, on the film, into an elongated rectangular image, projected onto the cinema screen. Special-purpose “slant lenses” are made that can correct for oblique viewing of a plane surface (A trapezium is mapped into a square). Driving mirrors are often anamorphic, since they must provide a good all round view of the road.

Anamorphic optics can be reflective (concave or convex mirrors), or refractive. If they are carefully designed and manufactured, anamorphic optical systems can achieve some valuable effects for Machine Vision applications. For example, simple curves of known geometric form can be “straightened”, thereby making image analysis easier. A particularly useful function of anamorphic optics is to provide high resolution at the centre of the camera’s field of view with a lower resolution near the periphery.

Designing and manufacturing optical-quality anamorphic surfaces is not as difficult or expensive as might be imagined. Using CAD ray-tracing programs and CNC machining, optical quality non-planar, non-spherical surfaces can be made with relative ease. These can then be replicated cheaply in plastic, using standard moulding techniques. (Variable-focus spectacle lenses are made to order in this way.) Anamorphic mirrors can be made by evaporation coating of such surfaces, using aluminium, silver or gold. Low-grade anamorphic mirrors can be made using metal-coated Mylar film, reflective wrapping paper or *Silverlux*™, stretched over a suitable former.

40.4 Method 4: Arbitrary Lighting Pattern

OBJECTIVE To generate a complex pattern of light that can be adjusted to suit individual applications.

TYPICAL APPLICATIONS

(a) Inspecting
- Complex objects: castings, mouldings, assemblies, etc. which may have multiple crevices and holes
- Glass-ware
- Curved shiny surfaces

(b) Verifying holograms (➋ *Fig. 40.3f*)

◘ Fig. 40.3
(Continued)

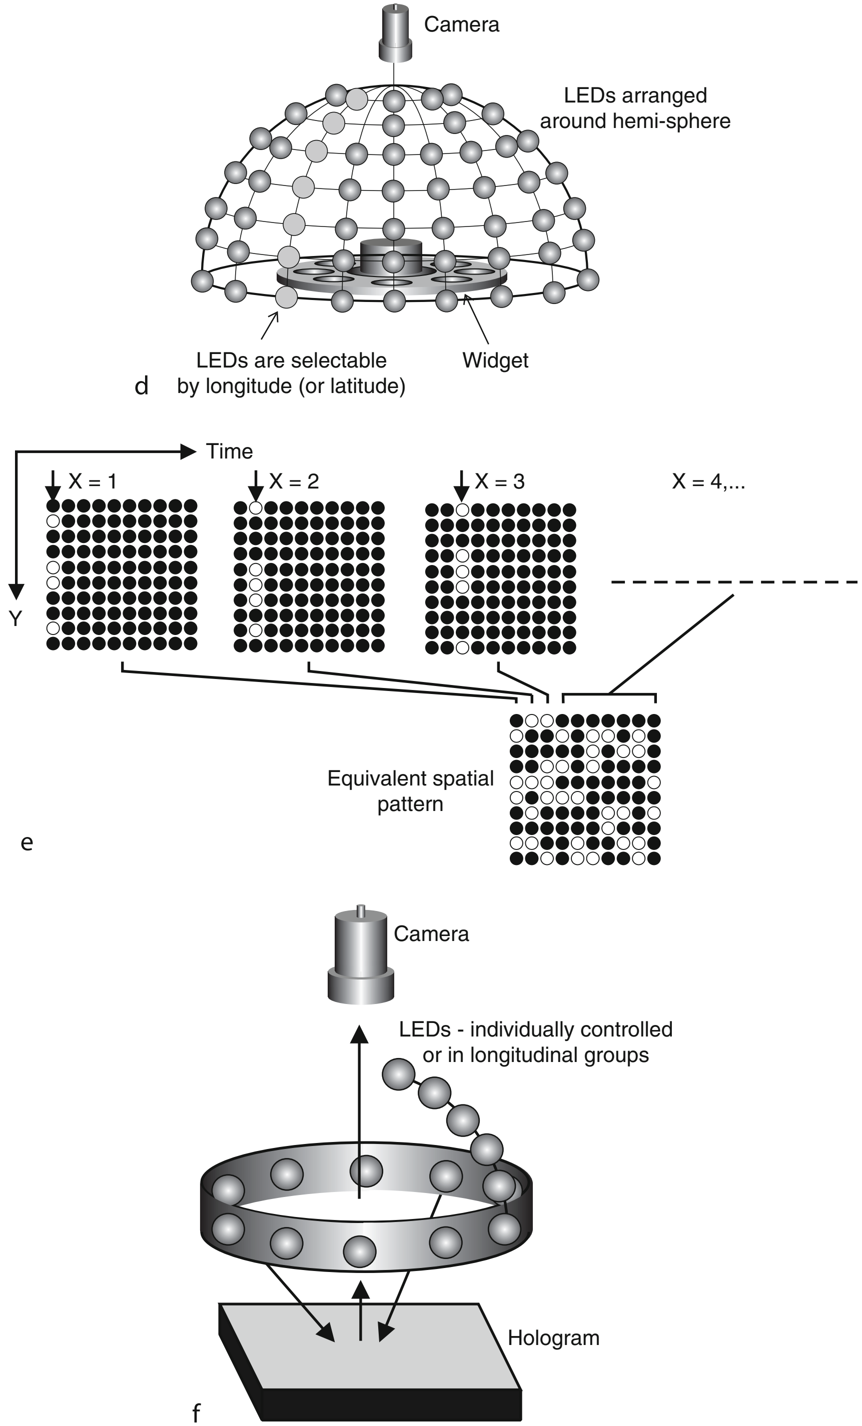

Fig. 40.3
(Continued)

EQUIPMENT One of the following:

(a) "Cat-o'-nine-tails" fibre optic bundle. The "loose" fibre ends are held in a grid to create the desired lighting pattern (➲ *Fig. 40.3a*)

(b) Printed circuit board, designed as a "bread board" with a large number of empty spaces. Single LEDs are then inserted as needed to define the desired pattern (➲ *Fig. 40.3b*)

(c) Back-light screen fitted with a suitable mask to create the desired lighting pattern

(d) Overhead or 50 mm slide projector, fitted with a suitable transparency to create the desired lighting pattern

(e) Array of LEDs, which can be strobed either individually or in groups. The array may be flat rectangular (➲ *Fig. 40.3c*), flat circular, folded in concertina fashion, cylindrical or hemispherical (➲ *Fig. 40.3d*)

(f) Computer with micro-mirror or LCD display projector. The computer "displays" the appropriate image onto the widget (A flying-spot projector cannot be used since this would create strobing effects.)

REMARKS (a) to (d) in the list above create fixed lighting patterns, while (e) and (f) provide a dynamic illumination effect in which the lighting pattern might be changed between successive video frames. While it would be useful to be able to control each LED in an array separately, this may not be convenient, particularly if it contains many diodes. A technique will therefore be described in which groups of LEDs (e.g., rows/columns in ➲ *Fig. 40.3c*, or lines of latitude/longitude in ➲ *Fig. 40.3d*) are switched together. For the sake of simplicity, we shall consider the rectangular array (➲ *Fig. 40.3e*). Contrary to intuition, this is not used to generate a 2D lighting pattern directly but instead creates a succession of "linear" patterns. There are *N* stages in this process, where *N* is the number of *X*-select lines. Each of these "linear" light patterns is obtained by illuminating the appropriate sub-set of the LEDs in one column of the array. While light cannot be stored, the charge patterns that this sequence generates in the camera can. The camera performs temporal integration of the light falling on its photo-detector array over (part of) one frame period, thereby producing a charge pattern that is the same as that would be produced by the equivalent static 2D pattern. Thus, at any given moment, one *X*-select line and several *Y*-select lines are set *ON* (➲ *Fig. 40.3c* and *e*). A different *X*-select line is then switched *ON* and a new bit-pattern is applied to the *Y*-select lines (The original *X*-select

Fig. 40.3

Creating arbitrary lighting patterns. (a) "Cat-o'-nine-tails" fibre optic bundle. (b) "Bread board" consists of a bare printed circuit board. (Current-limiting resistors are provided for each socket.) LEDs are inserted into the empty sockets, as needed. (c) Rectangular array of LEDs, Each column in the array is activated in turn, to define a "linear" light pattern, (d) LED array covering an hemisphere (For clarity, only the LEDs at the front of the hemisphere are shown here). For control purposes, this may be regarded as a folded version of the flat array. The LEDs may be grouped together along lines of latitude or longitude. (e) Sequence diagram for the fully populated rectangular array. (f) Verifying a hologram using a programmable light source. For clarity only a simple ring light is shown here.) When viewed in monochrome light, the intensity of a given point on a hologram varies with the angle of illumination. In white light, the colour changes.) Hence, by varying the lighting, a series of images can be obtained, which then be analysed easily, by template matching, to verify the identity of the hologram

line is, is of course, switched *OFF* first). This process is repeated by pulsing each *X*-select line in turn. Clearly, the camera integration time must be greater than *N.T*, where *T* is the flash duration (Notice that *T* also affects the magnitude of the charge pattern created in the camera and hence controls the image brightness). In this way, each LED can be controlled individually, even though several LEDs may be illuminated at the same time. However, only simple *ON/OFF* control is achieved. This arrangement is well suited for use in a prototyping system, or for applications in which the lighting pattern must be changed rapidly, perhaps between successive video frames. The LED array and fibre-optic methods are significant in the fact that the light pattern need not be flat. Methods (d) and (f) in the "*Equipment*" list effectively project a pattern of light emanating from a single, non-isotropic point source.
LAYOUT DIAGRAMS ➋ *Figure 40.3*

40.5 Method 5: Automatic Gain Control and Auto-Iris Lens

OBJECTIVE To compensate for varying light levels, when working in ambient lighting.
TYPICAL APPLICATIONS

- Surveillance and other security applications
- Monitoring the factory environment

EQUIPMENT Either of the following:

(a) Auto-iris lens. The output from the camera is fed back into the lens, which adjusts its aperture in an attempt to keep the video level constant
(b) Camera with automatic gain control (AGC). The camera adjusts its light-integration period in order to maintain a constant output level

OPTICAL ENVIRONMENT Slowly changing light levels can be accommodated by either method. It normally takes an auto-iris lens, or a camera AGC circuit, a few seconds to recover from a large step change in the light level.
REMARKS An auto-iris lens can operate either by computing the average or peak level from the video signal generated by the photo-sensor array. The former is more robust, since it is less susceptible to problems caused by glinting, although it does render the camera susceptible to saturation on highlights. Averaging is usually computed over the whole field of view but this need not be so; a small region in the centre of the field is often used instead. These two methods cannot be combined. The human eye has a dynamic range of about 10^{14}:1. Neither of these methods can match this; a high-grade video camera has a dynamic range of about 10^{9}:1. Notice that altering the iris size changes the depth of field and may increase aberrations for large apertures (small f-numbers). Raising the electronic gain increases camera noise.

40.6 Method 6: Back Illumination of Shiny Objects (Array Camera)

OBJECTIVES To view the silhouette of a shiny object.
TYPICAL APPLICATIONS

- Metrology and other applications where the edge contour must be located accurately
- Dimensional measurement of extrusions and lathe-turned objects

EQUIPMENT Collimator and telecentric lens. Both of these must be larger than the widget.
CAMERA Array.

MOTION Static.

GEOMETRY Particularly suitable for objects with spherical, cylindrical and conical surfaces. Appropriate for any elongated object whose outer edge is gently curved along the optical axis. Flat objects and those with sharp outer edges do not need the collimator, since the edge is well defined by the simpler technique (Method 7).

MATERIALS Any shiny/glossy material (e.g., polished metal, smooth plastic, rubber, glass, ceramic), painted, lacquered, wet, oily and waxy surfaces.

REMARKS When viewing a shiny widget using the simpler technique (Method 7), we underestimate the size of the widget dimensions (See ➋ *Fig. 40.4b*). The collimator prevents reflections of non-paraxial rays occurring at points inside the outer edge. The illumination diagram is not an appropriate way to represent this lighting arrangement, since the rays are not all coincident at a single point.

Back lighting using a collimator to avoid reflections of non-paraxial rays. (a) Optical arrangement. (b) The effect of non-paraxial rays on simple back-illumination, when the collimator is not used. (c) *Left:* Sample image, derived from a brightly polished metal sphere in front of a rectangular "light box." Ordinary back-illumination (Method 17) produces a light grey annulus around a dark grey disc. The grey band is caused by reflections of non-paraxial rays. *Centre.* Intensity profile shows the gradual change of intensity within this grey band. *Right.* True contour (outer curve) and the apparent edge contour (inner curve), obtained when a collimator is *not* used. Notice that the errors depend on the radius of the light source (The errors are greatest opposite the corners of the light source: at 45°, 135°, 225° and 315°.)

40.7 Method 7: Back Lighting of Matt Opaque Objects (Array Camera)

OBJECTIVE To view silhouettes of non-shiny matt opaque objects.

TYPICAL APPLICATIONS

- Dimensional measurement and inspection of laminate objects, such as flat metal stampings, pressings, plastic mouldings, leather cuttings, etc.
- Dimensional measurement and inspection of a very wide range of 3D objects.

EQUIPMENT Proprietry back-light unit, or light box of the type used in hospitals for viewing X-rays.

CAMERA Array.

MOTION Static.

GEOMETRY Thin laminate, or any 3D object in which the relevant measurements may be obtained from its silhouette.

MATERIALS Opaque, non-reflective.

REMARKS Back-lighting is ideal for shape analysis and high-precision metrology. It operates on the same principle as the industrial shadowgraph and hence is readily accepted by industrial engineers. It is one of the oldest and most important lighting-viewing methods used in Machine Vision, since it produces high-contrast images that are easy to process. It is important that the back-ground be almost uniform (Do not rely on the human eye to judge this; use an image processor). In this case, the intensity histogram will resemble that shown in ➜ *Fig. 40.5c* and it is sensible to threshold the image at the bottom of the "valley" (point P). In many instances, a good estimate for the threshold parameter is at the centre of the intensity range actually found in the image. For example, we can easily estimate the minimum and maximum intensities (A and B) and find the average value: P = (A + B)/2. More generally, we may relate A and B to the statistical properties of the image. For example, let us suppose that F_A percent of the pixels are darker than level A and that F_B percent of the pixels are darker than level B (Typically, we might take F_A to be 5% and F_B to be 95%). Then, the threshold (P) might be computed using the more general formula: $P = [K.A + (1 - K).B]$, where $0 < K < 1$. In this way, it is possible to make the thresholding process independent of the brightness of the back-light source.

DIAGRAMS ➜ *Figure 40.5*

40.8 Method 8: Back Lighting of Matt Opaque Objects (Line-Scan Camera)

OBJECTIVE To view silhouettes of non-shiny matt opaque objects.

TYPICAL APPLICATIONS

- Dimensional measurement and inspection of laminate objects, such as flat metal stampings, pressings, plastic mouldings, leather cuttings, etc.
- Dimensional measurement and inspection of a very wide range of 3D objects
- Measuring width and position of extrusions, cables, etc. Examining edge integrity of same

EQUIPMENT Line scan camera, plus one of the following:

- Masked back-lighting unit
- Fibre-optic line illuminator

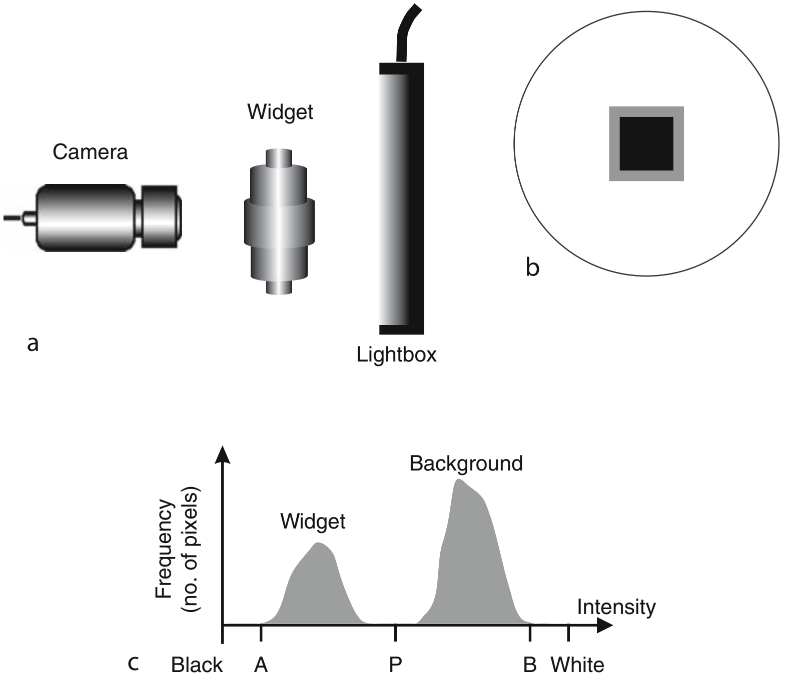

Fig. 40.5
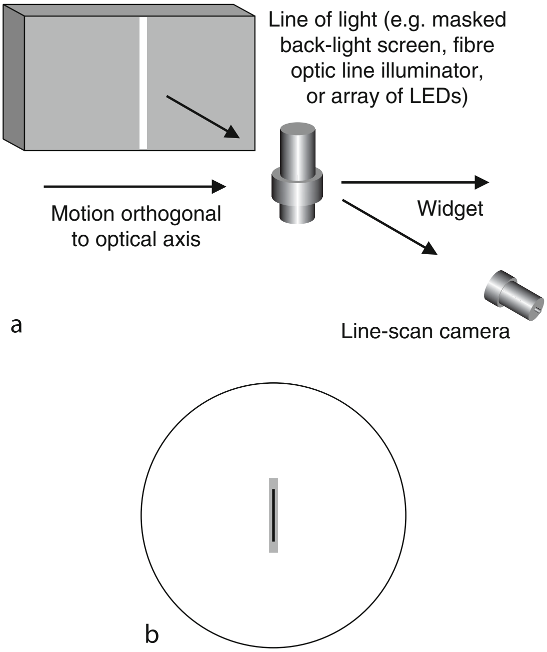
Back lighting of matt opaque objects. (a) Optical layout. (b) Illumination diagram. (c) Intensity histogram for an idealised case

- Linear array of LEDs with a diffusing screen
- Light box of the type used in hospitals for viewing X-rays

CAMERA Line scan.
MOTION Smooth or indexed linear movement.
GEOMETRY Thin laminate, or any 3D object in which the relevant measurements may be obtained from its silhouette.
MATERIALS Opaque, non-reflective.
REMARKS See notes for Method 7. Several manufacturers make specialist linear back-lighting units.
DIAGRAMS *Figure 40.6*

40.9 Method 9: Calculate the Field of View: I

OBJECTIVE To calculate the field of view (FOV) for a flat (2-dimensional) widget that is always presented for viewing in the same orientation. The same analysis can be applied to the silhouette of a 3-dimensional object.
GIVEN PARAMETERS, NOTATION AND ASSUMPTIONS Orientation of the widget is fixed.
X – Width of the widget, measured along the x-axis.
Y – Height of the widget, measured along the y-axis.



Line of light (e.g. masked back-light screen, fibre optic line illuminator, or array of LEDs)
Motion orthogonal to optical axis
Widget
Line-scan camera
a
b

Fig. 40.6
Back Lighting of matt opaque objects using a line-scan camera. (a) Optical layout. (b) Illumination diagram

Dx – Positional tolerance of the widget, measured along the x-axis.
Dy – Positional tolerance of the widget, measured along the y-axis.
Camera format:
  Array type
  Square image
  Pixels are square
  Resolution N^2 pixels
  Photo-detector spacing S

CALCULATED PARAMETERS

1. Size of the field of view (F = length of one side)

$$F = MAX((X + 2.Dx), (Y + 2.Dy))$$

   (In practice, the image projected by the lens onto the photo-detector array should be slightly larger than that array, to avoid “losing” edge pixels.)

2. Pixel size (length of one side)

$$F/N = MAX((X + 2.Dx), (Y + 2.Dy))/N$$

3. Minification required

$$M = F/[N.S] = MAX((X + 2.Dx), (Y + 2.Dy))/N.S$$

4. Processing efficiency (Compares the number of pixels in the minimum-enclosing-rectangle surrounding the widget, compared to the total number of pixels within the camera's field of view. We cannot estimate the "real" efficiency, since we have no idea how compact the widget is.)

$$10^2.X.Y/[MAX((X + 2.Dx), (Y + 2.Dy))]^2 \text{ percent.}$$

Assuming that Dx and Dy are small, this is approximately equal to

$$10^2.X.Y/[MAX(X, Y)]^2\text{percent}$$

If this figure is small, it may be worthwhile limiting the image processing to include only those pixels contained within a region of interest (ROI) of size X.Y. This contains $\{X.Y/[M.S]^2$ pixels.

Field of view (square)

Fig. 40.7

Calculating the FOV for a widget in fixed orientation. The field of view must be large enough to include the minimum-enclosing-rectangle, plus a "guard region," which accommodates the uncertainty in position of the widget

40.10 Method 10: Calculate the Field of View: II

OBJECTIVE To calculate the field of view (FOV) for a flat (2-dimensional) widget that is always presented for viewing in any orientation. The same analysis can be applied to the silhouette of a 3-dimensional object.

GIVEN PARAMETERS, NOTATION AND ASSUMPTIONS

X – Diameter of the minimum-enclosing-circle.

Dx – Positional tolerance of the widget, measured along the x-axis.

Dy – Positional tolerance of the widget, measured along the y-axis.

Camera format:

Array type

Square image

Pixels are square

Resolution N^2 pixels

Photo-detector spacing S

CALCULATED PARAMETERS

1. Size of the field of view (F = length of one side)

$$F = X + 2.MAX(Dx, Dy)$$

(In practice, the image projected by the lens onto the photo-detector array should be slightly larger than that array, to avoid "losing" edge pixels).

2. Pixel size (length of one side)

$$F/N = [X + 2.MAX(Dx, Dy)]/N$$

3. Minification required

$$M = F/[N.S] = [X + 2.MAX(Dx, Dy)]/[N.S]$$

4. Processing efficiency (See Method 1.)

$$10^2.X^2/[X + 2.MAX(Dx, Dy)]^2 \text{ percent.}$$

REMARKS The minimum-enclosing-circle can be computed by a straightforward image processing operator (QT operator *mbc*. The FOV calculation for a widget that is allowed to vary in orientation by a finite amount ($\pm\theta$, where $\theta < 180°$) is more complicated. This requires the computation of the dimensions of the largest minimum-enclosing-rectangle for a range of angles of rotation, $[-\theta, +\theta]$. The formula given above for F is safe but slightly pessimistic. The QT operator *fov* is described in ➋ Chap. 41.

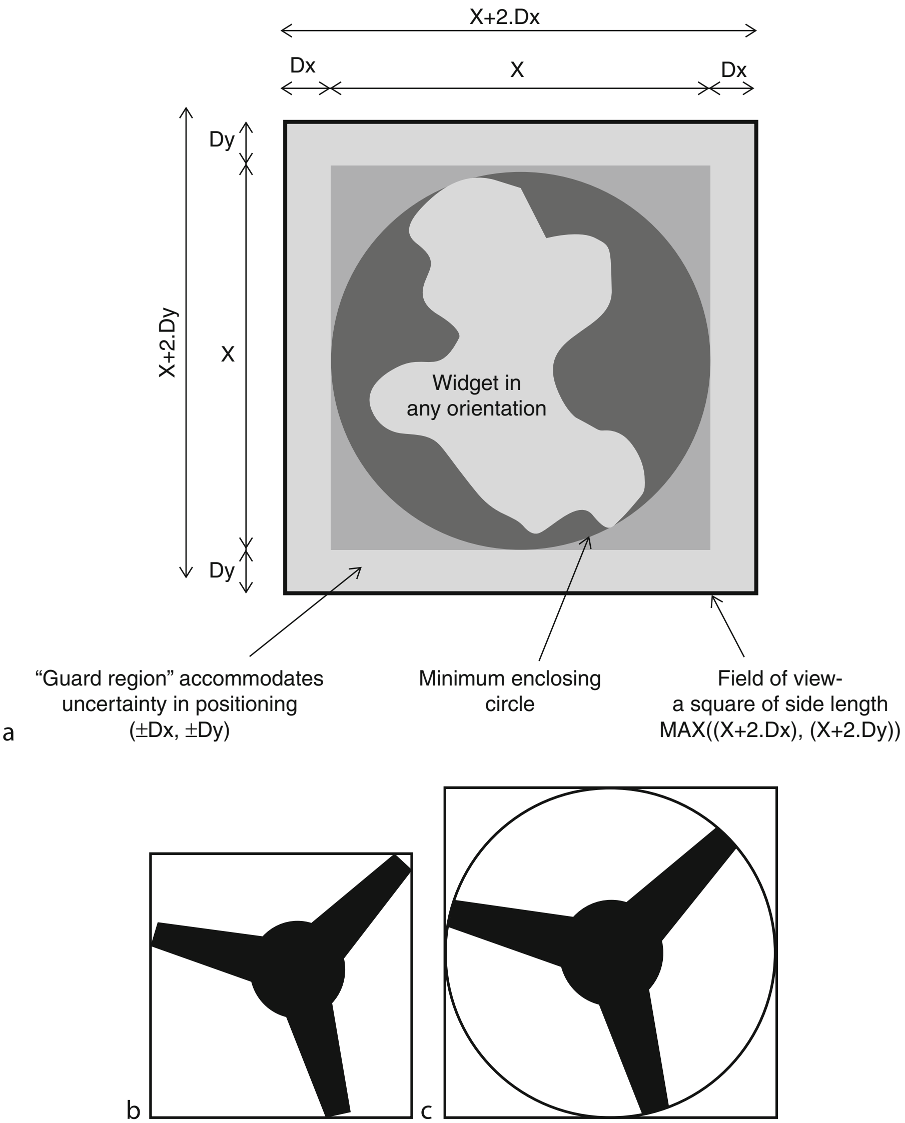
DIAGRAMS ➋ *Figure 40.8*

40.11 Method 11: Calibration: Calculating Spatial Resolution

OBJECTIVE To calculate the effective size of the pixels in a digital image.

ASSUMPTIONS AND NOTATION

- An array camera uses N^2 square photo-detectors of dimension D^2
- The photo-sensor array is based on a square grid of pitch S^2. Since there is a "dead space" between adjacent photo-detectors, D is less than S



◘ Fig. 40.8

Calculating the field of view for a widget in any orientation. (a) The FOV must be large enough to include the minimum-enclosing-circle, plus the ‘‘guard region.’’ X is the diameter of the minimum-enclosing-circle. (b) The FOV for the variable-orientation case *(right)* is usually larger than that needed for Method 1 *(left)*. In this example, 34% more pixels are needed

- The minification of the optical system is M. This is the ratio of the size of a feature as it appears in the image plane (i.e., on the photo-sensor array) to the size of the same feature within the original scene Minification is the reciprocal of magnification

CALCULATED PARAMETERS

1. Size of the field of view (F = length of one side)

$$F = N.S.M$$

2. Size of the virtual pixels

$$V = M.S$$

3. Size of the photo-detector array

$$P = N.S$$

4. Photo-sensor light-collecting efficiency (This is a function of the photo-sensor geometry and cannot be changed except by using a different camera.)

$$E = 100.D^{2/}S^2$$

   This means that E% of the photons projected onto each photo-detector in the array contribute towards its output signal.

5. Minimum-size feature (spot diameter/arc width) that can be seen (Nyquist limit)

$$2.M.S.$$

   In practice, a larger value is needed to obtain reliable measurements; a more realistic limit is about 2–3 times this value:

$$4.M.S \text{ or } 6.M.S.$$

   The maximum number of line-pairs that can be seen reliably is therefore about

$$N/8 \text{ or } N/12.$$

REMARKS Imagine looking into the lens towards the sensor array, with your eye located in the object plane. The sensor array appears *magnified* by a factor M. Hence, each of the photo-sensors appears to be of size $[M.D]^2$, located on a grid of pitch $[M.S]^2$. The integral of the light flux emanating from the square "covered" by the magnified photo-detector determines the intensity of the corresponding pixel within the digital image. It is not correct to say that the average intensity within the virtual pixel determines the pixel intensity, although this is a reasonably accurate approximation in regions of low spatial frequency. M can be determined experimentally using the following procedure.

CALIBRATION PROCEDURE

1. View a matt black disc of known diameter (φ), using back-illumination (Method 7). This disc is placed in the object plane. A high-contrast printed sheet with front lighting (Method 114) might suffice instead
2. Segment (threshold) the resulting digital image to isolate the image of the disc
3. Measure the height (H) and width (W) the image of the disc, in terms of pixels counted along the vertical and horizontal axes
4. Compute the parameters $M_h = \varphi/H$ and $M_v = \varphi/W$, which should be very nearly equal (If not, the camera's photo-detector array is not based on a square grid, the lens provides

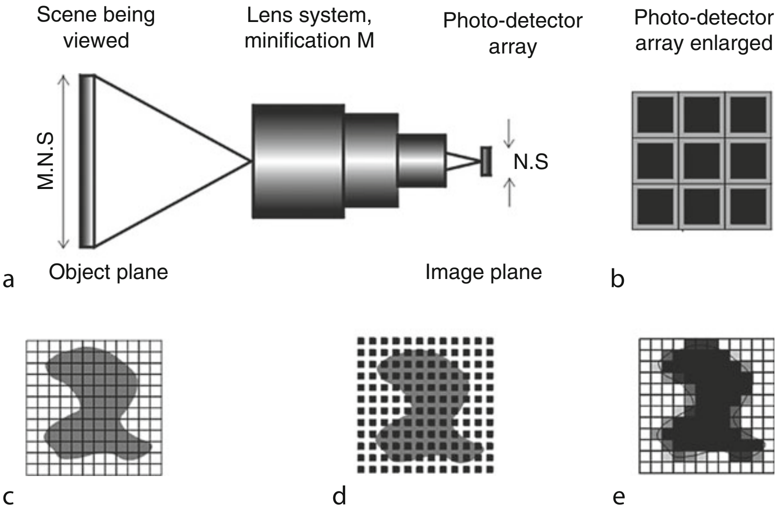


Fig. 40.9
Forming a digital image by sampling the intensities within a scene lying on a plane. (a) Optical system. (b) The optical system projects an image onto an array of non-contiguous photo-sensors (*black*). Since each one of these is smaller than the pitch of the array, there is a dead area around each one. (*grey*) (c) Binary object, with the virtual pixels superimposed. (d) The photo-detector array samples the intensity distribution within the scene. (e) Digital image with the outline of the binary object superimposed

different levels of minification along the vertical and horizontal axes, the test object is not normal to the optical axis, or the frame-grabber hardware is set up to generate non-square pixels)

5. Assuming that M_h and M_v are very nearly equal, take the minification to be the average:

$$M = (M_h + M_v)/2.$$

Another, more accurate measurement is given by

$$M = \varphi.\sqrt{(\pi/A)}$$

where A is the area of the image of the disc (i.e., number of pixels in this "blob").

40.12 Method 12: Circle of Light Projecting Radially Outwards

OBJECTIVE To project a continuous circle of light around the surface of a cylindrical bore.
TYPICAL APPLICATIONS

- Inspecting the bores of pipes, tubes, drains, sewers, etc.
- Examining holes in castings, mouldings and machined piece parts.

EQUIPMENT Any one of the following:

- Optical probe consisting of two axicons and a conical mirror (An axicon is a cone of transparent material. See Method 88).

- Laser fitted with diffractive optics to generate a continuous ring of light, and a conical mirror
- Standard ring light (LED or fibre optic) and a conical mirror
- Custom array of LEDs, arranged in a circle and projecting their beams outwards
- Custom fibre-optic ring light, with the fibres arranged to project light outwards, rather than forwards

CAMERA Array scan. Alternatively, a "wheel-spoke" or circular-scan camera would be useful, as this may simplify the image processing.

MOTION Indexed or continuous linear movement along the axis of the bore.

GEOMETRY Medium-large diameter bore (The probe must be able to enter the bore, leaving a sufficiently large gap to enable the camera to view its surface).

REMARKS Ideally, this method would produce the same effect as a point source of light that emits light uniformly in all directions within a plane. No rays are emitted except in that plane. If light from such a source were projected normally onto the internal surface of a cylinder, a bright circle of light would be created. In a practical optical system, a circle of finite diameter replaces the point source; all light rays then travel radially outwards from that circle. A circular light source can be created in a variety of ways:

- Using a circular array of "point" sources (e.g., LEDs or optical fibres)
- Diverting a hollow cylinder of light using a conical mirror. Such a light cylinder may be generated using a laser and a diffractive optics lens, or axicons

To reduce aberrations, a lens with a high f-number (i.e., small aperture) should be fitted to the camera.

LAYOUT DIAGRAMS ➲ *Figure 40.10*

40.13 Method 13: Circular Features

OBJECTIVE To sample a scene using circular, or "wheel-spoke" features.

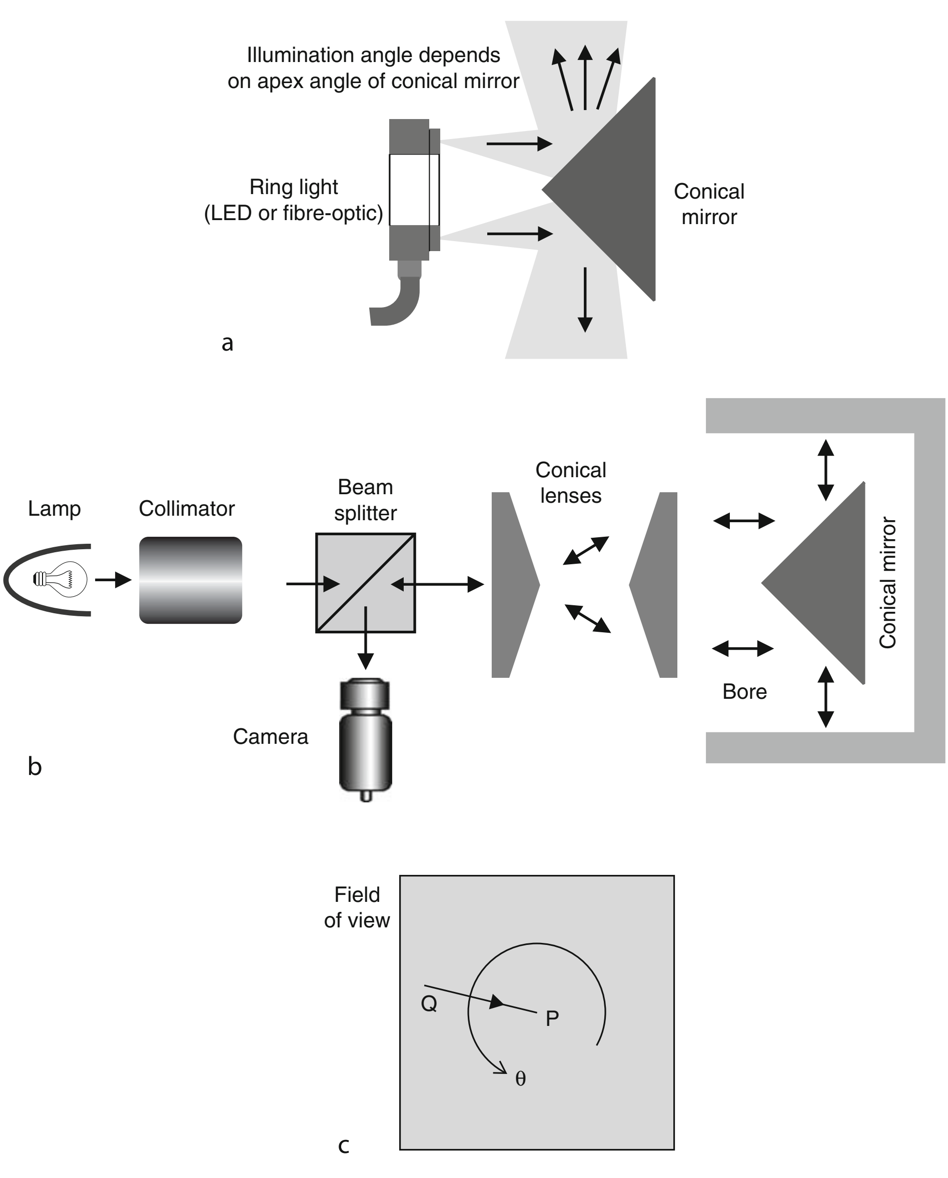
TYPICAL APPLICATIONS Inspecting tops of bottles, jars, tumblers, cans, circular holes, gears, bore surfaces: tubes, pipes, drains, etc.

EQUIPMENT Solid-state or CRT camera with a circular-scan, multi-ring, ring-and-wedge, spiral-scan or radial-scan pattern.

OPTICS Conventional lens. These cameras can also be used in conjunction with various lighting-viewing arrangements.

POSTURE The circular/radial features should be concentric with the camera's field of view.

REMARKS The sole reason for using non-standard scan patterns like those shown in figure is to avoid storing and manipulating "unwanted" pixels and to structure the image data in such a way that processing is made easier. Similar effects can be obtained by digitising the signal from a high-resolution array camera and then sampling the resultant digital image using software, or special purpose hardware. Although it is possible to build a variety of non-standard solid-sate photo-sensor arrays, tube cameras are generally easier and cheaper to use. The reason is that their scan patterns are more versatile and can be modified at will. For example, the pitch of a spiral raster can be adjusted by modifying the drive signals applied to the beam-deflection coils/plates. On the other hand, the array geometry of a solid-state photo-sensor is fixed during manufacture and it is very expensive to produce special-purpose devices to order. Electrically, a circular-scan camera (➲ *Fig. 40.11a*) is similar to a line-scan camera; its photo-detectors are



◘ Fig. 40.10

Circle of light projecting radially outwards. (a) Using a standard ring light and a conical mirror. (b) Using two axicons and a conical mirror. The beam-splitter enables coaxial illumination and viewing. (c) Camera's field of view. As the probe advances into the bore, surface features move along radial lines, such as PQ, disappearing from view when they reach the centre of the image, P. θ is the angular position

arranged around a circle. The ring-wedge detector (➔ *Fig. 40.11b*) is intended specifically for analysing Fourier transforms produced optically (Method 74). This array geometry makes use of the symmetry of Fourier transforms (i.e., $F(A, \omega) = F(-A, -\omega)$). The scan pattern shown in ➔ *Fig. 40.11c* produces a similar digitisation effect to that achieved by Method 98 (Rotating Dove Prism) A spiral scan (➔ *Fig. 40.11d*), produced by a modified vidicon, has been used to inspect bottle tops. The "wheel spoke" pattern in➔ *Fig. 40.11e* is similar to that used in rotating radar scanners. Possible uses of these cameras is evident elsewhere: Methods 116, 97, 66 and 59.

SCAN PATTERNS ➔ *Figure 40.11*

40.14 Method 14: Circularly Polarising Filter Suppresses Glinting

OBJECTIVE To suppress highlights due to glinting, when viewing bright shiny reflective objects.

TYPICAL APPLICATIONS Inspecting metal machine parts.

EQUIPMENT Polarising filter, IR-blocking filter.

CAMERA Array or line scan.

MOTION Static or linear motion.

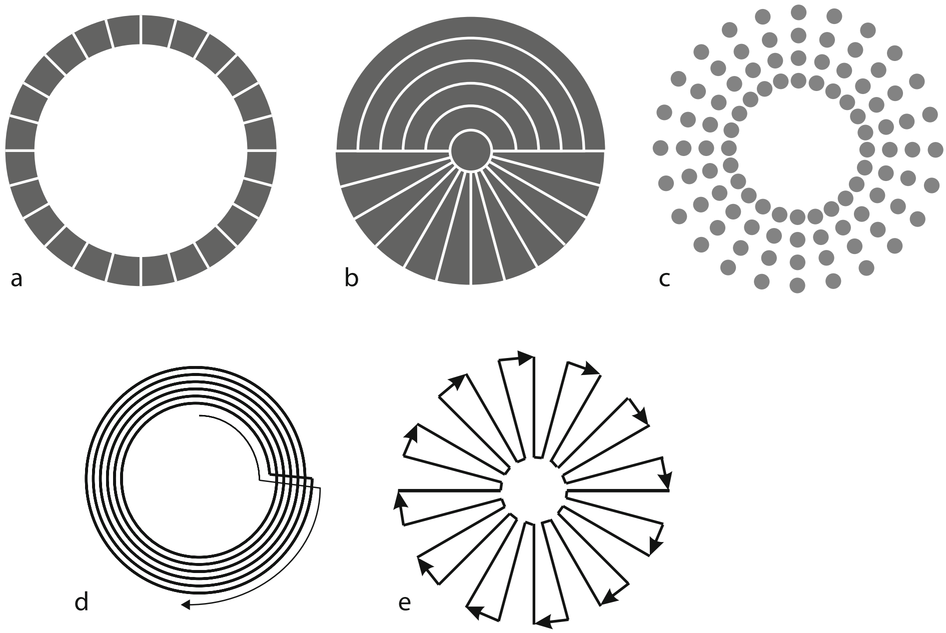


Fig. 40.11

Non-standard scan patterns. (a) Solid-state circular-scan array, consists of a single ring of photo-detectors. (b) Solid-state ring-and-wedge detector, designed to analyse optical Fourier transform patterns. (c) Solid-state array of photo-detectors arranged around a series of concentric rings. Notice that the photo-detectors are all the same size, to ensure that the sensitivity is constant throughout the whole field of view. (d) Spiral-scan (relies on a CRT camera). (e) Radial-scan pattern (relies on a CRT camera)

MATERIALS Bright metal.
REMARKS The outward (illumination) and return (i.e., after reflection) beams must both pass through the polariser. Some polarising filters do not function effectively in the near infrared wave-band. Moreover, incandescent lamps emit strongly in the NIR and solid-state image sensors are sensitive in this part of the spectrum. So, it may be necessary to place an IR-blocking filter between the widget and camera. Circular polarising filters must be inserted in the correct orientation in the optical path (They cannot be "flipped over"). Polarising material in the form of a rigid plastic sheet is available from several major optical manufacturers. When using a low-cost sheet polariser, highlights due to glinting appear as deep violet spots, which can be further attenuated by using a long-pass optical filter. To determine the correct orientation for a circular polariser, place it on a shiny metallic surface and observe the surface with the room lights on. Now, flip the polariser and try again. In the proper orientation, the metal surface looks dark and usually blue. This method can be used to make diffuse reflecting material more prominent.
LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.12*

40.15 Method 15: Coaxial Diffuse Illumination

OBJECTIVE To provide diffuse illumination without causing glinting.
TYPICAL APPLICATIONS Viewing small bright shiny objects, such as coins, electrical connectors, printed circuit boards.
EQUIPMENT Small incandescent filament lamp, LED array or fibre-optic illuminator, diffusing plate and beam-splitter.
GEOMETRY

- Mirror-like surfaces
- Complex, embossed, etc.

MATERIALS

- Bright metal surfaces
- Reflective plastic
- Lacquered/painted surfaces

REMARKS Excellent images can be obtained from mirror-like surfaces, which are often difficult to view using other methods. It appears as though the widget is illuminated by light emanating from a small area, corresponding to the front of the camera lens. Since this produces a much narrower illumination beam than Method 31, it is very sensitive to the geometry of the widget surface; it can readily detect embossing, engraving, stippling creasing, dimples, pimples, scratches and pits. This method relies on producing specular reflection. Hence, the widget must have a well-defined shape and be held in fixed orientation, to ensure that glinting is visible to the camera.
DIAGRAMS AND SAMPLE IMAGE ➋ *Figure 40.13*

40.16 Method 16: Coherent Flexible Fibre Optic Bundle

OBJECTIVES

- To transmit an image through a tortuous path
- To acquire an image from the end of a robotic arm

(c) Making a diffuse reflecting material more prominent Shiny metal object with stone. *Left:* ring light, no polariser. *Right*: Ring light and circular polariser. [Images kindly supplied by Spencer Luster, Light Works, Inc., URL http://www.lw4u.com]

TYPICAL APPLICATIONS

- Internal inspection of pipes, tubes, drains, sewers, air ducts, etc.
- In situ inspection of aero-engines, turbines, etc.

EQUIPMENT Flexible fibre optic (FO) bundle.
CAMERA Array scan.
LENS Lens is fitted to the end of the fibre optic bundle.
MOTION Static.

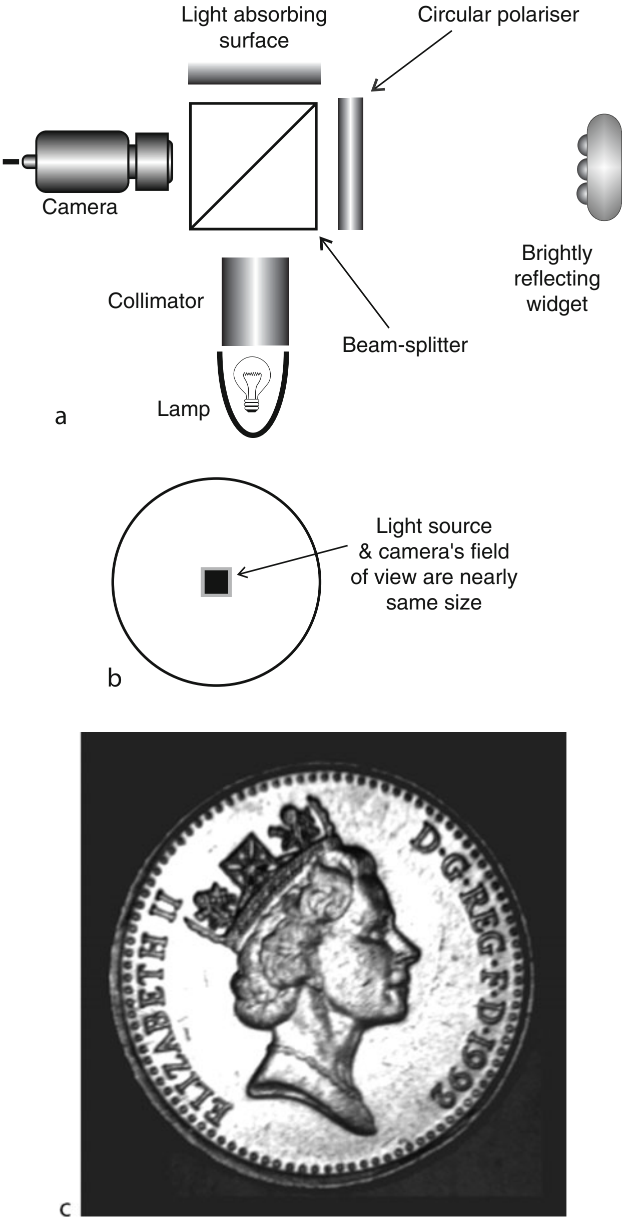

Fig. 40.13

Coaxial diffuse illumination. (a) Optical layout. The circular polariser is one option for providing lighting and is only needed when glinting occurs. (b) Illumination Diagram. (c) Sample image: Cupro-nickel coin. There is some wear evident on the flat surface (called the ''table''), above and below the queen's head

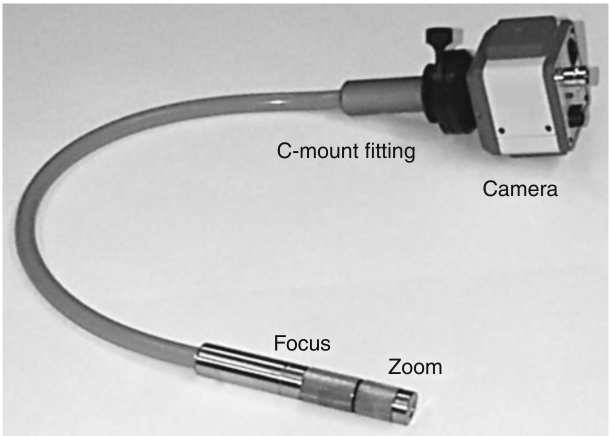

Fig. 40.14
Flexible fibre-optic imaging bundle. Much longer bundles (over 3 m) are available but are expensive

GEOMETRY Objects with holes.
REMARKS Flexible coherent fibre optic bundles for image transmission (as distinct from non-coherent lighting bundles) are more expensive than image conduit but are more versatile. Some very sophisticated FO bundles are used in medicine and are fitted with a variety of tools (surgical, lighting, air, vacuum, etc.). All FO bundles superimpose a fine mesh-like pattern onto an image (See Method 38.). Flexible fibre bundles can be constructed using glass, quartz (for viewing UV images), and plastic. However, they can be damaged relatively easily, by bending through too small a radius, heat (damages plastic bundles), radiation (ordinary glass turns brown) and continued flexing over a prolonged period. There is a gradual degradation of image quality, as the bundle is flexed repeatedly; individual fibres break, causing dark spots to appear in the image. For this reason, FO bundles are not recommended nowadays for use on robots; miniature cameras are normally preferred, instead.
PHOTOGRAPH ➋ *Figure 40.14*

40.17 Method 17: Collapse Image into Line

OBJECTIVE To detect linear features at a known angle, by integrating the intensity along one axis, to produce a 1-dimensional light pattern.
TYPICAL APPLICATIONS
- Counting slab- or disc-like objects, such as biscuits, cookies, tea bags, sweets, etc. stacked in a linear array
- Analysing the texture of cloth
- Detecting the level of a liquid in a glass bottle or jar
- Identifying blocks of text on a printed page, as a prelude to measuring line spacing and determining character size

EQUIPMENT Converging cylindrical (i.e., biconvex, or plano-convex) lens.
CAMERA Line scan.

MOTION Static.

REMARKS Consider *Fig. 40.15a*. For light rays travelling in a horizontal plane (Y is constant), the normal lens formulae apply. A light ray travelling in a vertical plane (X is constant) as it enters the cylindrical lens, emerges from it having undergone a simple vertical shift; the direction of travel is unchanged. The deflection is proportional to the thickness of the lens at the point of entry. To understand how this method can be applied in practice, consider a stack of flat disc-like objects of variable thickness (e.g., cookies). Looking sideways at the stack, we see a stripe pattern of no fixed period; each stripe corresponds to one cookie in the stack. Since the edges of cookies are rough and irregular, a simple intensity profile would not yield an accurate way to count them. However, by integrating the intensity, whether by image

processing, or optically as described here, a much more accurate estimate can be obtained. A cylindrical lens combined with Method 98 can provide an opto-mechanical implementation of the Radon Transform. (This is a useful image processing operator, which is used to detect linear structures in a scene.)
LAYOUT DIAGRAM AND SAMPLE IMAGE ➜ *Figure 40.15*

40.18 Method 18: Collecting Natural Light/Sun-Light

OBJECTIVE To illuminate the widget, or a colour calibration target, using natural light.
TYPICAL APPLICATIONS Calibration of colour vision systems, used for inspecting printing, paint-work and fabrics, etc., where precise colour matching is essential.
EQUIPMENT A light-pipe formed from a roll of *Silverlux*™.
REMARKS The light pipe is a straight, vertical tube, formed from a roll of *Silverlux*™ (This is a thin, flexible sheet of silvered aluminium.) The tube may be several metres long, typically with a diameter of about 250 mm. The top of this tube can be arranged to project through the factory roof and can be fitted with a variety of light-collecting optics (➜ *Fig. 40.16b*). The light-entry window can be masked to avoid direct illumination by sun-light, or deliberately arranged to collect as much light as possible, whatever the time of day and year. Among the options are:

- Hemi-spherical dome (collects maximum amount of light, from all parts of the sky)
- Cone (apex pointing down-wards, captures sun-light)
- Vertical tube with a black, rifled bore (captures diffused light, blocks sun-light except in the Tropics)
- Masks, louvres, etc. (block/admit sun-light for specific values of elevation and azimuth)

The spectrum of the light transmitted by the light pipe is a very close approximation to that existing in a natural environment and includes VIS, IR and UV components. Of course, care must be taken to prevent light from artificial sources from entering the pipe and to keep the light-collector clean.

LAYOUT DIAGRAM ➜ *Figure 40.16*

40.19 Method 19: Colour Filtering

OBJECTIVE To provide sharp discrimination between different optical wavelengths in near-UV, VIS and near-IR bands (Separates colours in VIS.).
TYPICAL APPLICATIONS

- Inspecting printing, examining labels on packaging, etc.
- Inspecting woven textiles and printed fabrics
- Reading resistor colour codes
- Used in conjunction with coloured lighting (e.g., switched LEDs), for inspecting holograms, analysing
- Analysing fluorescence (Methods 24 and 41)

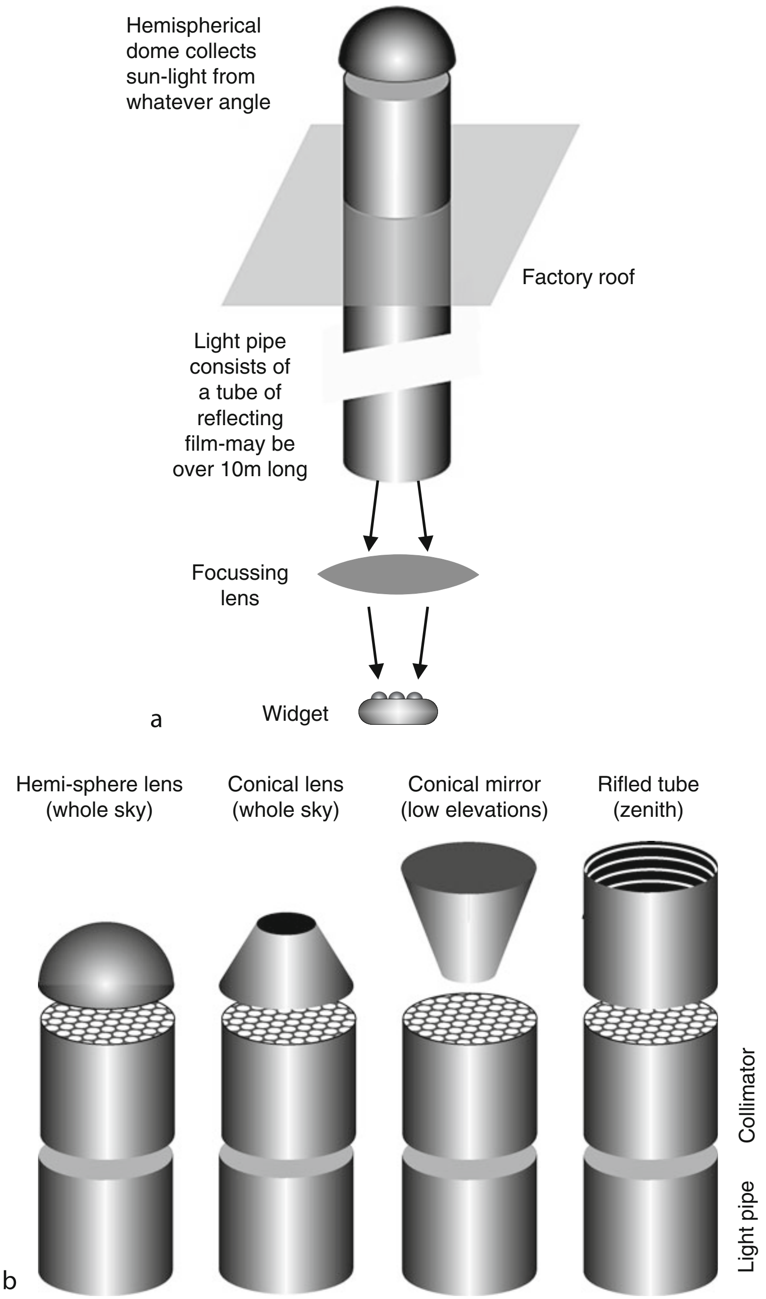

Fig. 40.16

Light pipe to produce natural lighting over a small area in the middle of a large building. (a) Optical arrangement (b) Selecting light rays from preferred directions. The collimator is optional

EQUIPMENT Coloured glass or gelatine filter, interference filter, dichroic filter.
REMARKS Optical filters are available in several forms. Filters approximating human colour detectors (intended for colour television applications) are available. Interference filters provide a sharper cut on/off characteristic than absorptive (i.e., coloured glass/gelatine) filters. Interference filters are more expensive and are susceptible to damage from moisture and heat. Interference filters change colour (i.e., cut-off wavelength changes) when they are tilted relative to the optical path. This allows fine tuning of the cut-on/cut-off wavelength (➲ *Fig. 40.17a*). Several factors must be borne in mind when choosing a filter:

(a) The camera's spectral response
(b) The emission spectrum of the light source
(c) The reflectance characteristics (i.e., colour variation) of the widget
(d) The absorption characteristics of the lenses and other elements in the optical system

Interference filters are available from all major optical manufacturers. A long-pass dichroic filter for which $\lambda_1 \approx 0.7$ μm is called a *cold mirror*; reflects VIS and transmits IR. A long-pass dichroic filter with $\lambda_1 \approx 0.7$ μm is called a *hot mirror*, since it reflects IR and transmits VIS. The latter is particularly useful for protecting the camera when inspecting very hot objects (e.g., red-hot steel).
FILTER CHARACTERISTICS ➲ *Figure 40.17*

40.20 Method 20: Combined Back and Front Illumination

OBJECTIVE To provide a method for viewing opaque objects which have piercings, so that edge and internal/surface features can be seen simultaneously.
TYPICAL APPLICATION Inspecting printed circuit boards, to verify that the holes and pads are aligned.
EQUIPMENT Back-lighting unit and flood lamps. Colour filters (optional).
CAMERA Colour or monochrome array camera.
MOTION Static.
GEOMETRY Has holes/piercings.
MATERIALS Opaque, non-shiny.
REMARKS The colour filters allow the images from the silhouette and front face to be separated or combined, as appropriate. Another simpler optical arrangement is possible, by simply omitting the colour filters. In this case, a monochrome camera can be used and the intensity of the front and back illumination sources must be carefully balanced, to ensure that the surface features and silhouette can both be seen clearly.
LAYOUT DIAGRAM ➲ *Figure 40.18*

40.21 Method 21: Field Splitter Combines Several Views

OBJECTIVE To select several views of an object and to combine them for a single camera.
TYPICAL APPLICATIONS

- Viewing the head and point of a long thin object (e.g., nail)
- Inspecting complex objects
- Inspecting a printed circuit board by comparing it with a "golden sample."

- Width measurement/positioning of web products (The camera views opposite edges of the web)
- Inspecting the pattern on a printed web, by comparing it with a golden sample, or another pattern displaced across or down web
- All round inspection of a widget
- Taking two orthogonal diameter measurements simultaneously to give better accuracy when assessing size and/or position

EQUIPMENT 45°/45°/90° prisms, or front-coated plane mirrors.

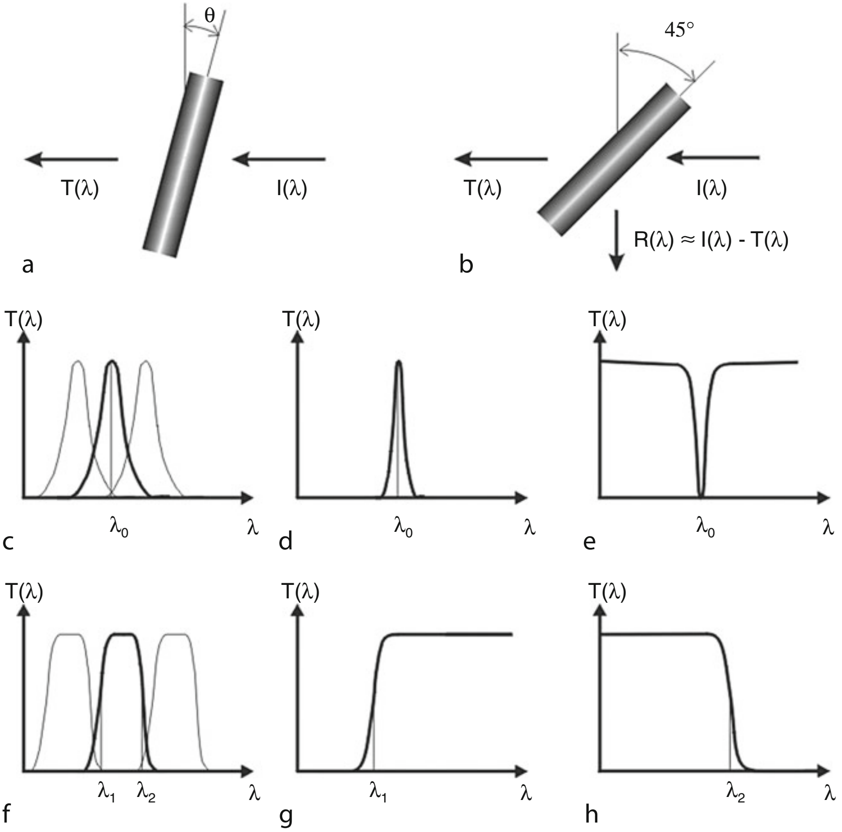
CAMERA Array.

LENS Standard lens.

MOTION Static.

GEOMETRY Long thin object.

REMARKS This method is an adaptation of the periscope. The optical path length may vary considerably in different parts of the camera's field of view, in which case the sub-images may be magnified by different amounts. Since miniature cameras have become available, this optical set-up is not nearly as important as it once was. The same effect can be achieved using low-cost video camera, with electronic switching of the video signals.



■ **Fig. 40.17**
(Continued)

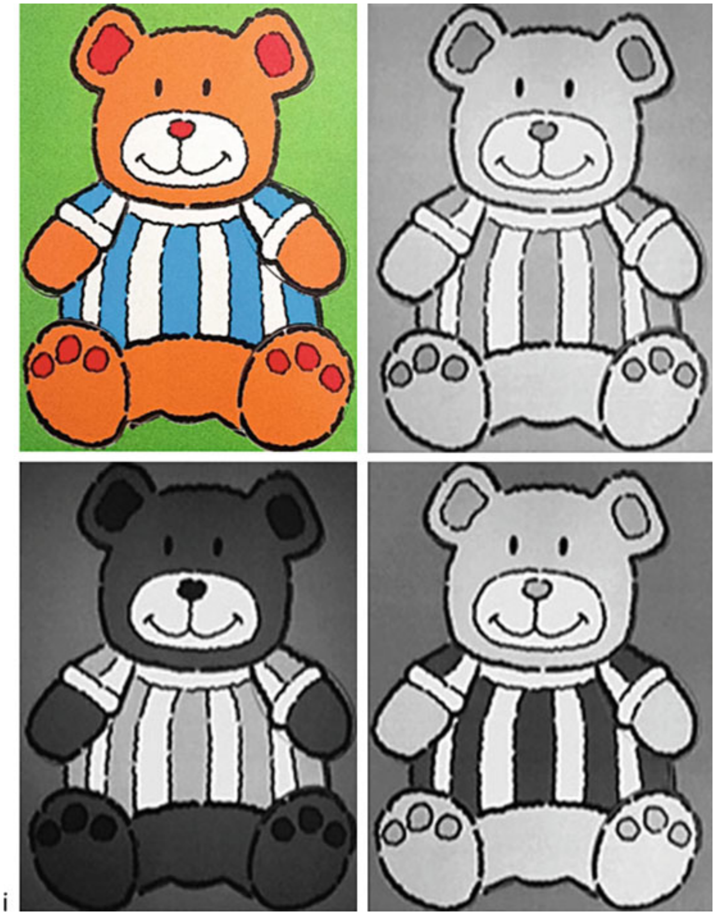


Fig. 40.17

Colour filtering (a) Interference filters, but not coloured glass/gelatine filters, can be tuned (i.e., λ_0 is changed slightly), by altering the tilt angle, θ. (b) Dichroic filters. The angle of incidence is fixed (45°). The incident beam is split into two components (transmitted and reflected beams), with complementary spectra. (c) Narrow band-pass filter. A family of filters is available, spanning the whole near-UV, VIS and near-IR spectrum. (d) Line-pass filter, transmits light within a very narrow range of wavelengths (monochromatic light, from a laser, sodium lamp, etc.), while blocking others. Such a filter can be used in conjunction with monochromatic lighting, in a system operating in bright ambient lighting. (e) Line-block filter, used to attenuate monochromatic light within a panchromatic spectrum. (f) Wide band-pass filter. Again, a range of filters covers the whole near-UV, VIS and near-IR spectrum. (g) Long-pass filter. The cut-off frequency, λ_1 may lie anywhere in the near-UV, VIS and near-IR spectrum. A UV-blocking filter has $\lambda_1 \approx 0.4\ \mu$m. If $\lambda_1 \approx 0.7\ \mu$m, the filter passes IR but not VIS. (h) Short-pass filter. An IR-blocking filter has $\lambda_2 \approx 0.7\ \mu$m. If $\lambda_2 \approx 0.4\ \mu$m, the filter passes UV but not VIS. A long-pass and short-pass filter can be combined, to create a band-pass filter which accepts a wider range of wavelengths than the fixed band-pass filters described in (f). (i) Example *Top left:* Sample images: child's toy. *Top right*: No filter. *Bottom left*: Short-pass filter ($\lambda_2 = 0.55\ \mu$m). *Bottom right*: Long-pass filter ($\lambda_1 = 0.55\ \mu$m)

GEOMETRY Annulus.

REMARKS The optical layout and notation are explained in ➋ *Fig. 40.20*. The camera should be fitted with a lens with a large *f*-number, to reduce aberrations. To understand this method, we use polar co-ordinates. The point (r, θ) ($r \geq R$) in the object plane, maps to the point (r-R, θ) in the image plane. Points in the object plane that lie within the central disc of radius R are all "removed" by the conical lens. This process may be pictured in the following way: Imagine that the scene being viewed is painted on a series of threads laid radially in the object plane. Now, imagine that each thread is pulled inwards a distance R towards the centre point (The thread collecting at the centre is cut off and ignored.). The new image formed by the paint on the remaining portions of the threads is exactly the same as that seen by the camera. This method is based in the same principle as the periscope. For a cone whose semi-angle is 45°, the number of pixels is reduced by 25%. If a thin annulus whose internal and external radii are R and (R + δ) ($\delta < < R$) is to be examined, the field of view of the camera can be reduced to a square of size $[2\ W]^2$. The number of pixels to be digitised and processed is then reduced by $100.[1 - (\delta/(R + \delta))^2]$ percent, which represents a very considerable saving. By reversing this optical set-up, we can generate an annulus of light from a collimated beam.

LAYOUT DIAGRAM ➋ *Figure 40.20*

40.23 Method 23: Continuously Moving Web

OBJECTIVE To examine a continuously moving web for creases, scratches, splits, cuts, stains, embedded foreign bodies, etc. The web may be opaque or transparent. In the latter case, there may be limited rear access, making it impossible to place even a miniature camera or lights behind the web.

TYPICAL APPLICATIONS In-process inspection of a wide variety of web products. The web may be plain or printed. Similar lighting-viewing methods can be used on flat rigid panels, such as metal sheet, plaster-board, printed circuit boards, etc.

EQUIPMENT Depending on the web's optical properties (transparency/opacity, surface gloss, presence/absence of piercing, embossing, etc.), various items of equipment are needed:

(a) For coaxial illumination and viewing of opaque film: diffusing filter and beam-splitter
(b) For diffuse front illumination of opaque film: diffusing filter, beam-splitter, diffusing screen
(c) For combined front- and back-illumination of transparent film, or web with piercings: retroreflector
(d) For dark-field or back-illumination of transparent film, or opaque web with piercings: broad-face light source

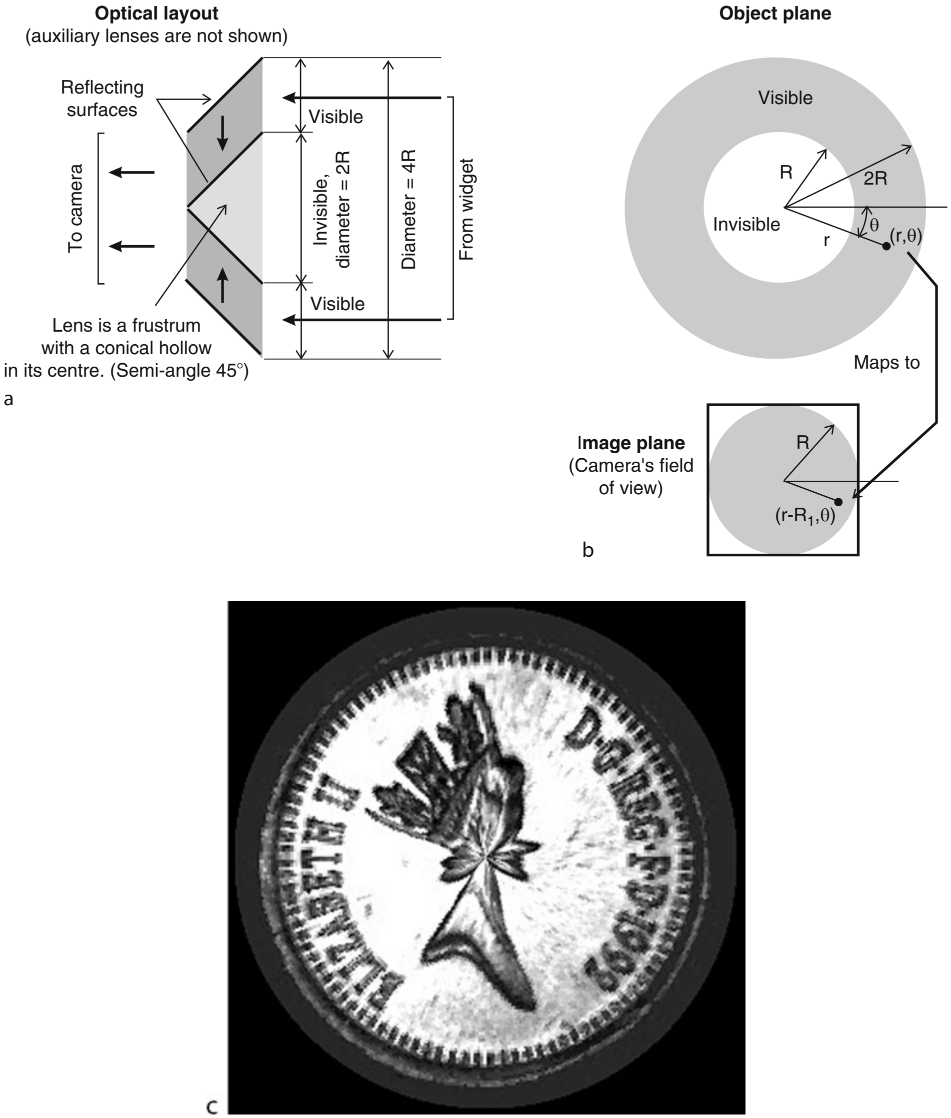
CAMERA Line-scan or array-scan.

MOTION Continuous linear motion.

GEOMETRY Flexible web held taut between rollers, or flat rigid material which may be in continuous form or discrete sheets.

MATERIALS Paper, card, metal film, clear or opaque plastic, glass, multi-layer laminate sheeting, knitted or woven materials. These may be transparent or opaque, shiny, matt or have a sheen.

REMARKS Several different lighting-viewing methods are illustrated in figure. Rolled, semi-fluid dough, clay, etc. may be inspected in a similar way. Retro-reflective sheet/ribbon can also be purchased from automobile spares retailers.



■ **Fig. 40.20**

Inspecting an annulus, without storing and processing unwanted pixels in the central region. (a) Optical arrangement, explaining how the image is formed. The white disc in the object plane, labelled "Invisible" vanishes. Each point (r, θ), within the grey annulus maps into a point (r-R, θ) in the image plane. (b) Sample image (simulated using QT, Chap. 21). *Left:* Original image of a coin. *Right:* Central region removed

LAYOUT DIAGRAMS ➔ *Figure 40.21*

40.24 Method 24: Crack Detection (Ferrous and Non-ferrous)

OBJECTIVE To view cracks in ferrous or non-ferrous components.
TYPICAL APPLICATIONS Detecting cracks in metal forgings, castings, plastic mouldings, ceramics, glassware, etc.
EQUIPMENT UV lamps, UV- and VIS-blocking filters and fluorescent "ink". See below for details.
MATERIALS Ferrous or non-ferrous.
SAMPLE PREPARATION There are three distinct methods in use:

Ferrous widgets (Magnetic-Fluorescent Particle Method)

1. Magnetise the widget. This might be achieved in a solenoid, or simply by passing a large electric current (e.g., 1,000 Amp) through the widget
2. Immerse the widget in a suspension containing very small particles that are both magnetic and fluorescent (Often referred to as "ink.") The ink particles adhere around the crack, where there is a high remnant field
3. Rinse the component gently (This removes most ink particles from the widget surface but does not dislodge them from around the crack, where there is a large remnant magnetic field)
4. Illuminate the widget using ultra-violet light
5. Observe the fluorescence in the visible waveband (It is important that we prevent ultra-violet light from entering the camera and spoiling the image, by using a UV-blocking filter). Cracks are visible as bright streaks

Non-ferrous widgets (Fluorescent Dye Penetrant Method)

1. Immerse the widget in low-viscosity dye. This should be chosen so that it can penetrate into the crack quickly, by capillary action
2. Dry the widget
3. Illuminate the widget using ultra-violet light
4. Coat the component in fine white powder, chosen so that it will "draw" the dye out of the cracks by capillary action
5. Illuminate the coated widget using ultra-violet light
6. Observe the fluorescence in the visible (VIS) waveband

In a slightly safer variant of this method, blue illumination is provided and fluorescence is observed in the orange-red part of the VIS spectrum.

Non-ferrous widgets (Visible Dye Penetrant Method)

As above, except that visible light (VIS) is used and a vividly coloured dye.

REMARKS Safety is a major concern when people are involved in either the magnetic-particle or dye penetrant methods. Prolonged exposure to even modest levels of UV radiation can induce skin cancer and damage eyes, by causing cataracts. Special attention must be paid to protecting the hands, arms, neck, chest and face. In addition, the ink may be based on noxious or inflammable chemicals, such as kerosene. It contains minute particles of iron oxide, which

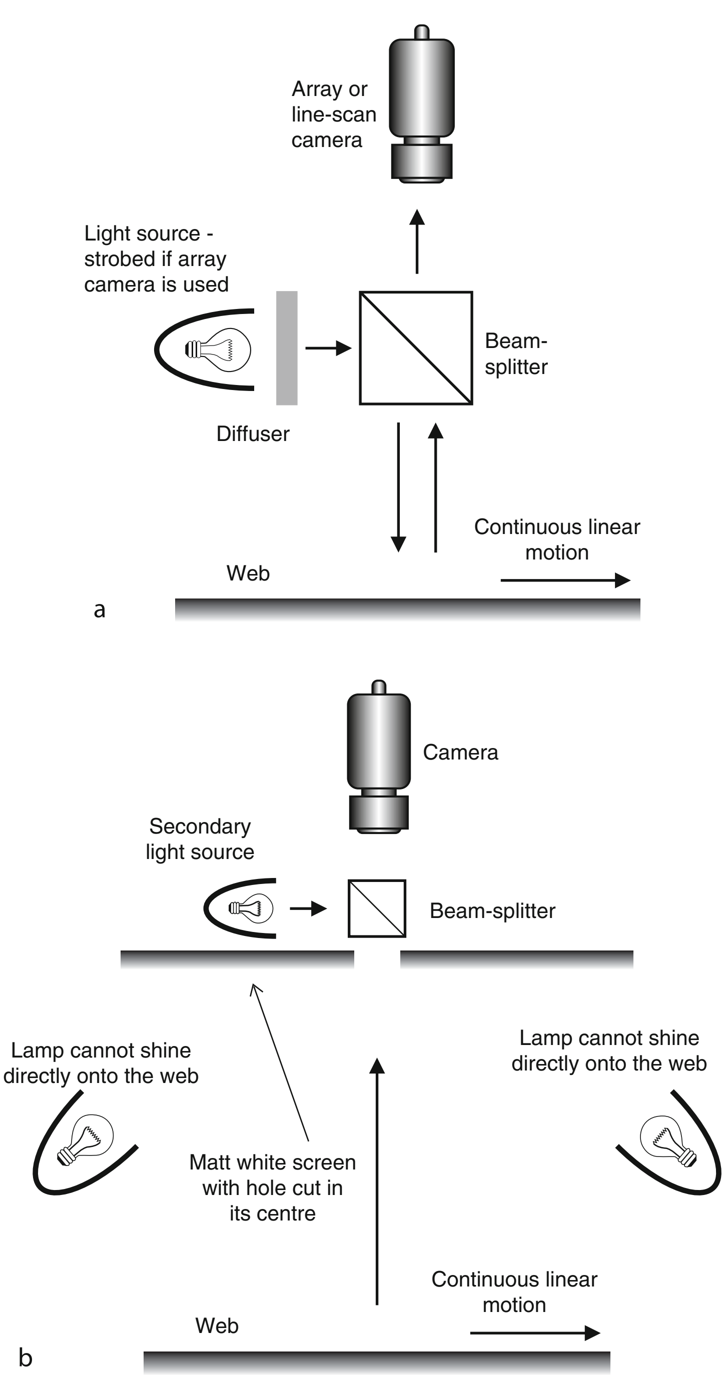

Fig. 40.21
(Continued)

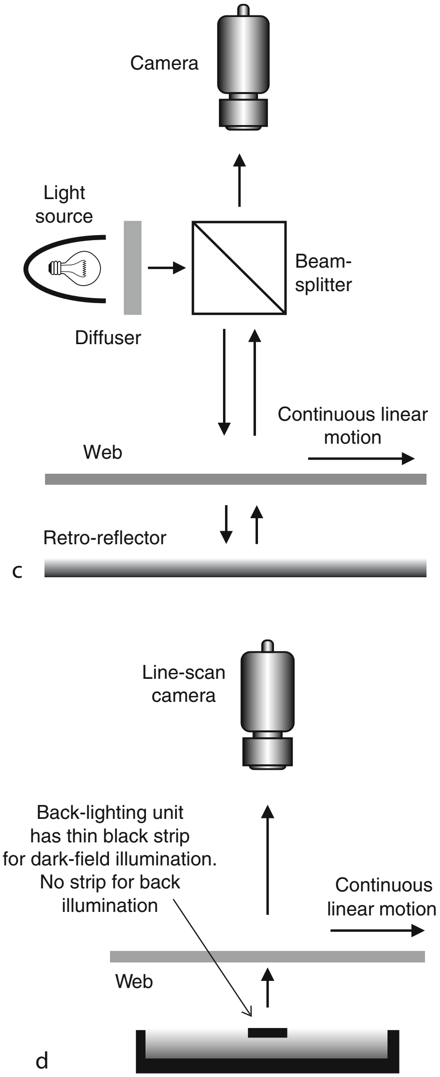

Fig. 40.21

Inspecting continuously moving web materials. (a) Optical layout for coaxial illumination and viewing of an opaque web. It may be necessary to offset the optical system slightly, so that reflections from the surface of the film can be avoided. This method is highly sensitive to undulations in the film surface and is therefore able to obtain good images of embossed patterns, as well as changes in surface reflectance. (b) Optical arrangement for diffuse front illumination of an opaque web. This is less sensitive to embossing and other surface undulations than the previous method. (c) Back illumination when there is limited rear access to the web. (d) Optical layout for dark-field and back-illumination of a transparent film

can cause skin irritation. Since only very low light levels are produced by fluorescence, a human inspector has be dark adapted. This may necessitate the inspector working in a small darkened and noisy booth, which is detrimental to his mental health. The health risks and unreliable performance achieved by human inspectors, together provide powerful motivation for automating this task, Image processing algorithms based on grey-scale morphology are often appropriate.

40.25 Method 25: Crossed Linear Polarisers Reduce Glinting

OBJECTIVE To reduce the effects of glinting, when examining shiny objects.

TYPICAL APPLICATIONS Examining painted and lacquered objects.

EQUIPMENT Two linear polarisers. Their easy axes are oriented at 90° to each other (Often referred to as *crossed polarisers.*).

CAMERA This method is well suited for use with cameras that suffer from optical overload. It is useful for both CRT and solid-state cameras. The latter may be line- or array-scan types.

GEOMETRY Suitable for objects with a complex shape that are difficult to accommodate by adjusting the geometry of the light source.

MATERIALS Bright shiny surfaces, such as polished metal, smooth plastic, glass, glazed ceramics, painted/lacquered surfaces, wet and oily objects.

REMARKS This method is based on the fact that specular reflection (produces glinting on a shiny surface) retains linear polarisation, whereas diffuse reflection does not. A shiny surface illuminated with light polarised at θ° reflects light that is also polarised at θ°. On the other hand, a diffuse reflector emits light that is almost uniformly polarised through all angles: 0–180°. Glinting is a pernicious problem in Machine Vision, as it frequently spoils image quality. Highlights due to glinting can, for example, give a false impression about the position of an object's outer edge. Glinting can also cause local optical overload of the camera, leading to:

(a) *Burn-in* (This is a problem in some older CRT cameras but is less important in solid-state cameras.)
(b) *Comet-tail effect* (Again, this is a problem for some CRT cameras but not with solid-state cameras)
(c) *Blooming* (This occurs in some solid-state and CRT sensors)

Some polarising filters do not function well in the near infra-red wave-band (Recall that the peak in the emission-spectrum of incandescent lamps and the peak in the sensitivity of solid-state image sensors are both in the NIR band). For this reason, it may be necessary to add an IR-blocking filter, to optimise image contrast. Low-cost plastic-sheet polarisers render bright highlights as spots of deep colour (e.g., violet, or red). To improve image quality still further, it may be advantageous to insert an appropriate optical filter between the polariser and the camera.

LAYOUT DIAGRAM AND SAMPLE IMAGES ➋ *Figure 40.22*

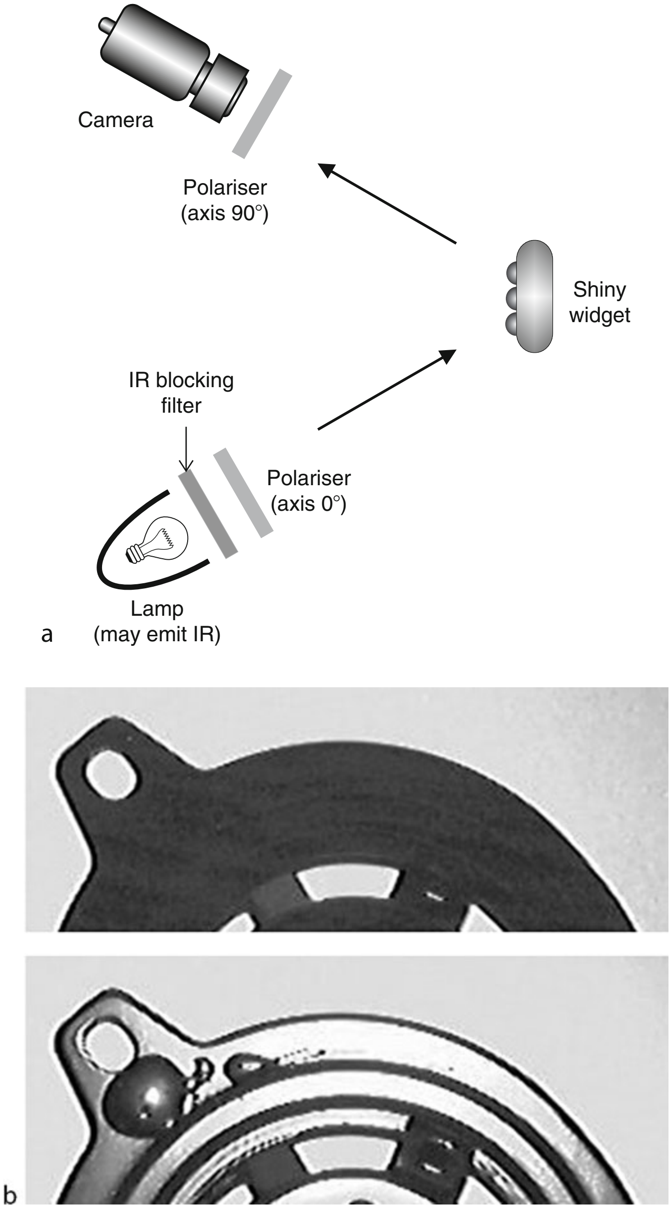

Fig. 40.22

Crossed polarisers eliminate glinting. (a) Optical layout. (b) Sample images: painted metal pressing. The paint is black, smooth and shiny. The back-ground (*white copier paper*) provides a good diffusing surface. *Top:* With polarisers in place, glinting is suppressed. *Bottom:* With no polarisers present, glinting occurs. Notice the highlights on the ''dollops'' of adhesive (*black, smooth and shiny*), near the round hole

40.26 Method 26: Dark Field Illumination (Array Camera)

OBJECTIVE To view silhouettes of transparent objects.
TYPICAL APPLICATIONS Shape analysis of glass and plastic bottles, jars, tumblers, etc.
EQUIPMENT Light box, with opaque black mask.
MATERIALS Transparent/clear glass, plastic. Transluscent materials.
CAMERA Array.
MOTION Static.
MATERIALS Transparent/clear glass, plastic. Transluscent materials.
REMARKS This method produces far better results than back-lighting on some transparent/transluscent objects, such as glass and plastic containers. When there is no object present, the camera receives no light at all, as it is facing the mask. A bottle, or jar, placed in the optical path receives light, which is diverted within and around the side walls, by refraction and internal reflection. Light therefore emerges to reach the camera, from those parts that are not illuminated directly from behind. Vertical edges and sudden variations in wall thickness are high-lighted particularly well. Hence, embossing, cracks and features such as "bird-swings" (filament of glass hanging between the side walls, across the inside of a bottle) and "spikes" ("stalagmite" of glass protruding inwards from the base or side-wall of a jar) are all highlighted by this method.
LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.23*

40.27 Method 27: Dark Field Illumination (Line-Scan Camera)

OBJECTIVE To view silhouettes of transparent objects.
TYPICAL APPLICATIONS Shape analysis of glass and plastic bottles, jars, tumblers, etc.
EQUIPMENT Light box, with thin black strip placed across its centre.
CAMERA Line scan.
MOTION Linear movement.
MATERIALS Transparent/clear glass, plastic. Transluscent materials.
REMARKS This method produces far better results than back-lighting on some transparent/transluscent objects, such as glass and plastic containers. When there is no object present, the line-scan camera receives no light at all, as it is facing the mask. A bottle, or jar, placed in the optical path receives light, which is diverted within and around the side walls, by refraction and internal reflection. Light therefore emerges to reach the camera, from those parts that are not illuminated directly from behind. Vertical edges and sudden variations in wall thickness are high-lighted particularly well. Hence, embossing, cracks and features such as "bird-swings" (filament of glass hanging between the side walls, across the inside of a bottle) and "spikes" ("stalagmite" of glass protruding inwards from the base or side-wall of a jar) are all highlighted by this method.
LAYOUT AND ILLUMINATION DIAGRAMS ➋ *Figure 40.24*

40.28 Method 28: Detect Pimples, Pits and Changes of Refractive Index

OBJECTIVE

- To detect and count liquid, or solidified, drops of a clear liquid lying on a clear transparent film or plate
- To detect sudden changes in refractive index in a smooth flat, or nearly flat, plate

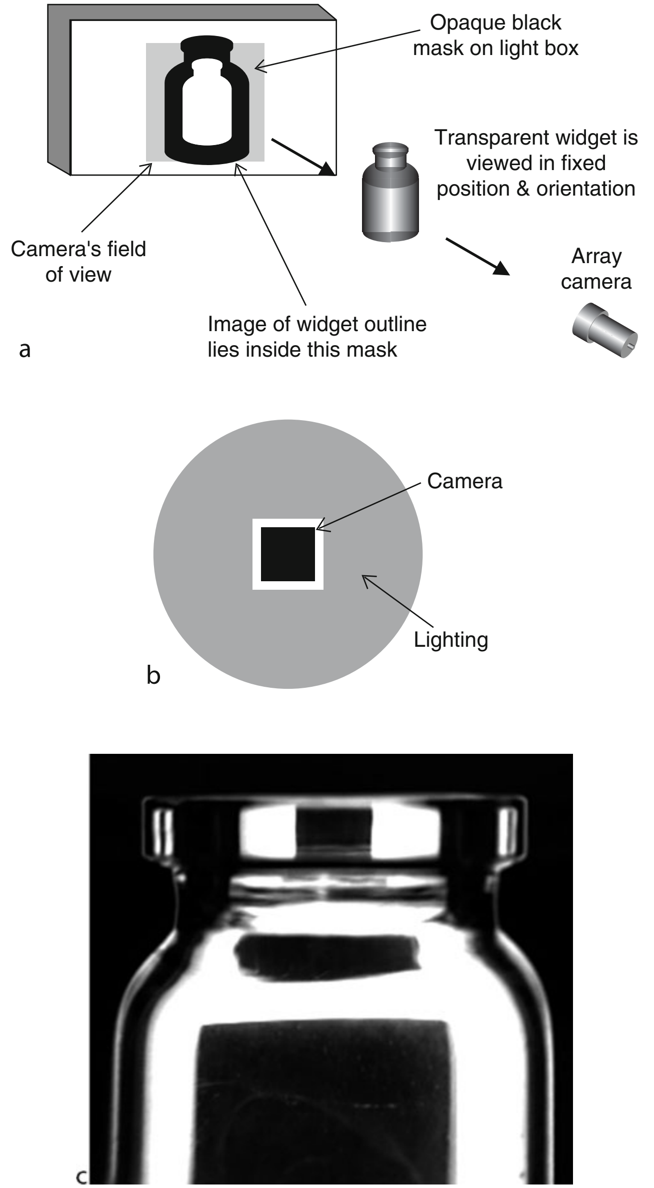

Fig. 40.23

Dark-field illumination using an array-scan camera. (a) Optical arrangement. (b) Illumination diagram (square mask). (c) Sample image: small glass vial

TYPICAL APPLICATIONS

- Inspecting plastic film
- Inspecting moulded glass
- Inspecting bi-focal lenses

b

Fig. 40.24
Dark-field illumination using a line-scan camera. (a) Optical arrangement. (b) Illumination diagram

EQUIPMENT Back-light unit, fitted with fine striped mask (line-scan camera) or checked mask (array-scan camera).
CAMERA Line-scan or array.
LENS Close focus.
MOTION Continuous linear motion for a line-scan camera. Static for an array type.
REMARKS This method detects changes in the slope of the surface. (i.e., large values in the second derivative of the film-thickness function) It is not able to produce highly accurate measurements but it does allow rapid identification and counting of drops of water and oil on clear glass and plastic sheeting. Pimples formed by solidified drops of plastic on sheeting can also be detected in this way, as can shallow pits with well-defined edges. This method works on the principle that a sloping surface deflects a light beam by refraction. If the slope changes suddenly, then the image of the background will appear distorted. Sudden changes in the refractive index can also be detected. ➲ *Figure 40.25d* It is a relatively simple matter to identify distortions and breaks in the continuity of the lines formed in the image. If a chess-board mask is used, the periodicity of the pattern is altered in one or both dimensions.
LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.25*

40.29 Method 29: Detecting Particles in a Swirling Liquid

OBJECTIVE To detect small particles (foreign bodies) in suspension in a clear liquid.

TYPICAL APPLICATIONS Detecting fibres, small pieces of glass, etc. in medicine vials.

EQUIPMENT

- Mechanical equipment to rotate the vial
- Dark-field illumination

CAMERA Array.

IMAGE ACQUISITION

(a) Rotate the vial at high speed

(b) Stop it suddenly

(c) Digitise an image. (Call this *I1*.)

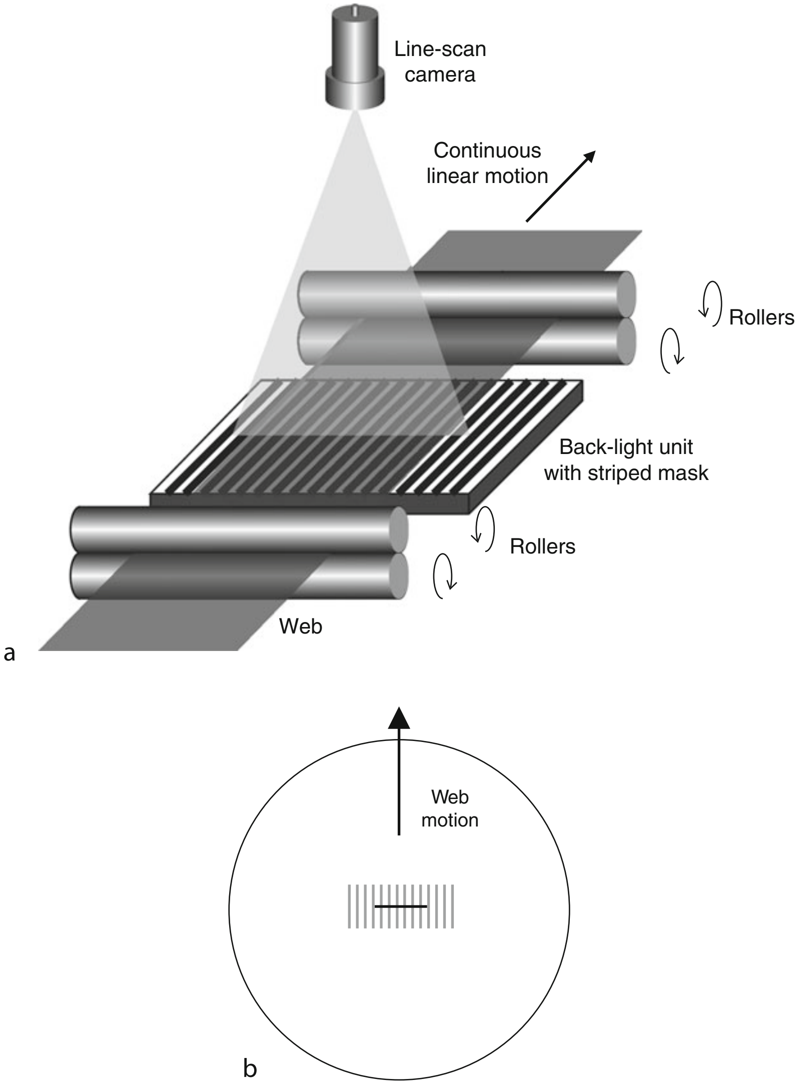

Fig. 40.25
(Continued)

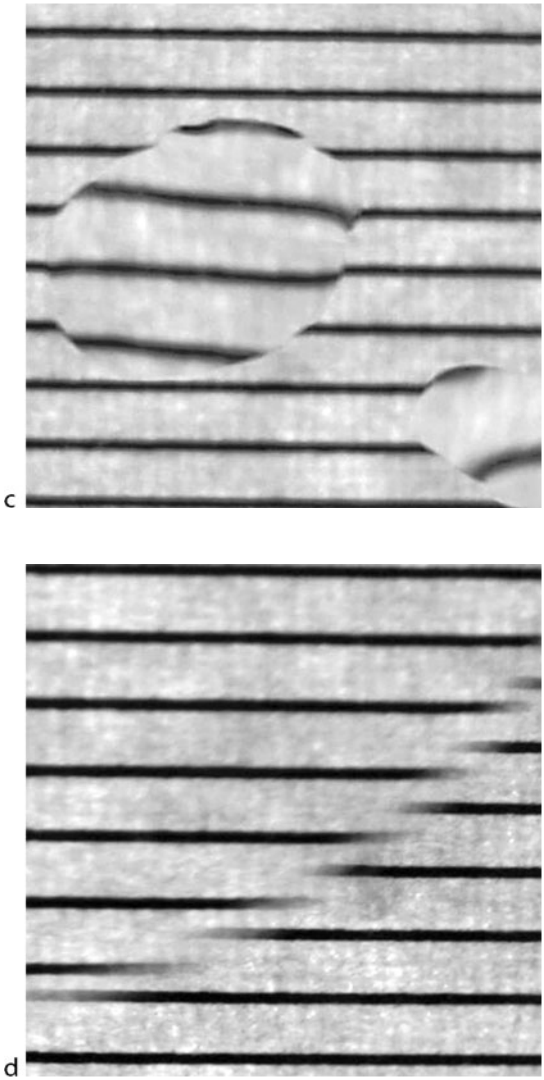

Fig. 40.25
Detecting geometric distortions and changes of refractive index on a transparent film (a) Optical layout. (b) Illumination diagram for the set-up based on a line-scan camera. (c) Sample image: Drops of water on a microscope slide. (To create this image, the back-ground consisted of an array of fine lines printed on ordinary white paper. In practice, a clear subtrate is preferable.) (d) Edge of the D-shaped short-focus lens element for bi-focal spectacles

(d) Wait for a short time
(e) Digitise an image. (Call this *I2*.)

MATERIALS AND GEOMETRY Clear liquid in a cylindrical glass or plastic container.

REMARKS This method was designed to detect small particulate foreign bodies that are denser than the liquid within the vial and which therefore naturally sink to its bottom, Small particles are

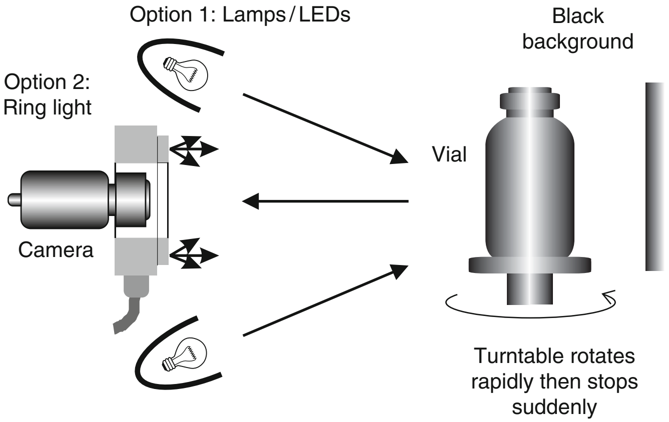

Fig. 40.26
Detecting particles in a swirling liquid. Notice that there are two lighting options shown here

not easily detected in the static liquid, when they are resting on the bottom or sides of the vial, since they cannot be distinguished from minor irregularities in the wall of the container. The vial is spun rapidly, causing the liquid to rotate with it. The liquid continues to swirl around for a few seconds after the vial has been stopped. By digitising two images in quick succession, when the particles are in different positions, it is possible to detect their motion. Images *I1* and *I2* are subtracted. Any shadows caused by imperfections in the wall of the vial are common to both images and hence are eliminated by the subtraction process. On the other hand, each moving particle creates one bright spot and one nearby dark spot in the difference image. Since the speed of rotation of the liquid is known approximately, these spots can be linked together, thereby allowing a more robust detection algorithm to be formulated. Vibration of the vial may be used instead of spinning but this does not allow pairs of spots to be linked.

LAYOUT DIAGRAM ➲ *Figure 40.26*

40.30 Method 30: Diffuse Coaxial Illumination

OBJECTIVE To provide diffuse illumination, with the camera effectively “looking through” the light source.

TYPICAL APPLICATIONS Coins, inspecting embossed and engraved surfaces.

EQUIPMENT Beam-splitter, diffusing screen. Circularly polarising filter (optional).

CAMERA Array or line scan.

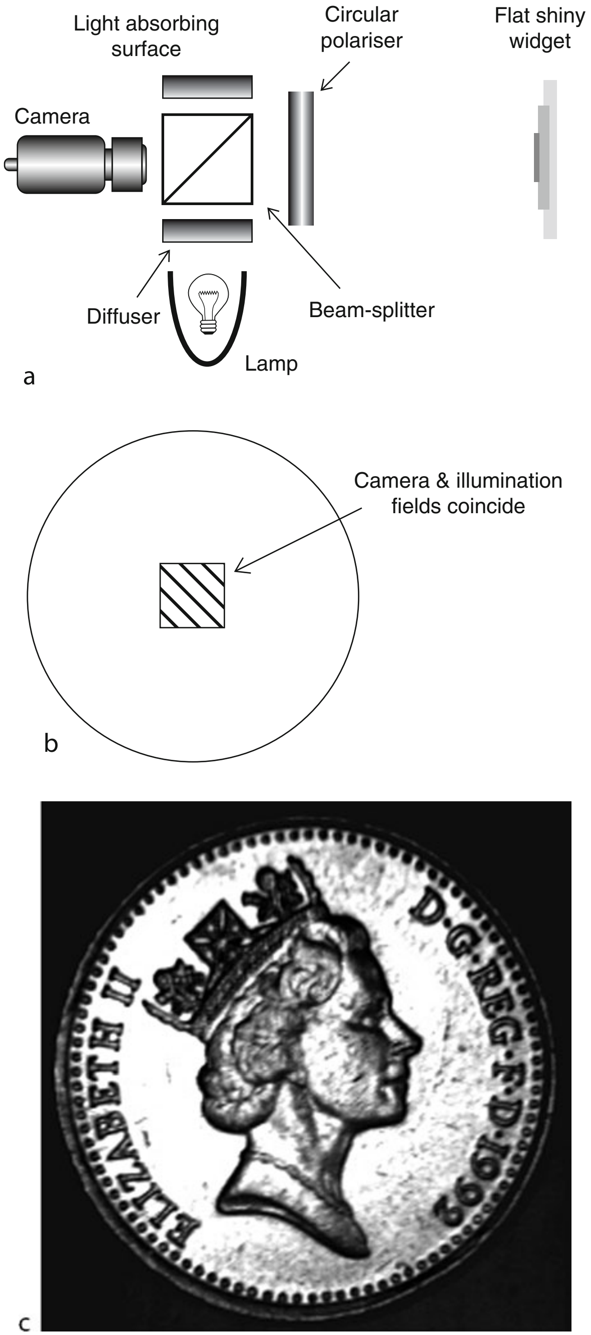
MOTION Static or linear motion.

GEOMETRY Flat with embossing or engraving.

MATERIALS Bright shiny metal.

REMARKS This is a very effective technique for viewing coins and similar objects. The flat surface (called the “table”) is bright and the embossing is dark.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.27*



◘ Fig. 40.27

Coaxial Diffuse Illumination. (a) Optical layout. (b) Illumination diagram. (c) Sample image: Coin

40.31 Method 31: Diffuse Front Illumination

OBJECTIVE To reduce the effects of glinting.
TYPICAL APPLICATIONS Inspecting objects with shiny, nearly planar surfaces, to detect scratches, cracks, pits, embossing, engraving, etc. shiny objects. Suitable for CDs, coins, electrical connectors, printed circuit boards, smooth plastic, glass, porcelain, etc.
EQUIPMENT Bright flood lamps (e.g., incandescent filament or fluorescent illuminator with a high-frequency driver) Diffusing screen with viewing aperture. This consists of a flat matt white board that has a small cut in its centre. It may be necessary to fit a short tube (painted matt black on its inside surface) into this hole, to prevent light reaching the camera directly from the lamps. A secondary light source and beam-splitter may be used to compensate for the dark aperture in the diffusing screen.
GEOMETRY Mirror-like surfaces and nearly flat surfaces with embossing, engraving, etc. Can also be useful for more complex structures, since it does not cast sharp shadows.
MATERIALS Bright metal, smooth plastic, glass, porcelain, etc., lacquered/painted surfaces.
REMARKS Excellent images of defects such as scratches can be obtained from mirror-like surfaces, which may be difficult to view otherwise. The secondary light source and beam-splitter avoid creating a reflection of the camera when viewing a mirror-like surface. In some applications, it is possible to eliminate them altogether.
LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.28*

40.32 Method 32: Dual Orthogonal-Beam X-ray Imaging

OBJECTIVE To inspect an object using two orthogonal X-ray beams.
TYPICAL APPLICATIONS Detecting foreign bodies in rigid packaged food products. The system is well suited to detecting contaminants in cartons containing multiple packages of food, as it can locate a foreign body in 3-dimensional space.
EQUIPMENT Two x-ray sources and two sensors.
CAMERA Two line-scan x-ray sensors.
MOTION Continuous linear motion.
REMARKS Several possible dual-beam x-ray systems were studied by simulation. The arrangement shown in ➲ *Fig. 40.29a* was found to be generally superior to the others. For example, the physical arrangement in which both x-ray beams are inclined at 45° to the horizontal generates images that are very difficult to understand and process.

TYPICAL APPLICATIONS Measuring the form of machined components, such as aircraft turbine blades.
EQUIPMENT Various optical components, including lenses, mirrors, dichroic mirrors.
CAMERA Line scan.
REMARKS This is a variation of the standard light-stripe triangulation method of range measurement. (Methods 66, 68 and 107) The optical system illustrated in figure projects alternating stripes of IR and VIS light onto the widget surface. The light scattered from the widget is then resolved using a dichroic mirror and appropriate filters. There are two cameras which sense the red and IR stripes independently. In the cited work, measurement tolerances of about 50 μm were achieved.

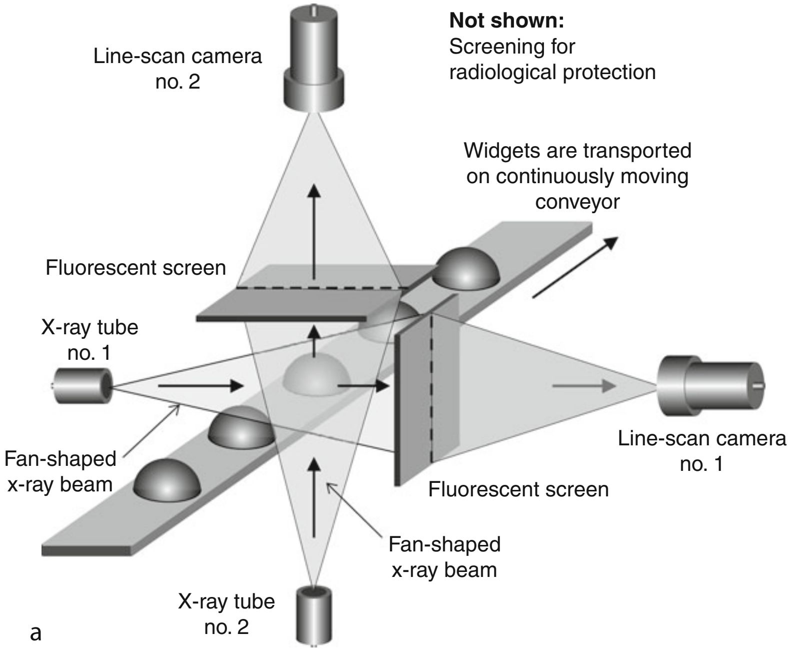

Fig. 40.29

Dual orthogonal-beam x-ray imaging. (a) Layout of the image acquisition system. (b) Sample images, displayed in negative form for easier viewing. six glass jars filled with savoury tomato sauce, were held on a card-board tray. *Top:* top view. *Bottom:* Side view. Three of the jars appear to be taller than the others because they are closer to the x-ray source (i.e., in a diverging beam). Some small foreign bodies present as bright spots. Notice that the top- and side-view images are aligned along the horizontal axis. *Images kindly supplied by Mr. Ralf Haberts, Pulsarr BV, Eindhoven Netherlands*

LENS Endoscope with C-mount fitting can be fitted in lieu of a standard lens.
MOTION Static.
GEOMETRY Holes, up to 1,000 mm deep. Longer coherent fibre optic bundles are expensive.
REMARKS The endoscope can be fitted with a mirror to allow it look backwards (mirror angle <45°), sideways (45°), or even forwards (>45°). The mirror can be rotated by hand, or

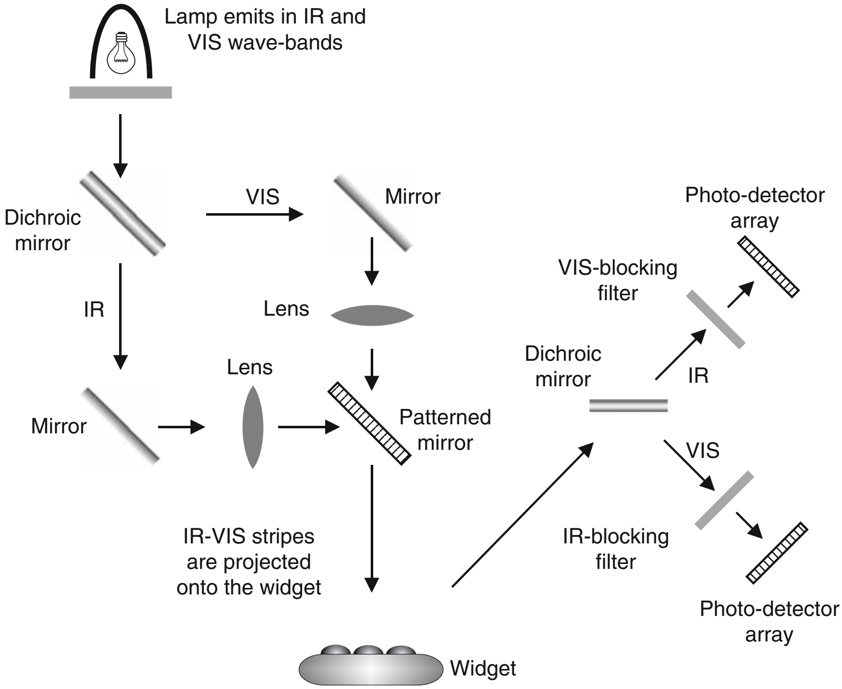

Fig. 40.30
Optical layout for dual–wavelength surface-height measurement

a motor. However, the image of features such as a ridge around the circumference of the bore also rotates. This can complicate the image processing needed. A circularly polarising filter can be added in front of the objective lens to eliminate problems due to glinting. The colour of the illumination can be altered by inserting a filter between the primary light source and the fibre-optic illumination bundle.

LAYOUT DIAGRAM AND SAMPLE IMAGE *Figure 40.31*

40.35 Method 35: Estimating Range During Image Capture

OBJECTIVE To focus a camera automatically and/or compensate for variations in the apparent size of a widget as its position relative to the camera changes.
TYPICAL APPLICATIONS Examining objects that cannot be held in a fixed position during image capture.
EQUIPMENT Two low-power, diode lasers.
CAMERA Array or line-scan.
MOTION Static or moving slowly.
GEOMETRY Has well defined flat region, roughly normal to the camera's line of sight.
MATERIALS Any material with a dispersive surface (i.e., not mirror-like).
REMARKS A simple range finder can be built using two lasers, or a single laser and a beam splitter. Two laser spots are projected onto the widget and their separation measured using the

camera and image processor. The range R can be estimated directly from the separation of the projected spots (S), using the formula:

$$R = R_0 + 2\,S.\cot(\theta)$$

where R_0 is the widget-camera distance when the spots converge. Notice that the sensitivity can be adjusted by changing the angle θ. The lasers can be switched off, if necessary, during image capture.

LAYOUT DIAGRAM ➔ *Figure 40.32*

(Continued)

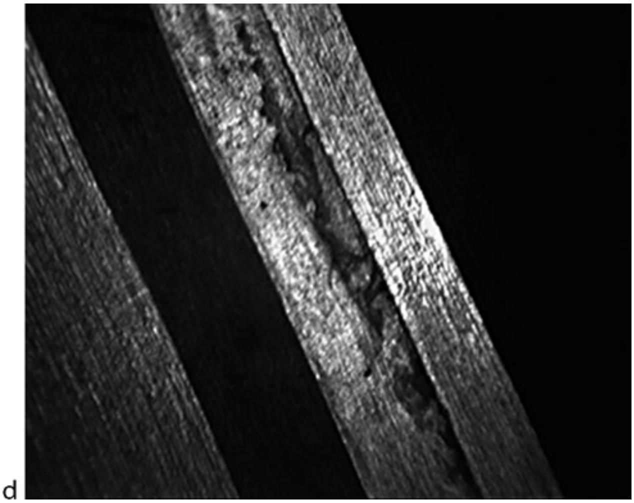

Fig. 40.31
Rigid endoscope. (a) Internal optical arrangement. Illumination is provided by optical fibres which lie parallel to the axis of the probe, between the relay-lens tube and the outer protective sheath. The mirror tube fits around the latter and can be rotated by hand or mechanically. (b) The angle of view can be adjusted by changing the angle of the mirror. (c) Industrial endoscope. (d) Sample image. Notice the variable intensity, due to the variable angle of the lighting on the widget surface. As the mirror tube is rotated, the diagonal feature (circumferential ridge inside the bore) also rotates

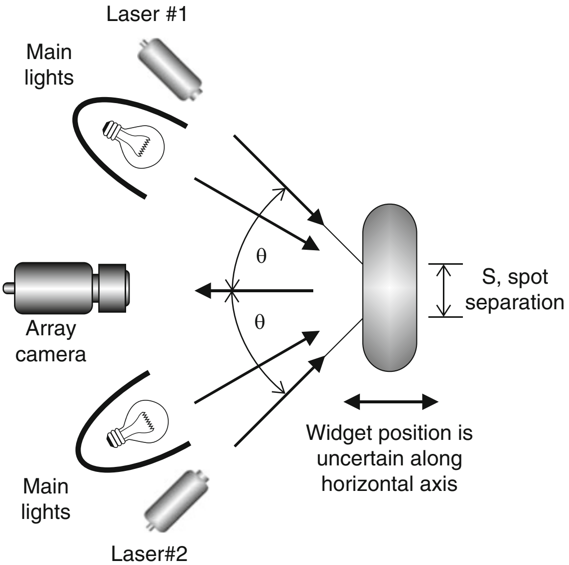

Fig. 40.32
Estimating range using two lasers to estimate the camera-widget distance

40.36 Method 36: Examine the Inside of a Pipe

OBJECTIVES To view inside a tube or pipe.
TYPICAL APPLICATIONS Inspecting sewers, drains, industrial pipework, etc. Inspecting nuclear installations is of particular interest.
EQUIPMENT Self-propelled probe, carrying one or two miniature cameras, LED lighting.
CAMERA Two miniature cameras.
LENS Light weight, miniature.
MOTION Self propelled, using electrical or pneumatic motors.
GEOMETRY Cylindrical or square bore of nearly constant diameter.
REMARKS The cavity being inspected must be reasonably dry and free from dust. In some applications, it may be possible to clean the lights and camera lens in situ, using an air purge. Since exposed solid-state devices are carried deep inside the cavity, its temperature must not exceed about 60°. Radiation levels must also be low. If the camera drags an "umbilical" cord behind it, carrying all power and video signals, the depth of penetration will be limited. On-board image storage will, of course, circumvent this restriction. Self-propelled inspection probes have been devised for pipe inspection using pneumatic and electric motors. The vehicle may travel on wheels, or "walk." Larger autonomous probes, some with on-board image storage and processing, have been in use for many years in the gas, water and petroleum industries and for inspecting tunnels, drains and sewers. In some situations, structured light (Methods 24 and 41) is used to examine the geometry of the cavity.

Fig. 40.33
Examining the side-wall of a narrow tube using two sub-miniature CCD cameras, mounted on a motorised platform. LEDs provides the illumination. The "umbilical chord" carries the video signals, power for the cameras, LEDs and the motor. By substituting a conical mirror for the mirrors, almost 360° of the side wall can be examined. (See Method 116.)

40.37 Method 37: Fast Electronic Shutter

OBJECTIVE To provide electronically controlled sampling of an optical image, enabling a standard video camera to observe continuous or repeated motion, or fast transient events, without the use of stroboscopic illumination.

TYPICAL APPLICATIONS An electronic shutter can be used in a wide variety of situations, where stroboscopic illumination would normally be indicated but safety considerations prohibit its use.

EQUIPMENT Liquid crystal light valve, operating as an optical shutter. This may be external to, or an integral part, of the camera.

CAMERA Highly sensitive, progressive-scan, array camera.

LENS Small *f*-number, to collect maximum amount of light.

MOTION Continuous or repeated motion, or rapidly changing scene.

REMARKS Since this method uses continuous illumination, it is inherently safe. On the other hand, stroboscopic illumination presents considerable health and safety risks: inducing epileptic fits (even in people not previously known to be susceptible to epilepsy), triggering migraine and making moving/rotating machinery appear to be stationery. To achieve satisfactory operation of the camera (i.e., good signal: noise ratio), it might be necessary to apply very high levels of illumination. Since the output from the photo-sensor array is proportional to the product of the time that the shutter is "open" and the illumination intensity, observing short-duration events might require very bright lamps dissipating a lot of heat. Care should be taken to avoid excessive heating, if incandescent filament lamps are being used.

LAYOUT AND TIMING DIAGRAMS ❯ *Figure 40.34*

40.38 Method 38: Fibre Optic Image Conduit/Cross Section Converter

OBJECTIVES

- To bend and/or twist the light path when viewing in awkward locations
- To remove the camera from a harmful environment, protecting the camera from extremes of dirt, moisture, oil, heat, radiation, and vibration
- To provide a small and rugged alternative to a reducing lens system
- To convert x-rays or UV into visible light (VIS)

TYPICAL APPLICATIONS Viewing inside areas that are hot, chemically or biologically dangerous, radio-active, or under low/high pressure. (The image conduit is inserted in the wall of the work area.)

EQUIPMENT Fibre optic image conduit.

CAMERA Array scan.

LENS Standard lenses.

MOTION Static or dynamic

GEOMETRY Objects with holes.

REMARKS Fibre-optic image conduit consists of a large number of glass fibres, fused together to form a solid rod, or block. The conduit transmits an image projected onto one end of the rod undistorted to the opposite end, where it can be viewed by eye, or a video camera. Image conduit is normally supplied with ground and polished ends. By heating it in a gas flame, image conduit can be bent to conform to any prescribed path with minimal transmission

◘ Fig. 40.34

Fast electronic shutter. (a) Optical layout. The lamp positions indicated here are not critical; they may be placed wherever they are needed, to optimise the image contrast. (b) Combining safe strobing (The frequency is equal to the video frame rate: 50/60 Hz.) and an electronic shutter. This method provides the same effect as low frequency strobing, but avoids its dangers. Notice that either the lighting or the shutter can be used to limit the total number of photons reaching the photo-sensor array; the light integration period is of duration *$MIN(T_L,T_S)$* seconds

loss. Image conduit rods typically range in diameter from 1.5–6 mm, with fibre diameters from 12–100 μm. The numerical aperture is typically 0.64, making the receiving end of the rod is somewhat selective about the direction of the incoming light rays that it will transmit. A cross-section converter usually has a much greater diameter and hence must be pre-formed during manufacture. Image conduit may superimpose a fine “chicken-wire” pattern onto the image

(➋ *Fig. 40.35c*) and this may require the use of special image processing operators. Components based on image conduit technology are made to provide special functions such as:

- Quarter twist (90°)
- Half twist (180°)
- Right angle bend
- Right angle with quarter/half twist
- Change of image size. (enlarging or reducing by a factor of about 3, or less)
- Detectors for UV or x-rays. (The front face of the conduit, or cross-section converter, is simply coated with an appropriate scintillator material. The efficient optical coupling achieved in this way allows a sensitive and rugged x-ray, or UV, sensor to be built.)

Image conduit and standard fibre optic face plates provide the basis for effective camera protection in quite hostile environments. Of course, it is important to check that the glass used in the construct of the image conduit is appropriate for that hazard.

LAYOUT DIAGRAM ➋ *Figure 40.35*

40.39 Method 39: Fish-Eye Lens Views Inside Hole

OBJECTIVE To view inside a hole.
TYPICAL APPLICATIONS Inspecting:

- Holes in castings
- Pipes, tubes, drains, sewers, etc
- Automobile engine cylinders by entering through the fuel-air inlet or exhaust ports

EQUIPMENT Fish-eye lens and ring light. The latter may consist of either an array of LEDs or a fibre-optic ring light.
CAMERA Array.
LENS Fish-eye or semi-fish eye lens.
MOTION Static.
REMARKS The lens may be incorporated into an endoscope, enabling it to enter the hole. A fish-eye lens has a large depth of focus, so it is usually quite easy to maintain good focus over the whole of the camera's field of view. The viewing angle of a fish-eye lens may be 150° or more.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.36*

40.40 Method 40: Flexible Inspection Cell/Robot Vision Cell

OBJECTIVE To provide a flexible inspection/parts handling environment, capable of implementing several of the important lighting-viewing methods described elsewhere in this chapter. The system should allow the user to adjust the directions of both lighting and viewing, the size of the camera's field of view, the viewing background and insert appropriate optical

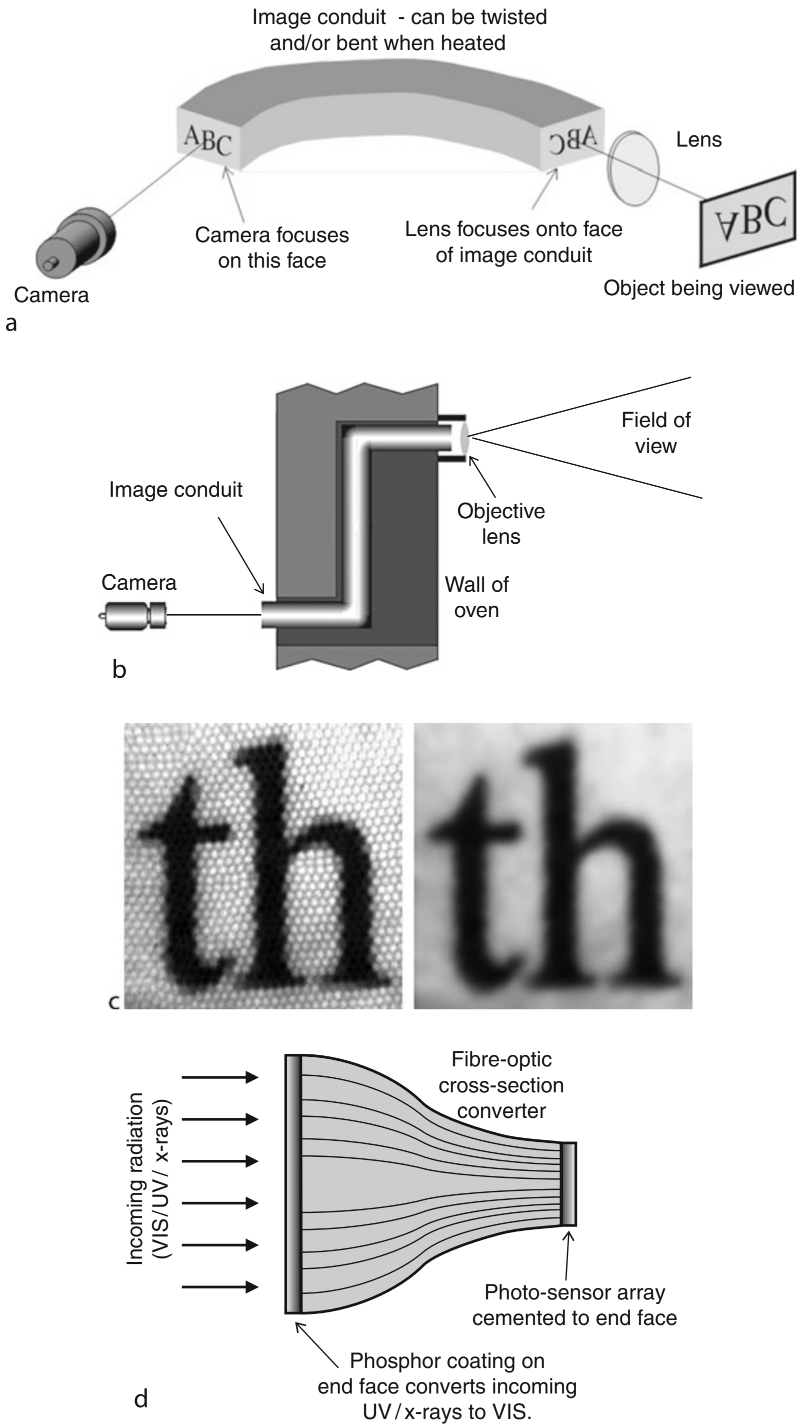

Fig. 40.35
(Continued)

elements (e.g., filters, diffusers and polarisers) in the optical path. A *Flexible Inspection Cell (FIC)* may be built around any of the popular manipulators: (X, Y, Z, θ)-table, gantry robot, SCARA robot *(Selective Compliance Assembly Robot Arm)* or revolute robot (multi-axis articulated arm).

TYPICAL APPLICATIONS Inspecting complex objects, assemblies of parts and low-volume applications. (When objects are made in small quantities, it may not be cost-effective to design and build a bespoke image acquisition sub-system.) An important application of an FIC is in prototyping vision systems.

EQUIPMENT Four of the most important types of robot can be integrated into an FIC:

(1) (X, Y, θ)-table or (X, Y, Z, θ)-table. (➲ *Fig. 40.37a*, *b*)
(2) Gantry robot. ➲ *Figure 40.37c*
(3) SCARA robot. ➲ *Figure 40.37e–h*
(4) Multi-axis articulated arm (revolute robot, ➲ *Fig. 40.37i*)

In addition the following items are needed:

(a) Computer-controlled lights. (VIS, UV and IR, as appropriate)
(b) Laser light-stripe generator (to create depth maps, Method 107)
(c) Pattern projector (ruggedised slide projector, Method 68)
(d) Several cameras facing different backgrounds (black, mid-grey, white/self-luminous). These may be either array- or line-scan types
(e) Standard, wide-angle and telephoto lenses, to provide different magnifications. (It is usually easier to calibrate a multi-camera system with fixed lenses, rather than use variable zoom lenses.) The lenses may be auto-iris type, to compensate for changes in lighting levels
(f) A variety of filters, diffusers and polarisers

MOTION Image acquisition normally takes place when the widget is static, using an array camera. Most robots allow the user to define which points in state space are to be visited but not the path between them. Hence, while it is moving, there is some uncertainty about exactly where the robot is at any given moment. However, accurately defined linear and rotary scans can be provided by an (X, Y, Z, θ)-table, driven by stepper motors. A line-scan camera can then be used. (c.f. Methods 59 and 83).

WIDGET HANDLING MECHANISMS It is possible to design a FIC around a variety of robotic manipulators. Four of the principal types are discussed below.

(X, Y, Z, θ)-table (➲ *Fig. 40.37a–b*) Provides $2^{1}/_{2}$, 3, $3^{1}/_{2}$ or 4 degrees of freedom. Avoiding collisions between the manipulator and static objects, such as lights, cameras and their support structures, is straightforward, as the work space is a cuboid. A FIC can be designed around any convenient translation stage, including devices, where the work volume is large (in excess of 1 m^3), or very small and providing micron-level position tolerances. Good

▪ **Fig. 40.35**

Fibre-optic image conduit used to bend/twist the light path in an imaging system. (a) Optical layout. (b) Image conduit embedded in the wall of a hazardous viewing environment protects the camera from heat, dirt, moisture or radiation. (c) Sample image: *Left.* Original. Notice the "chicken-wire" pattern caused by the finite diameter of the optical fibres. *Right:* Low-pass (blurring) filter effectively removes the "chicken-wire" pattern. Fig. 40.36 (Continued)

precision and repeatability can be achieved if stepper motor drives and optical position feedback are used. By using other types of motor and gear mechanisms, accuracy and speed of movement can be traded against each other, as the application demands. The maximum permissible payload is good. Cameras and lights can be placed anywhere above the viewing platform, as there is no obstacle for the lighting. A large number and wide variety of lamps (e.g., IR, VIS and UV) can be used, as access is not limited. Since the widget rests directly on the viewing background (as perceived by an overhead camera), the latter may become scratched/dirty quite quickly. It is easy to fit jigs for holding awkwardly shaped widgets, as they are being inspected. A pick-and-place arm can be used for loading/unloading widgets onto the table. This is a convenient low-cost, “do it yourself” solution, capable of satisfying the needs of a wide variety of applications and it can be tailored easily for specific requirements.

Gantry robot (➲ *Fig. 40.37c–d*) Provides $2^1/_2$, 3, $3^1/_2$ or 4 degrees of freedom (i.e., same as the FIC based on an (X, Y, Z, θ)-table). The work space is a cuboid. Access for lighting is slightly limited by the legs. (This ignores the fact that a gantry robot can hang from the ceiling, rather than stand on the floor.) The legs can be used for mounting small lighting modules, for example using fibre optics or LEDs. The payload is likely to be lower than that for the (X,Y, θ)-table and the gripper obscures part of the widget. It is not possible to use an overhead camera, unless the robot releases the widget and then moves away, prior to image capture. We can add a camera mounted below and looking through the table-top. (➲ *Fig. 40.37d*) A mirror folds the optical path, allowing the camera and its lens to be moved out of harm’s way. However, the protective window and mirror must be regarded as sacrificial components, since there is a danger that the robot will drop a widget onto them. LED lighting can also be built into the table-top. This camera views the widget against a complicated and uncontrolled background (i.e., the gripper and under-side of the robot arm).

SCARA robot (➲ *Fig. 40.37e–h*) Provides $2^1/_2$, 3, $3^1/_2$ or 4 degrees of freedom. The work space is a vertical cylinder with a crescent-shaped cross section in the horizontal plane. Access for lighting is good, as the only obstacle is the arm-support column. Provided it is not too tall, a rigid pillar holding a series of small lamps (e.g., LEDs) can be placed safely beneath the robot’s arm, close to that column. An overhead camera cannot see a widget held in the gripper. However, a view looking upwards can be obtained by a camera fitted into the table-top (➲ *Fig. 40.37d*).

Revolute robot (➲ *Fig. 40.37i*) Typically, provides 4–6 degrees of freedom. Designing a FIC around a revolute robot can be difficult, since the work volume is large: almost a complete sphere. It is difficult to control a non-deterministic revolute robot to prevent it from colliding with static objects, such as cameras, lights and the support scaffolding. (For every point on the robot’s trajectory in multi-dimensional state space, the collision-avoidance program must take into account the position of every point on the arm, gripper and widget.)

However, two useful FIC configurations exist:

◘ Fig. 40.36

Examining a hole without entering it. (a) Optical set-up. (b) Sample image: Female screw thread. (c) Sample image: bore of diameter 56 mm and depth 78 mm. The bright concentric rings are reflections from shallow circumferential ridges. The short dark streaks at the top and bottom of the bright central annulus are circular ports opening into the base of the main chamber. (For an overall view of this object, see ➲ *Fig. 40.81c*.)

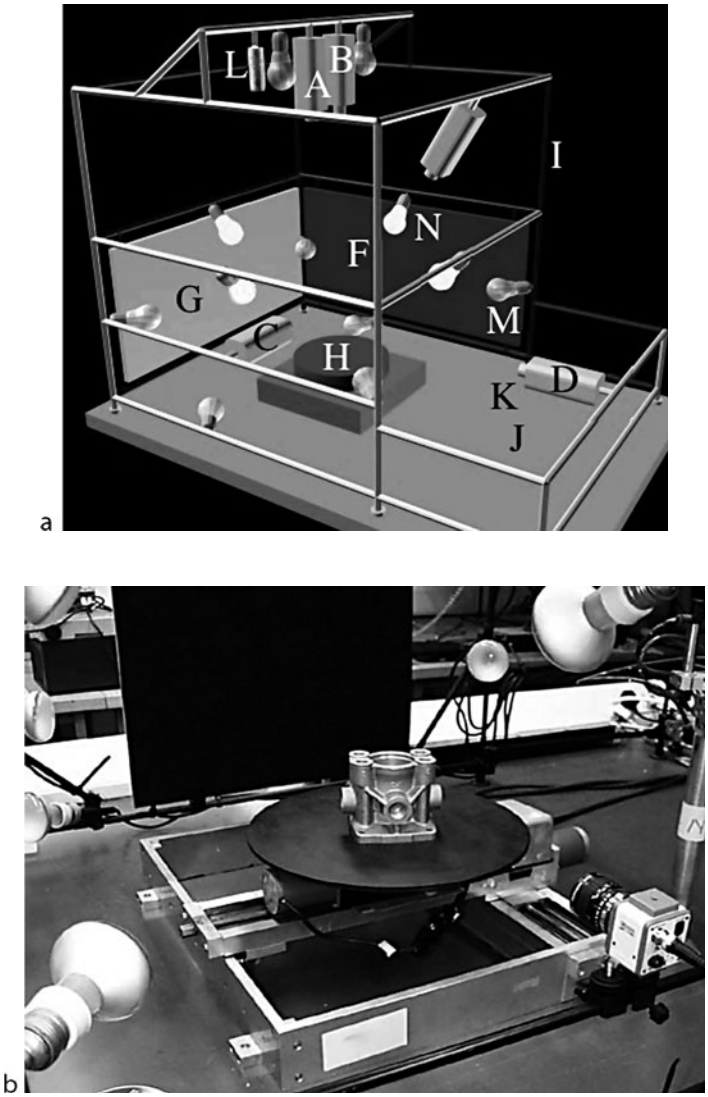

Fig. 40.37
(Continued)

1. Place the camera on the robot arm. (See Method 124)
2. Attach the camera to the body of the robot

The latter is particularly convenient, since the camera rotates with the arm and widget, allowing us to adjust the direction of lighting by simply moving the robot (i.e., varying θ in ➲ *Fig. 40.37i*). Although there is no simple relationship between the pose of the robot and the image received by the camera, the major effects can be summarised thus:

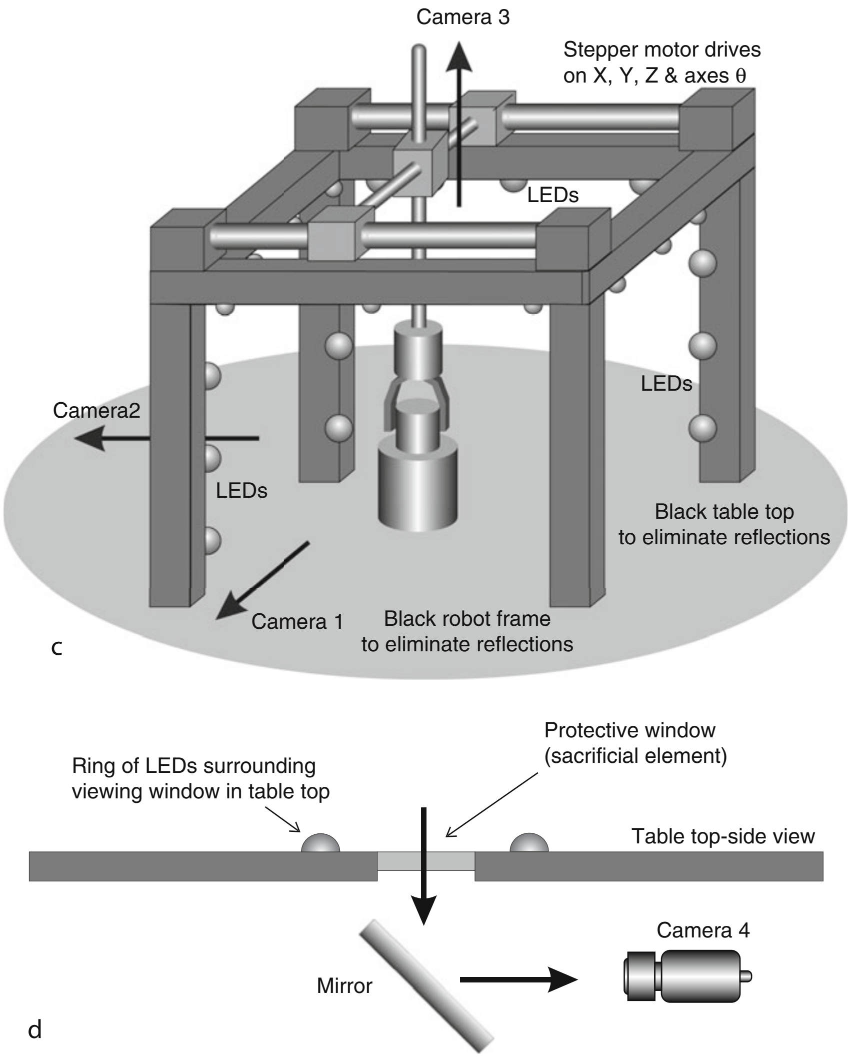

Fig. 40.37
(Continued)

Robot axis	Most significant change is to:
θ (rotation in the horizontal plane)	Lighting direction
ϕ/φ (shoulder and elbow joints)	Magnification/focus and vertical shift
δ (pitch)	Vertical scale in the image plane
ε (roll)	Horizontal scale in the image plane
Yaw (Not shown in *Fig. 40.37i*.)	Image rotation

■ **Fig. 40.37 (Continued)**

REMARKS The FIC was originally devised in response to the development of Flexible Manufacturing Systems and is intended to provide an inspection facility of commensurate versatility. A well-designed FIC can implement many of the lighting-viewing methods described elsewhere in this chapter but is limited to inspecting objects within a somewhat limited range of sizes (typically 25–200 mm). A filter wheel can be used to adjust the camera's spectral response, to insert a secondary lens or polariser into the optical path. ➔ *Figure 40.37j* An FIC, controlled remotely via the Internet, may be useful for prototyping vision systems for distant factories, without ever visiting them. The ALIS 600 system (➔ *Fig. 40.37k*) is similar in

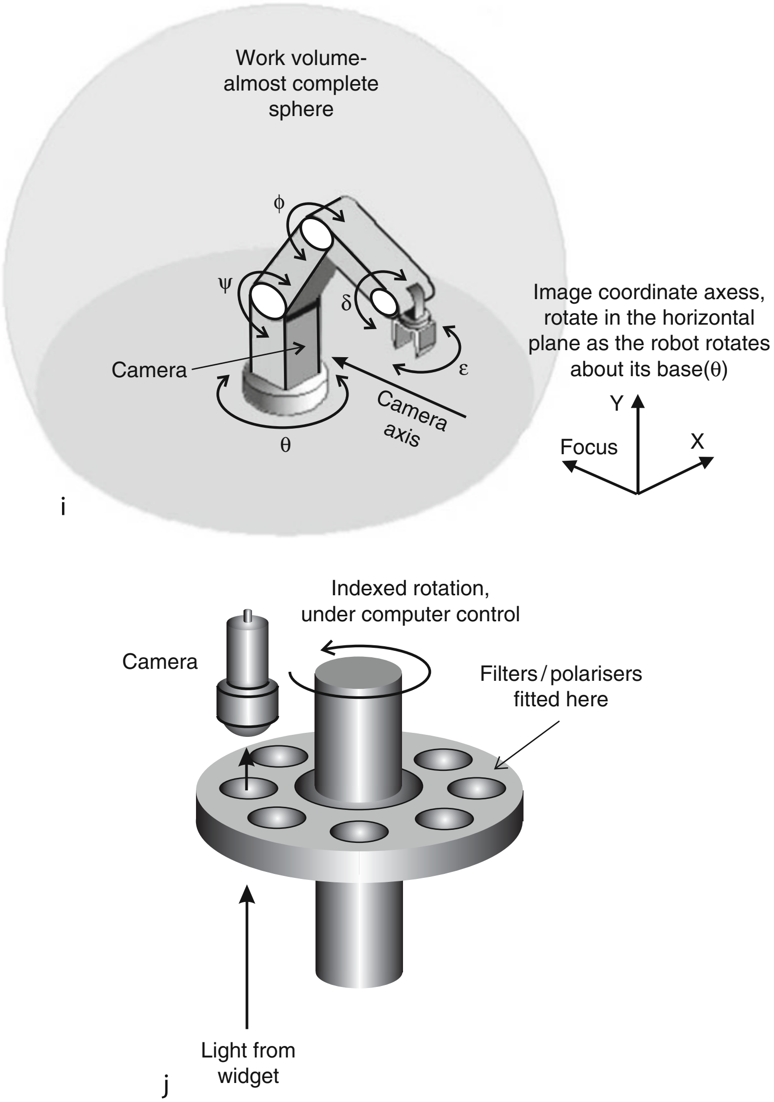

Fig. 40.37
(Continued)

general concept to the FIC described in *Fig. 40.37a* but has no robotic manipulator. Hence, all adjustments are made by hand. This might not matter too much if a vision engineer is available on-site. However, the FICs described here are intended to be operated remotely, via a LAN, WAN or cell-phone network, so that the vision engineer does not have to travel unnecessarily. The human-computer interface needed to control a remotely-operated FIC requires careful attention.

(60 W filament type). In a more recent development, lighting is provided by a set of eight white multi-LED arrays. (c) Design for a FIC based on a gantry robot. The lighting is provided by a series of small LED modules, attached to the robot's frame in such a way that they will not interfere with its movement. (d) Adding a fourth camera to the FIC based on a gantry robot. (Side view through the table-top.) A similar arrangement can be used in conjunction with the FICs based on SCARA and revolute robots. (e) Visualising the work space for a SCARA robot. That region in 3D space swept by the robot arm is called the *work space* (or *work volume*) and must be kept clear of obstacles, to avoid collisions. The work space for a SCARA robot consists of a vertical cylinder, with a crescent-shaped cross section, and a "bridge," with clearance height H1, stretching between it and the arm-support column. In practice, a slightly larger region of 3D space, called the *guard volume*, must also be kept clear if the widget extends beyond the end of the robot's arm. The intersections of the work space and guard volumes with the horizontal plane, forms the *work envelope* (black crescent) and *guard region*. These are simply convenient ways for visualising the robot's work space. [Artwork by David Batchelor]. (f) Illumination for a FIC, based on a SCARA robot can be provided by a series of lamps, possibly arrays of LEDs, mounted on rigid pillars. Provided the lighting pillar is not taller than H1, it can fit safely beneath the robot's arm close to its base. (g) Relationship between the work envelope and the guard region for a SCARA robot. (h) Layout (plan view) for an inspection cell based on a SCARA robot, providing front, side and back illumination. During inspection, the widget is held at point A by the robot. To obtain high-precision measurements, additional cameras, with narrow fields of view may be stacked above cameras 1 and 2. Of course, it is not possible for an overhead camera to view a widget held in the robot's gripper, although it can see objects lying on the table. (This is not always convenient, as the robot is required to release its grasp, move out of the field of view during image capture and then pick up the widget again.) A camera, looking vertically upwards, through a window set into the table-top may be used instead. (See part (d) of this diagram.). (i) Work space for a multi-axis articulated arm (revolute robot). By placing the camera on the body of the robot, we can adjust the direction of lighting from a fixed point source at will. This effectively defines a set of coordinate axes that rotate with the robot (θ varies). The image coordinates are XY. (j) Filter wheel. May be used with any of the cameras within a FIC to alter its spectral response. (k) Schematic layout for a multi-function lighting system. Based on the ALIS 600 system, manufactured by Dolan Jenner, Inc. Unlike the FIC, all adjustments to the camera, lights and widget are made manually

40.41 Method 41: Fluorescence and Phosphorescence

OBJECTIVE To use fluorescence or phosphorescence to differentiate between materials which otherwise appear to be indistinguishable (i.e., they have the very similar colour, shade, sheen and texture).

TYPICAL APPLICATIONS *Manufacturing industry:* detecting leakage and spots of oil, grease and various organic chemicals. *Food:* detecting spillage of fillings from pies, cakes, etc. (differentiating the contents from the pastry case), detecting kernel of the stones in cherry flesh, detecting nematode worm infestation in the flesh of fish.

EQUIPMENT Ultra-violet light source. (For safety's sake, the lamp must be shielded to prevent stray UV light from damaging the eyes of workers nearby.) UV-blocking filter, VIS-blocking filter.

CAMERA Array camera, which must be quite sensitive to detect the low light levels emitted during fluorescence. Phosphorescence often requires an even more sensitive camera, since the light output is lower.

LENS Low *f*-number, to collect the maximum amount of light.

MATERIALS Organic materials (e.g., food), paper, cloth, some plastics, oil, grease, etc. frequently fluoresce. Some materials, most notably paper, have fluorescent whiteners added to make them during manufacture to make them *"brighter than white."* (In the 1960s, this slogan was used to promote sales of a popular domestic detergent which had a fluorescent whitener in it.)

REMARKS Fluorescence is the property of a material which glows in one wave-band (long wave-length, e.g., visible light) when it is irradiated with another (short wavelengths, e.g., ultra-violet) However, the process is more general than the familiar UV-VIS fluorescence. For example, some materials glow in the orange-red part of the spectrum, when illuminated with blue light. Certain materials have a visible glow when they are irradiated with x-rays. Fluorescence stops when the illumination is switched off, while phosphorescence continues for a short while after it is removed. Some substances fluoresce at a particular wavelength, which can be identified using optical band-pass filters. It is important to follow strict safety practices when working with short-wavelength radiation (UV and x-rays), since it can injure both skin and eyes.

LAYOUT DIAGRAM AND SAMPLE IMAGES ➲ *Figure 40.38*

40.42 Method 42: Focussed Annulus of Light

OBJECTIVE To obtain a focussed annulus of light. Using this method, a thin, continuous bright ring of light can be projected onto a plane surface.

TYPICAL APPLICATIONS Viewing tops of cans, jars, bottles, etc.

EQUIPMENT

- Ring light
- Lens with its centre removed. (This allows the camera to view the widget directly.)

CAMERA Array or circular scan.

MOTION Static.

GEOMETRY Annulus: the centre of the widget is assumed to be unimportant and does not need to be inspected.

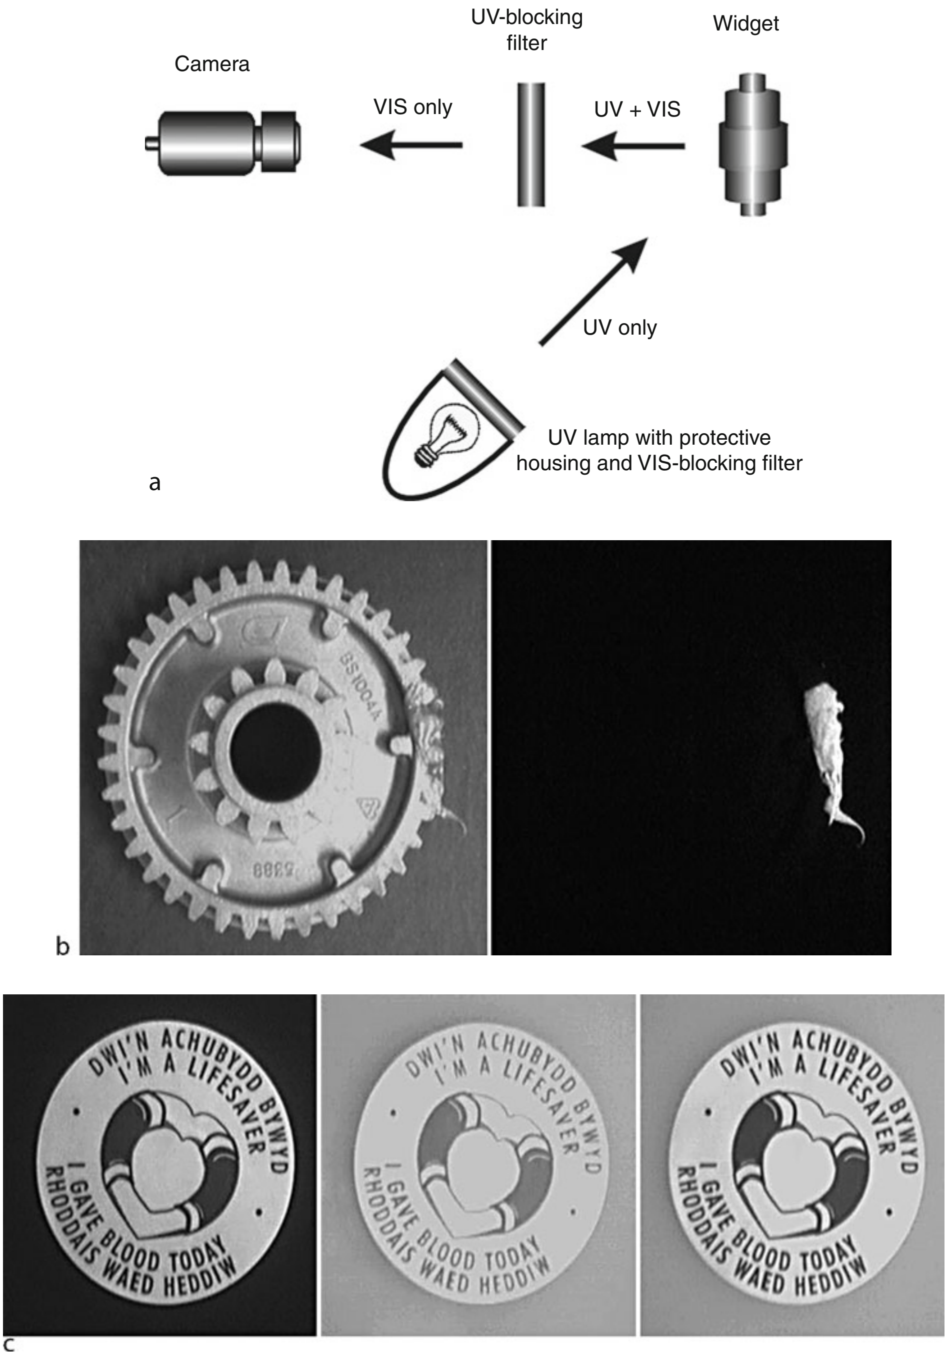

Fig. 40.38
(Continued)

REMARKS A fibre optic ring light produces a thin circle of light, whereas a LED array generates a set of bright points, interspersed with darker areas. This uneven illumination pattern can be smoothed out by adding a diffuser but this broadens the circle of light. A plastic lens can be machined easily, by milling out the centre of a conventional lens. For large widgets, a plastic Fresnel lens can be effective but colour aberration may generate coloured bands on the inner and outer edges of the annulus. This effect can be overcome, if narrow-band lighting is used. Care must be taken to ensure that rays from the ring light cannot reach the widget without first travelling through the lens.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.39*

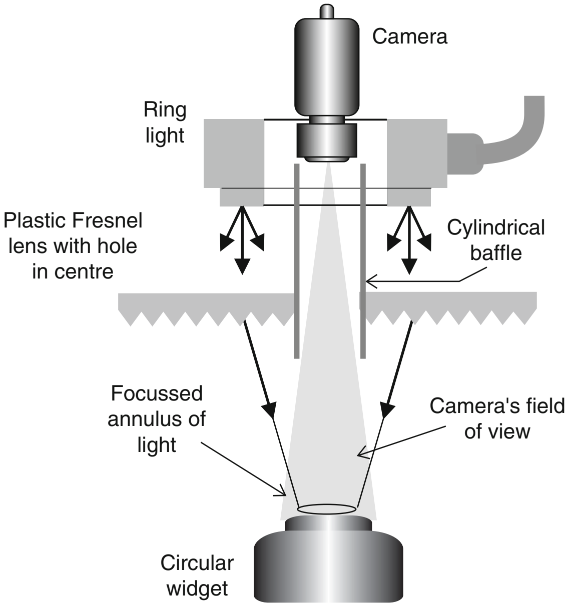

Fig. 40.39
Focussed annulus of light

Fig. 40.38
Fluorescence and phosphorescence. (a) Optical layout for ultra-violet fluorescence. (b) Sample image: Grease on a zinc die-cast gear. *Left:* Viewed in ambient lighting. *Right:* Illuminated in ultra-violet and viewed in the VIS wave-band. (c) Sample images: Self-adhesive paper label (white), with red printing and attached to a sheet of white perspex (plexiglass) *Left:* Illuminated in ultra-violet and viewed in the visible wave-band. A UV-blocking filter and VIS-blocking filter were both used. Notice that the white paper fluoresces strongly, due to the brightener added during manufacture. Neither the perspex nor the red ink fluoresce. *Centre:* Viewed in white light, with no filter. *Right:* Viewed in white light, with a green filter. (A green filter attenuates red light, from the printing, and hence optimises the contrast.) (d) Optical set-up for phosphorescence

40.43 Method 43: Forced Thermal Emission

OBJECTIVES To visualise heat emission from objects that are cold initially.
TYPICAL APPLICATIONS Investigating solid objects for internal cracks, voids, air bubbles, etc. To investigate underlying structures whose appearance has been homogenised by paint or other surface treatment.
EQUIPMENT Microwave, eddy current, laser, IR or hot-air heater. Alternatively, the sample to be examined can be heated, by forced vibration.
CAMERA Thermal imager.
OPTICS Lenses are probably germanium, although these are very expensive. (Germanium is opaque to visible light). Reflective (mirror) optics are cheaper to produce, by evaporating gold onto a suitable substrate, but are not so easy to use.
MOTION Static.
REMARKS This is an expensive method to implement, because thermal imagers and their lenses are costly. However it does offer some unique advantages, in being able to visualise underlying structure without the use of penetrating radiation. For example, a component consisting of metal and rubber bonded together, will display marked temperature differences as heat is applied locally, even if it is covered in paint, or lacquer. There are two reasons why a crack may appear brighter than the surrounding material. Firstly, flexing a structure increases stress locally around a crack, or inclusion, and thereby raises the temperature in that region. Secondly, a crack acts in a similar way to a black body radiator, which has a high IR emissivity (about 0.9). Compare this to that of polished metal, which has a much lower emissivity: approximately 0.1–0.2.

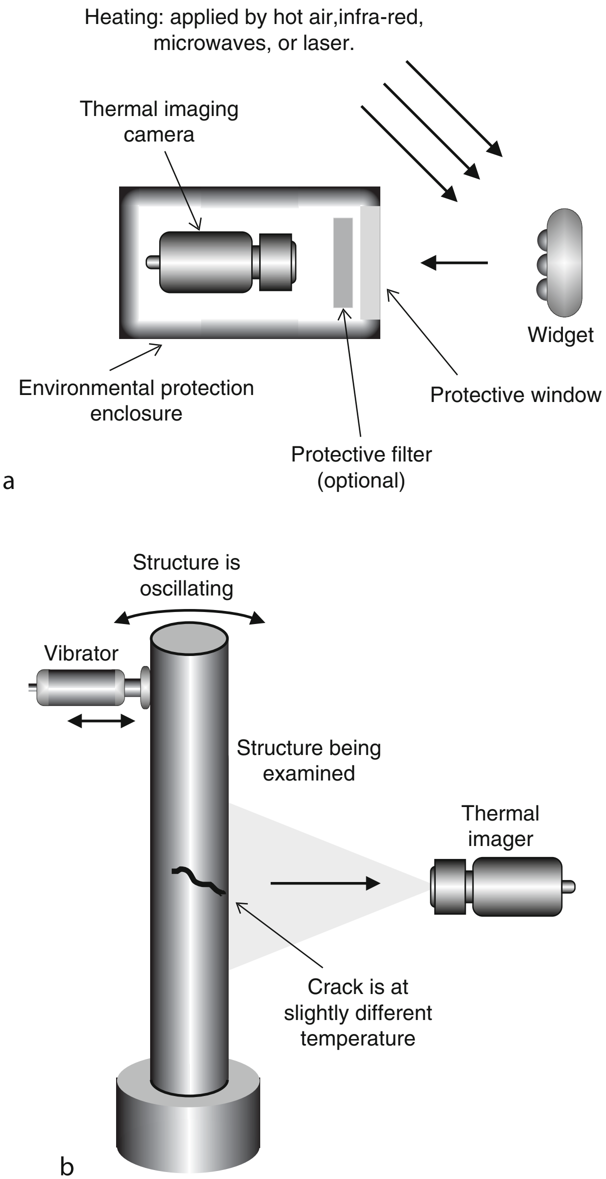
LAYOUT DIAGRAMS ➜ *Figure 40.40*

40.44 Method 44: Generating Light with Arbitrary Spectrum

OBJECTIVE To generate light with an arbitrary spectrum. The spectrum can be adjusted automatically during a multi-frame image-capture sequence.
TYPICAL APPLICATIONS Colour analysis.
EQUIPMENT Xenon lamp or other pan-chromatic light source, Two cylindrical and two standard lenses, two diffraction gratings, optical mask. The last mentioned can be fixed, a motorised slit, or a programmable LCD light switch.
CAMERA Array or line-scan.
REMARKS Let λ be the wavelength; L(λ) the spectrum of the light source; M(λ) the mask weighting function and D(λ) the desired spectrum. Then, we should choose M(λ) such that

$$\mathrm{M}(\lambda) = \mathrm{D}(\lambda)/\mathrm{L}(\lambda).$$

For the sake of accuracy, we must ensure that L(λ) never approaches zero. For this reason, we should choose a lamp which has a nearly flat spectral output; L(λ) is nearly constant over the appropriate range of wavelengths. The mask can be fixed (e.g., 50 mm slide); a motorised slit (to generate monochromatic light of variable wavelength and/or variable-width waveband), or fully programmable (using an LCD light switch).



Heating: applied by hot air,infra-red, microwaves, or laser.

LAYOUT DIAGRAM *Figure 40.41*

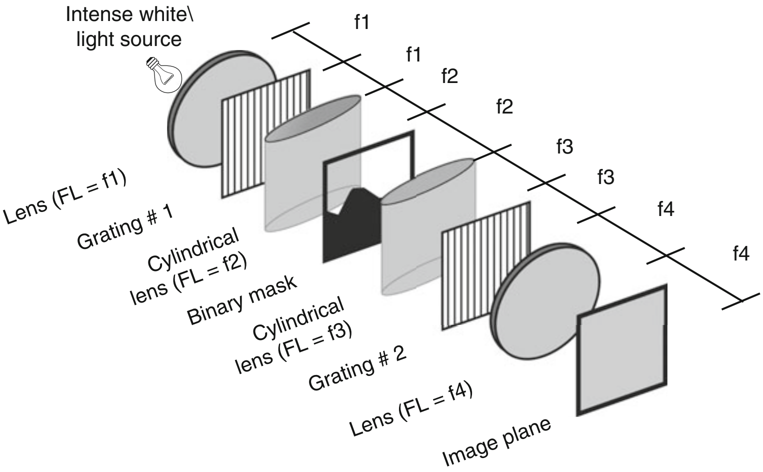

Fig. 40.41
Generating light with an arbitrary spectrum

40.45 Method 45: Granular Material (Pellets) in Free Flight

OBJECTIVE To inspect granular material or pellets in free flight.
TYPICAL APPLICATIONS Inspecting materials such as

- Seeds, nuts, peas, beans, etc
- Breakfast cereals and similar processed food products and semi-processed food materials
- Low value confectionary (i.e., not fragile chocolates)
- Gravel-like minerals
- Industrial materials in the form of pellets, frozen droplets, etc

EQUIPMENT

- High-speed conveyor, capable of projecting the pellets to be inspected into nearly horizontal flight past the camera. Alternatively, a slide-way may be used instead
- Array of air jets, activated by the image processor, to deflect "bad" pellets
- Long linear light source, such one of the following
    1. Fluorescent tube driven at high frequency (to avoid strobing effects)
    2. Linear array of LEDs
    3. Fibre optic bundle with a linear output aperture
    4. Tube of *TIRF* film
    5. Rod of glass/perspex with light injected at on/both ends

CAMERA Line-scan.
MOTION Continuous nearly linear motion is provided by the high-speed conveyor. Notice that the pellets being inspected have a finite velocity component along the camera's optical axis. This is unlikely to cause problems with focussing but must be taken into account when designing the *accept/reject* deflector system.
MATERIALS Granulated materials, powder and pellets.
REMARKS A suitable viewing background for a line-scan camera can be provided by a rotating cylinder, kept clean by continuous washing/brushing. By careful design of the

lighting, it is possible to avoid illuminating the background, in which case accumulations of debris are unimportant, (This remark refers only to Machine Vision, not to hygiene.) It is, of course possible, to rotate the optical system by about 45° and use a slide-way, instead of the conveyor belt. It is important for proper operation of the *accept/reject* deflector system that the velocity of pellets passing through the light beams be known accurately. Rapid-response air jets (with switching speeds of tens of milliseconds) are available commercially.

LAYOUT DIAGRAMS ➋ *Figure 40.42*

40.46 Method 46: Grazing Illumination

OBJECTIVES

- To highlight shallow surface features, created by engraving, embossing, rolling, pressing, stamping, casting, moulding, etc
- To detect surface imperfections, such as scratches, cracks, pits, dirt, dust, grit, etc. on a smooth mirror-like surface

TYPICAL APPLICATIONS Inspecting flat machined metal surfaces, plastic, glass, glossy painted and lacquered surfaces, plastic sheeting, ceramic tiles, etc.

EQUIPMENT Collimator. For close-range operation, it may not be necessary to use a collimator. In some applications, a very small ("point") source of light, such as a LED or fibre optic light guide, is adequate.

CAMERA Array.

LENS Short focus.

MOTION Static.

GEOMETRY Nominally flat and smooth. Both depressions and raised features are visible.

MATERIALS Any reflective surface.

REMARKS Care must be taken to prevent the camera from seeing a reflection of itself. (This can usually be achieved by tilting the widget slightly.) Linear features, such as scratches and cracks that are approximately normal to the light path are highlighted, Cliff-like edges facing the light source tend to cause glinting, while those facing away create shadows. Linear features that are nearly parallel to the light beam are suppressed. This anisotropy can cause difficulties but is useful in certain situations.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.43*

40.47 Method 47: Hand-held Sensor for Fixed-range Close-up View

OBJECTIVE To view an object at fixed, close range in high magnification using a hand-held sensor.

TYPICAL APPLICATIONS

- Sampled inspection of paint-work, machined and polished surfaces
- Reading dot-matrix codes
- Reading alpha-numeric codes and labels (e.g., product batch numbers, best-before and sell-by dates)
- Hardness testing

(c) Mirror with a lot of surface dirt, a finger-print and two scratches (A third diagonal scratch is invisible when lit from this direction). A clean and perfect mirror, would be very dark. (d) Coin. In both cases, the light is projected from the left. Notice that the textured background is clearly visible outside the shadow of the coin

EQUIPMENT Purpose-built optical head shown in ➜ *Fig. 40.44*.
LENS Close-up lens is part of the optical head.
MOTION Static. Probe is hand held.
GEOMETRY Nearly flat within small field of view.
MATERIALS Free from dust, lint, swarf, etc.
REMARKS Old-fashioned oscilloscope cameras were built on this principle. A probe of this kind was developed specifically for viewing moles and other skin features. During image acquisition, the probe is held against the surface being inspected by a human operator, or a compliant robot. The dome on the probe has a hole its centre, so there is no obstruction to the camera’s view. The inside of the dome should be blackened, to eliminate reflections of unwanted stray light. If dust is a serious problem, an air purge may be used to keep the front window clean. In any case, the dome should be removable, to

Fig. 44
Hand-held sensor for fixed-range close-up viewing of small surface defects

allow easy cleaning of the front surface of the protective window. The dome may be replaced by a wire cage, or cone, if greater viewing distances and/or a larger field of view are needed. Tri-colour or NIR LEDs may be used to adjust the spectral balance of the light. The LEDs can be strobed, to “freeze” the motion of the surface and/or increase their light output. The direction of the light incident on the widget surface can also be adjusted by controlling each device individually.

LAYOUT DIAGRAM ➲ *Figure 40.44*

40.48 Method 48: Hardness Testing

OBJECTIVES To measure the hardness of a metal surface.
TYPICAL APPLICATIONS Measurement of cutting tools (drill, milling tool, etc.) specialised steels, etc.
EQUIPMENT Vickers or Brinell hardness tester.
CAMERA Array.
LENS High magnification.
MOTION Static.
GEOMETRY Smooth and flat at the point where the hardness is to be tested. It may be necessary to machine a small flat section (about 2 × 2mm^2) prior to hardness testing.
MATERIALS Steel.
REMARKS The Vickers method of testing for hardness uses a diamond tool, which is pressed into the surface with a known force. The Brinell test uses a spherical tool. The size of the

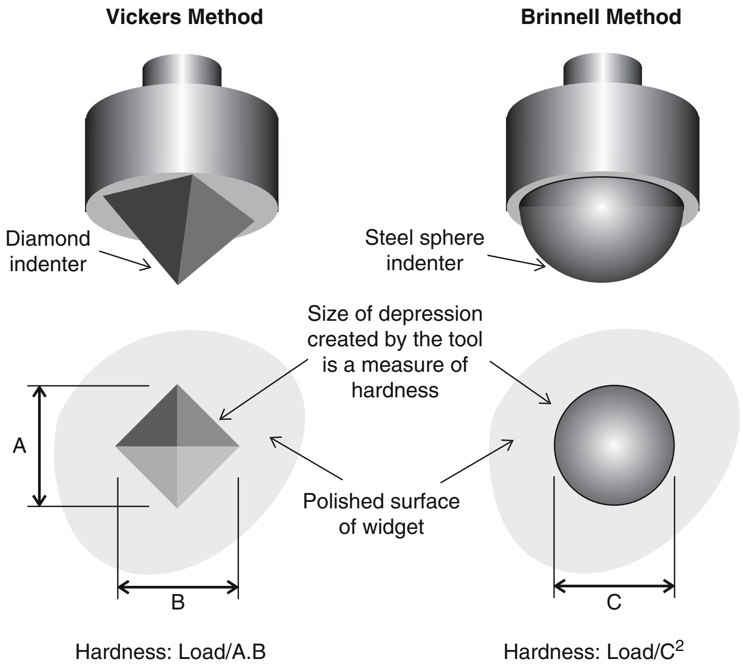

Fig. 40.45
Measuring surface hardness

indentation is measured and indicates the surface hardness. Commercial devices for automatic hardness testing use image processing to measure the size of the indentation. Diffuse illumination is achieved by Method 31.

LAYOUT DIAGRAM ➋ *Figure 40.45*

40.49 Method 49: Height Analysis by Projecting Patterns

OBJECTIVE To provide a rapid method of obtaining information about the 3D geometry of a surface.

TYPICAL APPLICATIONS Inspecting mouldings, castings, food products, such as cakes, loaves, etc.

EQUIPMENT Computer-controlled LCD projector, acting as a spatial light modulator.

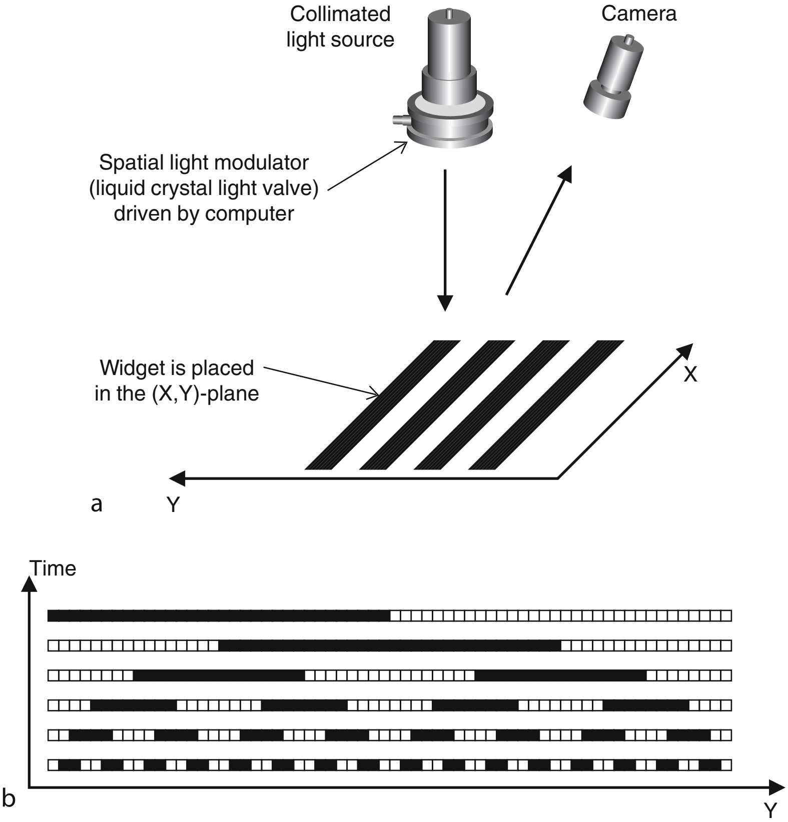
CAMERA Array.

MOTION The widget must be static during a pre-defined number of video frames (typically 4–16).

GEOMETRY The widget surface should not be overly complicated, nor have a large number of step-like features.

MATERIALS Matt, non-reflective. Plastics, ceramics, painted surfaces.

REMARKS When a set of parallel lines is projected onto a surface, the position of each bright-dark, or dark-bright, transition point can provide information about its height. However, this results in some ambiguity in the measured height values if, as often happens, adjacent light stripes cannot be distinguished. This ambiguity can be resolved by the *Coded Light Approach*, in which a small number of binary images is projected onto the widget in turn. This results in an absolute measurement of surface height and allows us to construct a depth map relatively quickly. A sequence of binary images is projected onto the widget surface, using a spatial light modulator. (One such device resembles an LCD class-room projector.) The number of each row in this series of images is represented using the Gray code. (See ➲ *Fig. 40.46b*. Despite its name, this generates a series of *2-level* illumination patterns.) Suppose that we project *n* images in quick succession. (Typically *n* = 10, This takes ten video field periods and hence can be



Collimated light source

Widget is placed in the (X,Y)-plane
X
a
Y
Time
b
Y

Fig. 40.46

Projecting a series of illumination patterns to measure surface height. (a) Optical arrangement. (b) Gray code lighting pattern. This requires six video frames and resolves the surface height into 64 different levels. The same pattern is projected for all X values

performed in less than half a second.) All widget points illuminated by the same line in the illumination pattern see the same (temporal) sequence of bright-dark-bright transitions. The image processing is straightforward as this requires only simple thresholding. Moreover, it can be made to be tolerant of changes in the surface reflectance, by simply noting the image brightness when each point is illuminated (intensity = $I_{on}(x,y)$) and when it is not (intensity = $I_{off}(x,y)$). We then apply spatially dependent thresholding at level $(I_{on}(x,y)) + (I_{off}(x,y))/2$ to the (x,y) pixel. After *n* images have been projected, each point is associated with an *n*-bit code, which can be interpreted using a 2^n-element look-up table, to give the surface height measurement. Suppose that we have observed the following image sequence during a sequence consisting of *n* projected illumination patterns.

$$[Q_1(x,y), Q_2(x,y), \ldots, Q_n(x,y)]$$

($Q_i(x,y) = 0$ *or* 1, for all $i = 1,\ldots, n$.) Then, the height of the surface at the position (x,y) can be inferred by noting which row in the projected pattern has the following Gray code

$$(Q_1, Q_2, \ldots, Q_n)$$

Once the row number has been deduced, the usual triangulation formula is used to calculate the surface height. Although this method requires several video frames to generate a fairly crude depth map ($<< 2^n$ different height contours), it is rather faster than some alternative structured-lighting arrangements. (Methods 24, 41 and 107) Suppose that we mistakenly infer that one of the $Q_i(x,y)$, $(i = 1,\ldots,n)$ is *0* when it should be *1*, or vice versa. The effect on the estimate of surface height is limited to an error of ±1 levels.

LAYOUT DIAGRAM ➋ *Figure 40.46*

40.50 Method 50: High Resolution View of Web

OBJECTIVE To inspect a wide continuously moving web at high speed, so that small defects can be detected.

TYPICAL APPLICATIONS Inspecting a wide variety of web and sheet products, including glass, steel, paper, plastic film, etc. and flat objects, such as bare printed circuit boards, flat-pack furniture components, plaster-board, etc.

EQUIPMENT Specially constructed camera mounting system, providing minimal overlap between the fields of view of adjacent cameras. The cameras are aligned so that they effectively form one continuous line sensor. The camera mounting bar should have a low coefficient of thermal expansion.

CAMERA Several line-scan sensors.

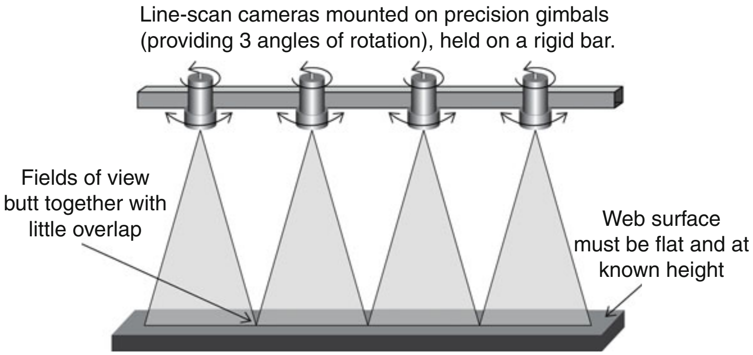
LENS It may be necessary to use custom lenses so that they fit within the small space available on the mounting bar.

MOTION Continuous motion, closely controlled speed.

GEOMETRY Continuous web or sheet.

MATERIALS Paper, card, steel, plastic, etc.

REMARKS In one system built in the mid-1980s, an effective cross-web resolution of about 5×10^4 pixels was achieved. Lighting was effected by a series of fibre-optic line illuminators,



Line-scan cameras mounted on precision gimbals (providing 3 angles of rotation), held on a rigid bar.
Fields of view butt together with little overlap
Web surface must be flat and at known height

Fig. 40.47
Multiple line-scan-cameras viewing a wide web

with feedback control of light levels. At that time, to achieve the required processing speed (2.7×10^{10} MIPs) field-programmable gate arrays. (FPGAs) were used. Nowadays, several general-purpose processors, operating concurrently, would probably be used instead. Lighting was effected by a series of fibre-optic line illuminators. This system was devised for inspecting bare printed circuit boards and the associated art-work. There was minimal overlap between the fields of view of the individual cameras, which were carefully aligned using precision gimbals.
LAYOUT DIAGRAM ➔ *Figure 40.47*

40.51 Method 51: Highly Variable Ambient Lighting

OBJECTIVE To operate a vision system in high ambient lighting conditions, which may be highly variable.
TYPICAL APPLICATIONS
- Working out of doors.
- Working in situations where it is not possible to provide effective shrouding against variations in natural light levels.
- Operating a structured lighting system without shrouding ambient light.

EQUIPMENT
- Source of nearly monochromatic light, e.g., laser, high intensity sodium vapour lamp.
- Narrow pass-band filter, matched to the light source.

CAMERA Monochrome – there is no ability to sense colours.
MATERIALS The spectral response of the object to the particular wavelength of light emitted from the lamp must be high.
REMARKS This technique relies on the fact that ambient light is normally panchromatic and hence contains a relatively small amount energy within the narrow pass band of the filter. On the other hand, a monochromatic light source such as a sodium vapour lamp emits most of its output energy within the filter pass-band. Since the illumination is monochromatic, it is impossible to sense different colours. An alternative is to use pulsed lighting. Two frames are

(b) Spectral characteristics of the ambient lighting (E(λ)), lamps (L(λ)) and filter (F(λ)). The spectral composition of the light reaching the camera is given by the following expression. [E(λ) + L(λ)].W(λ).F(λ) where W(λ) is the spectral reflectivity function of the widget

captured in quick succession, one with the lights on and the other with the lights off. The resulting images are then subtracted. The difference image shows the effects of the illumination, as if there were no ambient light. The applied illumination must be of comparable brightness to that of the ambient light. The camera should not have automatic gain control (AGC) switched on.

LAYOUT DIAGRAM AND FILTER CHARACTERISTICS ➲ *Figure 40.48*

40.52 Method 52: Homogenising Illumination

OBJECTIVES To provide uniform illumination, eliminating variations in intensity due to lamp deficiencies and limitations.
TYPICAL APPLICATIONS Providing uniform lighting over a large area is crucial for the successful solution of a very wide range of applications including print inspection, analysis of surface texture, etc.
EQUIPMENT Diffuser, which may use a surface effect (e.g., ground glass), dispersion within a translucent material, "randomised" fibre optic bundle, scattering from a roughened surface, or diffractive optics.
REMARKS Many of the most important lighting-viewing methods described in this chapter (e.g., front, back and dark-field illumination) rely upon the provision of highly uniform diffuse lighting over a large area. It is often impossible to provide this with a naked light source; some sort of diffuser is required between the lamp(s) and the widget. Filament lamps, discharge tubes and LEDs do not generate homogenous beams of light (➋ *Fig. 40.49b*). In the past, diffusers almost always depended upon light being dispersed as it travels through a sheet of translucent material but, nowadays, fibre-optic, diffractive or reflective diffusers may be preferable in some situations (➋ *Fig. 40.49a*). The traditional method of producing diffusers uses etched, shot-blasted or ground surfaces, while translucent plastic sheeting ("opal") uses material that contains numerous tiny particles that disperse the light and provides a much cheaper alternative for large optical systems. A "randomised" fibre-optic bundle can also be used to produce a diffusing effect. However, very much more effective homogenisation can often be achieved using a diffraction plate. Diffusers of this kind can be made in the form of flexible or rigid sheeting. They can do much more than simply homogenise the light projected onto the widget. For example, they can shape the output beam so that its cross-section is an ellipse, circle, rectangle or square. One manufacturer produces diffractive diffusers that can generate output beams that have:

(a) Narrow, medium or wide angles (1°–70°).
(b) Elliptical cross-section (ratio of longest to shortest axis up to 50:1).

Diffusers are also needed sometimes for homogenising the micro-variations in the light output from fibre optic illuminators.

LAYOUT DIAGRAMS AND SAMPLE IMAGES ➋ *Figure 40.49*

40.53 Method 53: Hypercentric (Pericentric) Lens

OBJECTIVE To obtain top and an all-round side views of an object (The bottom is not viewed).
TYPICAL APPLICATIONS Inspecting cylindrical objects and mechanical components.
EQUIPMENT Hypercentric lens.
CAMERA Single array camera.
MOTION Static.
GEOMETRY Approximately cylindrical.
MATERIALS Not critical.

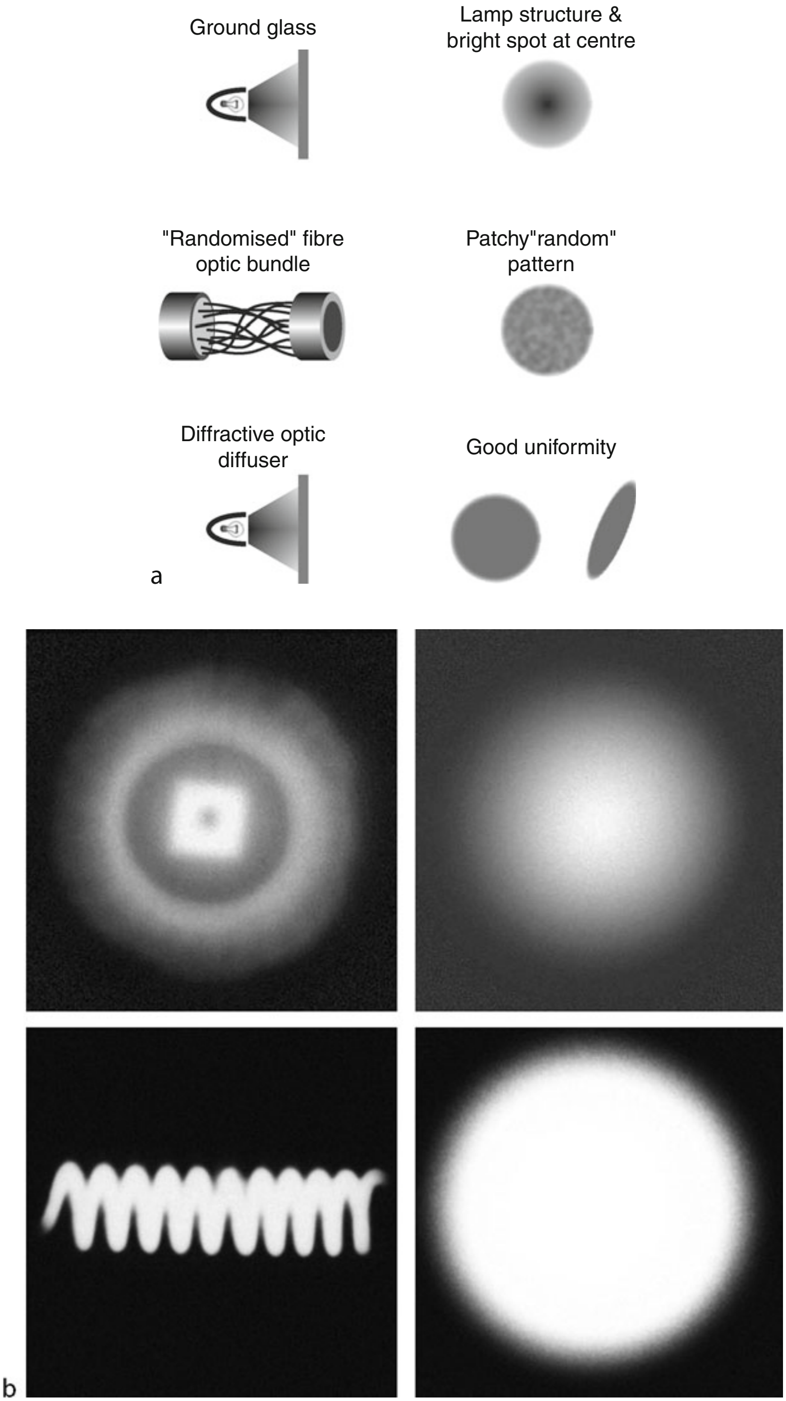

Fig. 40.49
(Continued)

REMARKS A hypercentric lens, alternatively called a pericentric lens, provides a converging view of an object. This allows the top and sides of an object such as a cube or cylinder to be viewed simultaneously (Recall that a fish-eye lens provides a diverging view). A hypercentric lens receives rays of light as if they all originate from a single point, the convergence point.

LAYOUT DIAGRAM ➋ *Figure 40.50*

40.54 Method 54: Illuminate Top Surface Only

OBJECTIVE To illuminate the top surface of an extrusion without projecting light onto the background.
TYPICAL APPLICATIONS Inspecting extruded flat topped cakes, confectionery bars, food and other products of variable height.
EQUIPMENT Source of collimated light with well defined beam width.
CAMERA Line scan camera (may use colour).
MOTION Continuous linear motion.
GEOMETRY Nearly flat top, height variable but held within closely controlled limits.
REMARKS A collimated beam of defined width is projected onto the surface, at an inclined angle. Provided the top surface of the extrusion varies within certain limits, it remains well lit, within the camera's very narrow field of view. However, the top of an under-height or over-height extrusion is dark. The background is also dark. It is possible to use two light sources, one shining down-stream and the other up-stream, to avoid casting shadows around step-like features.
LAYOUT DIAGRAM ➋ *Figure 40.51*

40.55 Method 55: Illuminating a Wide Moving Web

OBJECTIVE To provide a thin band of light on a continuously moving web (i.e., a product made in the form of a flat or nearly flat sheet).
TYPICAL APPLICATIONS Inspecting fabric, printing, dough rolled into a sheet, plastic film, sheet glass, floor and wall tiles, wall panels, flat panels for domestic kitchen equipment (refrigerator, cookers, etc.), printed circuit boards.

Fig. 40.49
(a) Techniques for homogenising illumination (b) Sample images: *Top-left:* Output from a LED is non-uniform and clearly shows details of its internal structure; *Top-right:* Homogenised beam produced from the LED by a diffractive diffuser; *Bottom-left:* The beam from an incandescent filament lamp, clearly showing the details of the hot wire coil; *Bottom-right:* Homogenised beam produced by a diffractive diffuser applied to the light from the filament lamp. Notice that this device also adjusts the aspect ratio of the beam cross-section. A similar beam-stretching effect applied to the LED would, of course, produce a beam with an elliptical cross-section, which might be desirable in some circumstances. It is perfectly feasible to adjust the eccentricity of the beam profile

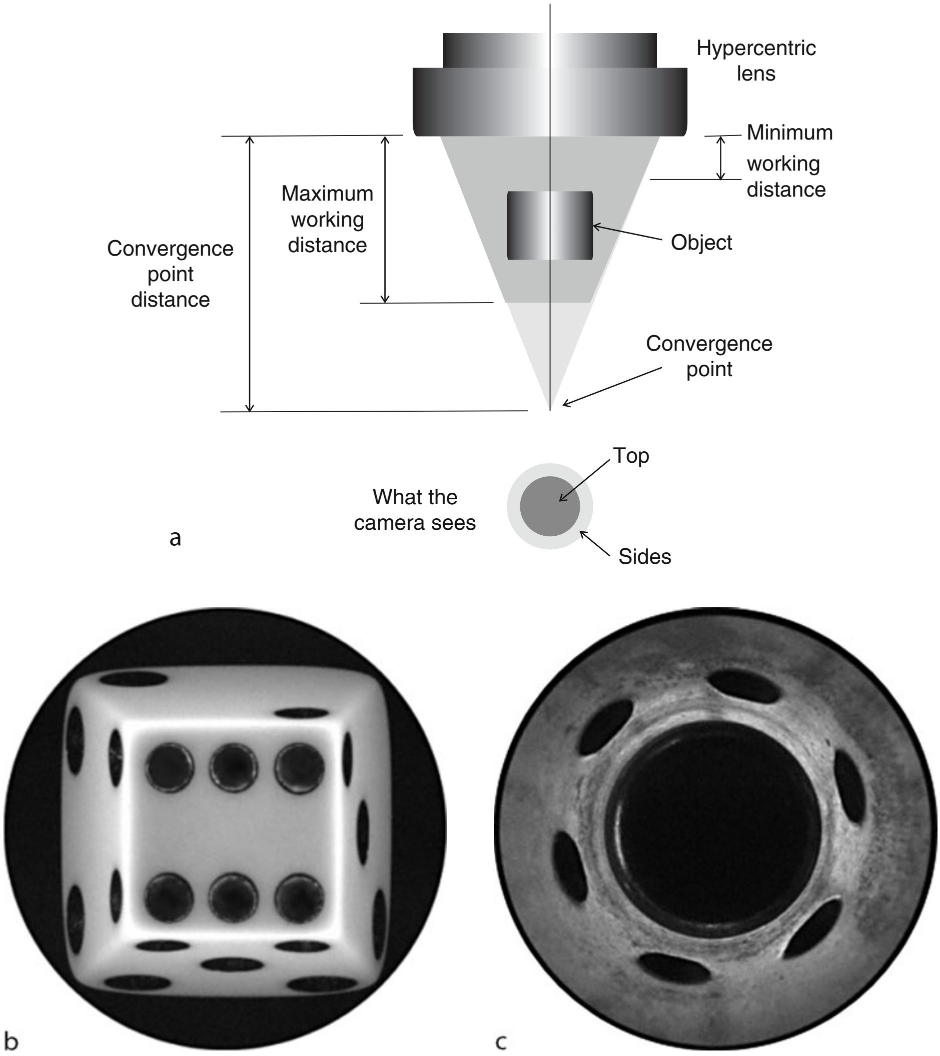

Fig. 40.50
Hypercentric lens (a) Viewing cone. (b) Gaming die. (c) Cylinder with six side ports [Images kindly supplied by Spencer Luster, Light Works. http://www.lw4u.com]

EQUIPMENT One of the following:

(1) Fluorescent tube(s).

(2) Glass/perspex (plexiglass) rod, coated with white paint, except for a narrow strip, which is kept clear. The end faces are optically polished. A lamp is placed at one end of the rod and a sheet of retro-reflective material at the other (This can be purchased from any automobile spares supplier). Alternatively, lamps can be placed at both ends.

(3) Tube formed by rolling a sheet of *totally internally reflecting film (TIRF)*.

Illuminated section of top of conveyor - remainder is dark
Range of allowed product heights = W.cosec(θ)
Continuous product (e.g. extrusion)
Conveyor
Camera's line of sight

Fig. 40.51
Illuminating an extrusion but not its background

(4) An array of LEDs, with a suitable diffuser. LED replacements for linear fluorescent tubes are now available
(5) Fibre optic cross-section converter, with a linear output aperture *(line illuminator)*.
(6) Laser fitted with cylindrical lens.

CAMERA Line scan.

MOTION Continuous linear motion. A similar system optical, used in conjunction with rotary motion, can also be devised.

GEOMETRY Approximate limits for the maximum web width are as follows:

- 2 m, using fluorescent tubes.
- 2 m, using a coated glass/plastic rod.
- 2 m, using TIRF.
- Virtually unlimited, using LEDs (10 m is perfectly feasible but expensive).
- 300 mm, using fibre optics (Cost is the limiting factor).
- About 500 mm, using a laser that is eye safe.

REMARKS There several ways to project a line of light on to a flat surface.

FLUORESCENT TUBES The light output from a fluorescent tube fluctuates markedly at a frequency equal to twice that of the mains electricity supply: 100/120 Hz. Hence, a fluorescent tube driven directly from the mains supply may well generate hum bars with a camera operating at 50/60 frames/s (*Fig. 40.52e*). Thermal inertia reduces this effect with incandescent filament lamps. For this reason, fluorescent tubes are normally driven by a high-frequency power source (typically 10–50 KHz), to avoid creating strobing effects. Sometimes, it is useful to synchronise the camera's pixel clock, the fluorescent-tube power unit and the web-drive mechanism. (This will probably require the use of a shaft-position encoder, attached to one of the web-drive rollers, and phase-lock loops, for frequency multiplication). In this way, we can ensure that, within limits, the pixel size is independent of the web

speed and thereby avoid producing hum bars. Moreover, the lighting cycle is synchronised to the web motion, so each repeated pattern (e.g., printing or embossing) is viewed under the same lighting conditions. Fluorescent lamps emit light around 360°, so it is normal to use a cylindrical reflector to limit the beam angle. Additional focussing, to generate a finer line, can be achieved, using a low-cost cylindrical Fresnel lens. It is not possible to change the colour of the projected light, except by placing a filter in the optical path (In view of the size, this would probably be a low-precision filter based on a gelatine film). The brightness of a flourescent tube is lower at the ends than the central region. It is therefore sensible not to use the end 10–15 cm for illuminating the web.

COATED GLASS ROD This method is used when it is important to produce a long thin light source that has few small-scale irregularities (When viewed at a macroscopic scale, a fibre-optic illuminator appears to produce a uniform illumination field. However, when the illumination pattern is examined more closely, irregularities can be seen, due to the finite size of the individual fibres in the matrix. The situation is worse with arrays of LEDs, since the size of the individual illumination elements is much greater). Clearly, it is important to ensure that the light output from the rod is nearly constant. Simple analysis shows how this can be achieved.

Rod illuminated at one end. Let us make the following assumptions:

(a) The rod is uniform along its whole length, X_0.

(b) As it travels along the rod, the energy within a beam of light decays exponentially, as a function of the distance travelled, *X*. (This refers to a single beam and ignores the beam returned by the retro-reflector.) Then, the light energy within the rod is proportional to

$$\exp(-A.X)$$

where the rate of light loss is determined by the parameter, *A*.

(c) The proportion of light energy returned down the rod by the retro-reflector is determined by a constant K ($K \leq 1$).

(d) All light returning to the end of the rod adjacent to the lamp is then lost.

Then, the total light energy at a distance X from the lamp is the sum of the forward and return beams and is given by S(X), where

$$S(X) = \exp(-A.X) + K.\exp(-2.A.X_0).\exp(AX)$$

To show that this produces a nearly uniform light distribution along the rod, let us substitute some typical values into this equation. Suppose that there is a 20% light loss along

Fig. 40.52

Illuminating a *straight line*. (a) Fluorescent tubes. (b) Coated glass or perspex (plexiglass) rod. In an alternative arrangement, lamps can be placed at both ends of the rod. (c) Total internally reflecting film (TIRF). Again, lamps can be placed at one or both ends of the tube. (d) Fibre optic line illuminator. *Top:* Close-up view of the ends of the fibres. Notice how uneven the light pattern is. *Centre:* intensity integrated vertically. This indicates the line intensity profile that would be achieved if a cylindrical lens were used to focus the light onto a plane. *Bottom:* Simple intensity profile. This is what a perfect line-scan camera (i.e., zero width and infinite resolution) would see if it looked directly at the fibre-optic illuminator. (e) Hum bars produced using fluorescent lighting, driven from the mains electricity supply

the rod (i.e., $\exp(-A.X_0) = 0.8$; $-A.X_0 = 0.223$) and that $K = 0.9$ (10% light loss at the retro-reflector), then

$S(0) = 1.576$; $S(X_0) = 1.520$; $S_{min} = 1.517$

(This represents −3.55% change compared to S(0). Compare this with the equivalent entry in the table below).

Light injected at both ends of the rod. The formula is revised as follows:

$$S(X) = \exp(-A.X) + \exp(-A.(X_0 - X))$$

In this case, the intensity variation is rather better, as the following change table shows:

Light fall-off parameter along the length of the rod: $\exp(-A.X_0)$	Intensity at the ends of the rod $S(0) = S(X_0)$	Intensity at the middle of the rod $S(X_0/2)$	Change[a] (%)
0.8 ($A.X_0 = 0.22$)	1.8	1.789	0.69
0.5 ($A.X_0 = 0.69$)	1.5	1.414	5.73
0.3 ($A.X_0 = 1.20$)	1.3	1.095	15.77
0.1 ($A.X_0 = 2.3$)	1.1	0.632	42.55

[a] Values in the column labelled *Change* are calculated using the formula: $100.[S(0)-S(X_0/2)]/S(0)$

This table shows that it is important to maintain a high light level inside the rod, compared to that emitted from the slit in the coating. In other words, the slit should be as narrow as possible. It is possible to change the colour of the projected light mechanically, by inserting a filter in front of each light source.

TOTAL INTERNALLY REFLECTING FILM (TIRF) TIRF was the name given originally to a product of the 3M Company. It consists of a sheet of clear, transparent material which is smooth on one side and has a series of fine ridges on the other. The film acts like a set of parallel, lossy optical fibres, so that light injected at one end of the sheet will be scattered over its whole surface. The rolled tube thus acts as a long thin light source. To a first approximation, the brightness falls exponentially as the beam travels along the roll of TIRF. Again, it is difficult to change the colour of the projected light automatically.

LED ARRAY It is a simple matter to set up a long line of LEDs but it requires careful adjustment to obtain a uniform beam; individual LEDs must be carefully matched in colour and brightness, and they must be aligned optically. The LEDs can be of any colour, including non-VIS light. The colour can even be switched (Multi-LED modules are available containing red, green and blue diodes in a single package). In addition, LEDs can be strobed, to increase the brightness for a short period during image acquisition. Using electronic switching of individual diodes, a point of light can be made to "run along" the array. Since LEDs are fairly large (compared to individual optical fibres), a diffuser is normally needed. By placing the diffuser a little way away from the LEDs, their beams overlap, thereby improving the uniformity along the array. This may broaden the projected beam.

FIBRE OPTIC BUNDLE A fibre optic bundle can provide a very bright and very thin line illuminator. "Randomised" bundles improve the uniformity of illumination that can be achieved. Uniformity must be considered on two scales: macroscopic uniformity is usually

good but microscopic changes of brightness are troublesome (See ➋ *Fig. 40.53d*). If the fibres are of comparable size to the virtual pixels (real pixels projected backwards through the lens) artefacts, due to Moiré effects, can be produced in the digital image. Small-scale non-uniformity can be improved using a diffuser, but this spoils the main advantage of this method: the precise shape of the output aperture. As a fibre bundle is flexed, individual fibres may break, resulting in local dark spots in the line of light. The colour of illumination can be changed mechanically. (Filters have to be inserted mechanically in the optical path). This option is expensive and the length of the line is limited, compared to other methods.
LASER AND CYLINDRICAL LENS A diode laser, fitted with cylindrical or diffractive lens, is often used to project a line of light onto a widget, for 3D measurement (i.e., range/depth map acquisition. See Method 107) Using the same optical arrangement here is tempting but not always successful. Firstly, it produces speckle patterns which cause brightness variations in the digital image (For range measurement, speckle is not important, because the technique relies on measuring the position, but not the intensity, of the projected line). Secondly, the projected line is very thin and can easily become misaligned with the camera's field of view. Thirdly, it is a good idea to avoid using lasers if at all possible, on the grounds of safety. Fourthly, it is not possible to change the colour of the line of light, since this is determined by the laser.

40.57 Method 57: Injecting Light into Glassware

OBJECTIVE To view edge defects on a transparent plate or sheet of clear glass or plastic.
TYPICAL APPLICATIONS Detecting chipping on the edges/corners of glass or plastic sheeting.
EQUIPMENT One, two or more light sources. To inspect sheet material, 'linear' sources would probably be used. A fibre-optic bundle with a "linear" aperture, or a line of LEDs would be appropriate. A laser, fitted with a cylindrical lens and generating a fan-shaped beam, can also be used.

MATERIALS Transparent glass or plastic.

REMARKS Light is injected into the transparent sheet along one or more edges. The light is transmitted by total internal reflection through the sheet, approximately parallel to the surface, until it arrives at a point where it is damaged. The jagged surface of a chip scatters light through a wide range of angles. It may be necessary to experiment with the placement and angle of the light sources to obtain the best effect. This method is also able to highlight cracks in the glass, provided they are approximately orthogonal to the path of the light through the glass. This method can be modified to inspect the rim of a circular object, such as a the mouth of a bottle, jar or drinking glass. In this case, a ring light is used to project light into the rim.

40.58 Method 58: Inspecting a Flat Moving Web Using a Laser Scanner

OBJECTIVE To inspect a flat web, providing very high resolution.

TYPICAL APPLICATIONS Inspecting magnetic recording surfaces, steel strip, plastic film, and wide variety of other "strip" products.

EQUIPMENT Flying-spot laser scanner, with a rotating multi-facet mirror, or a mirror mounted on a galvanometer. One or more photo-multipliers may be used to measure the scattered light. A parabolic-cylindrical mirror is optional.

CAMERA None, image is constructed from video signal generated by the photo-detector.

MOTION Web is moving continuously, at known speed.

GEOMETRY Flat.

MATERIALS Smooth, may be matte or shiny.

REMARKS Flying-spot laser scanners are able to provide high resolution sensing of a wide, fast-moving web. A continuous digital "image" is generated; it is not segmented into distinct frames. Since the reflected/scattered light from a single laser beam can be analysed by several photo-detectors simultaneously, it is possible to generate multi-channel images that combine both near-specular and non-specular components (Each channel is monochromatic). The mechanical scanning devices shown in ➋ *Fig. 40.55b* and *c* both steer the beam over a fan-shaped region of space. Hence, the angle of incidence varies across the web. This can be corrected using a parabolic-cylindrical mirror. Using the arrangement shown in ➋ *Fig. 40.55d*, the cross-web deflection of the beam is proportional to

$$[1 - \cos(\theta)]/\sin(\theta)$$

where θ is the angle of the scanning mirror. (θ is a linear function of time for the rotating-mirror scanner). Hence, θ should be kept small to ensure regular spatial sampling across the web (Typically, $-30^\circ \leq \theta \leq 30^\circ$). For many web-inspection applications, particularly those requiring only the detection of spot-like defects, scan linearity is unimportant. Laser scanners are better suited to this type of application, rather than precise metrology. Other scanning methods exist, including Bragg cells (acousto-optic modulators) and piezo-mirrors.

Laser scanner for inspecting a flat web. (a) Overall view, showing various possible positions for the photo-sensor. Several photo-sensors may be used simultaneously giving a set of images that are all aligned exactly. The scanning head may be located so that the incident beam strikes the web obliquely, as shown here, or normally. (b) Using a multi-faceted mirror to deflect the laser beam. (c) Using a small, light-weight mirror, mounted on a resonant galvanometer. It may be possible to use a programmable (i.e., non-resonant) galvanometer but this does reduce the operating speed. (d) By placing the scanning head at the focal point of a parabolic mirror, it is possible to produce a scanning beam that is always parallel to the optical axis. A similar effect could, in theory, be obtained using a lens but it would be extremely expensive to scan a wide web in this way

40.59 Method 59: Inspecting a Rotating Object

OBJECTIVE To view an object while it is rotating continuously. Either the end or curved surfaces of a cylinder may be examined.
TYPICAL APPLICATIONS Inspecting objects such as

- Porcelain plates, mounted on the potter’s wheel, or decorating turn-table.
- Lathe-turned objects, while they are still mounted on the machine.
- CDs, gears, O-rings, tyres, cans, jars, bottles and numerous other circularly symmetrical components.
- Widgets that possess features such as concentric circles, radial lines (“wheel-spoke” patterns) and spirals.
- Printed, engraved, embossed features around the circumference of a disc, sphere, cylinder or cone: helices, paraxial lines, etc.

EQUIPMENT Line-scan camera. Turn-table, lathe, or other rotary mechanism.
CAMERA Line-scan.
MOTION Continuous or indexed circular motion.
GEOMETRY Circularly symmetrical components.

REMARKS The camera can view the end face (camera 1 in ➋ *Fig. 40.56a*, or the side of a cylindrical object (camera 2). Images are addressed by their polar co-ordinates.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.56*

40.60 Method 60: Internal Analysis of an Aerosol Spray or Dust Cloud

OBJECTIVES

- To measure the size distribution of microscopic, air-borne droplets or particles.
- To measure droplet/particle density in a succession of cross-section samples, taken within the same plane, at pre-determined time intervals.

TYPICAL APPLICATIONS Measuring particle/droplet size and density in coating jets, fuel/paint sprays, smoke plumes, etc.

EQUIPMENT

- The cell illustrated in ➋ *Fig. 40.57a* includes a laser and various lenses and is used for droplet/particle size analysis.
- The optical system shown in ➋ *Fig. 40.57b* is useful for determining the droplet/particle density.

In both cases, environmental-protection enclosures are necessary for the laser and camera. Air curtains can be used to keep exposed optical surfaces clean. They can also be kept dry and dust free, by electro-static means: applying a high electrical potential of appropriate polarity (Conductive glasses are made especially for this purpose and should be used in both protective windows).

CAMERA Array. It may be necessary to synchronise the camera and laser for the second method. This may require the digitisation and storage of one or more separate video frames.

REMARKS In the first method, the camera sees the far-field diffraction pattern and is insensitive to variations in the droplet/particle density across the aerosol. This yields the Fourier transform of the particle cloud and can give valuable information about the distribution of droplet/particle sizes. The second method provides a macroscopic (cross-sectional) view of the spray cone, at a number of moments in time. It is relatively insensitive to droplet/particle size but is able to provide information about their (macroscopic) spatio-temporal distribution.

LAYOUT DIAGRAM ➋ *Figure 40.57*

40.61 Method 61: Internal Features on Transparent Objects

OBJECTIVE To highlight features in transparent materials, i.e., opaque impurities, air bubbles, physical features such as cracks, crizzles (shallow cracks), scratches, embossing, ‘bird-swings’ (a filament of glass stretching across the inside of a bottle), ‘spikes’ (a ‘stalagmite’ of glass), flash, sprue, shards of glass or other loose transparent material.

TYPICAL APPLICATIONS Detecting faults in bottles, jars, tumblers, other types of glassware and clear plastics.
EQUIPMENT Back-lighting unit.
CAMERA Array or line-scan.
MOTION Static (array camera) or continuous linear/circular motion (line-scan camera).
MATERIALS Transparent/transluscent materials.
REMARKS The optical arrangement is the same as that shown for Method 17 (array camera), or Method 18 (line-scan camera). Certain features, such as embossing and cracks, may be

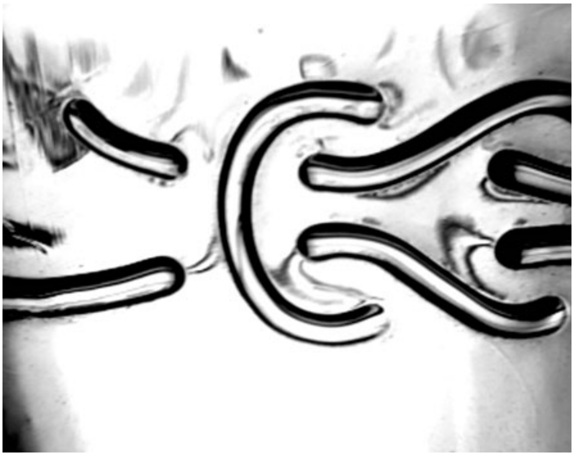

Fig. 40.58
Embossed glass bottle

seen better by this technique than by dark-field illumination (Methods 20 and 21). Visibility of a physical protusion (e.g., embossing) depends on its orientation (Does it project towards the camera, or away from it?). Similarly, the visibility of a crack depends upon its angle, relative to the lighting and camera. It is usually best to experiment with back-illumination and dark-field illumination, in order to choose the optimal lighting-viewing method for a given application.

SAMPLE IMAGE *Figure 40.58*

40.62 Method 62: Laser Bore Scanner

OBJECTIVES To inspect a blind cylindrical hole.

TYPICAL APPLICATIONS

- Inspecting bores of hydraulics cylinders and combustion cylinders for automobile engines.
- Inspecting/measuring internal (female) screw threads.

EQUIPMENT Laser bore scanner shown figure.

CAMERA None – image is constructed from the (non-standard) video signal generated by the photo-sensor.

MOTION Scanner tube moves at a controlled speed into the bore during scanning.

GEOMETRY Straight cylindrical bore.

MATERIALS Matt or shiny bore surface.

REMARKS The mirror at the end of the scanner can be rotated through 360°, thereby enabling an all-round examination of the side wall of the bore. This mirror can be oriented at 45° (for a normal view of the side-wall), or at some other angle (providing forward or back-ward views). This scanner was devised in the 1970s by SIRA Ltd., Chislehurst, Kent, U.K., for inspecting hydraulics components for automobile brake mechanisms. It was designed to detect scratches and cracks. The brake cylinder was moved linearly and the probe rotated inside it.

LAYOUT DIAGRAM ➋ *Figure 40.59*

40.63 Method 63: Laser Pattern Projector

OBJECTIVE Project a simple pre-defined pattern, such as an array of spots or a grid, onto the widget to provide the basis for high-speed, low-precision measurement of 3D shape.
TYPICAL APPLICATIONS Inspecting objects such as loaves, cakes, pies and other food products, where high precision measurement of surface shape is not required but high speed of operation is.
EQUIPMENT Laser, fitted with special-purpose diffractive optical filter.
REMARKS Standard pattern generators available are:

(1) Multiple parallel stripes (up to about seven stripes).
(2) Single pair of crossed lines.
(3) Grids (about 7 by 7 lines).
(4) Multiple spots (up to about 11*11 array).
(5) Single circle.
(6) Concentric circles (up to about seven).

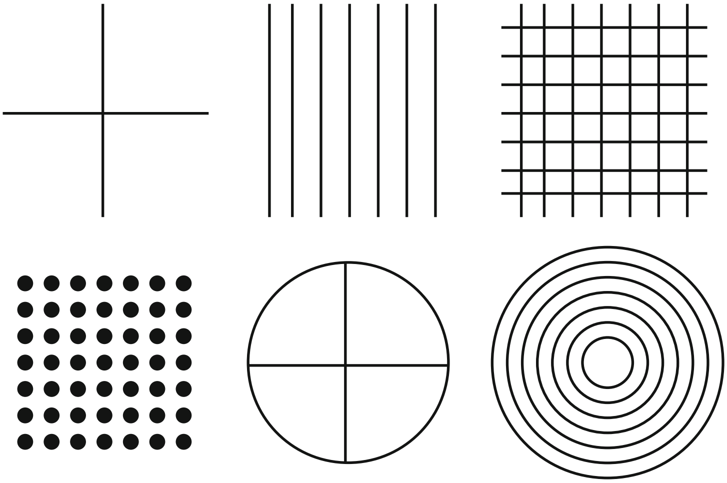

Fig. 40.60
Sample projected patterns generated by diffractive optics fitted to a low-power (diode) laser

These filters are often supplied to fit red solid-state (diode) lasers, although there is no reason why other wavelengths cannot be used. The projector is used in a structured light/triangulation lighting-viewing arrangement (Method 107).
SAMPLE PATTERNS ➲ *Figure 40.60*

40.64 Method 64: Locate Object with Zero Contrast

OBJECTIVE To obtain a silhouette of an object on a continuously moving smooth conveyor belt, when there is low contrast between the object and its background.
TYPICAL APPLICATIONS
(a) Locating con-rods (grey) on a smooth grey conveyor belt.
(b) Examining extrusions (e.g., food products) for gross variations of thickness.
EQUIPMENT Two laser stripe generators, or projectors fitted with rectangular masks.
CAMERA Line scan.
MOTION Continuous linear.
GEOMETRY Any objects whose thickness exceeds a certain minimal amount, determined by the optical set-up.
REMARKS This is the *CONSIGHT* optical arrangement, originally devised for locating con-rods on a smooth conveyor belt. When there is no widget present, the two laser fan-beams converge on the conveyor to form a single line of light, which coincides with the line-scan camera's field of view. When an object is present, the beams no longer converge and form two stripes, displaced to the sides of the camera's field of view. Hence, the camera observes a bright stripe, when no object is present but does not see any light at all when an object in place. Notice that the surface of the conveyor belt must be smooth and flat. There is no need for the object to present any colour or contrast change, compared to the conveyor belt surface.

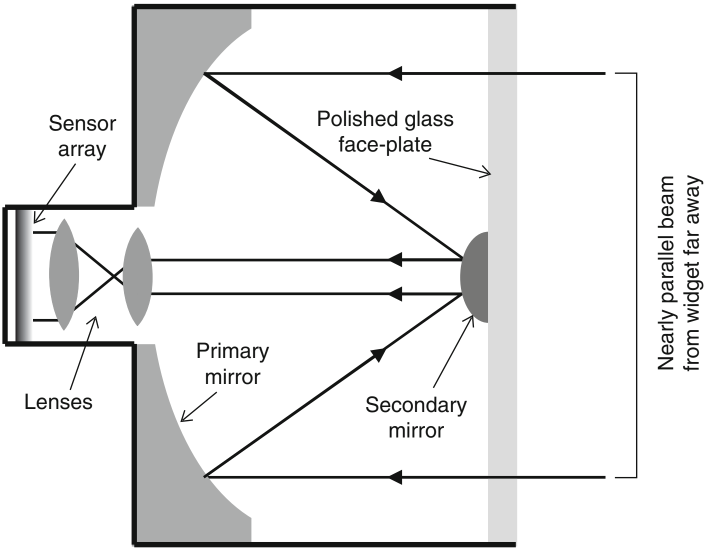
40.65 Method 65: Long Focus Optical System Using Mirrors

OBJECTIVE To provide a lens with a very long focal length (up to 2,000 mm).
TYPICAL APPLICATIONS

- Inspecting objects, or scenes, from a large distance, for reasons of safety, inaccessibility, etc.



Sensor array
Polished glass face-plate
Nearly parallel beam from widget far away
Lenses
Primary mirror
Secondary mirror

Fig. 40.62
Catadioptric system

- In situ inspection of pipework, electrical insulators on pylons, brickwork, masonry, roofing, etc.
- Examining small objects/features from a large distance.

EQUIPMENT Catadioptic system. This consists of an integrated mirror and lens optical system.

CAMERA Array.

LENS Catadioptic (mirror-lens) system.

MOTION It is important to suppress vibration of the camera, since the large working distance makes this method susceptible to the slightest movement.

GEOMETRY The object or scene to be viewed can be far way away, perhaps as much a 100 m.

REMARKS Catadioptric systems are widely used in astronomical telescopes and by photographers who cherish them because they provide a long-focus, light-weight system. Reflective optical systems are capable of operating over a very wide spectral range (covering UV, VIS and IR) and are immune from certain types of aberration that afflict lens systems, especially chromatic aberration. In their advertising one company suggests that it is possible to view the whiskers of a tiger from a safe distance! Catadioptric systems do not have a wide depth of field and the field of view is much smaller than the focal length. Mis-focussing causes a point source of light to appear as a bright ring. Achieving satisfactory illumination over a large distance may also require a sophisticated mirror-lens system, since standard luminaries do not usually control the lighting angles accurately. A catadioptic system can serve a similar function to a telecentric lens.

LAYOUT DIAGRAM ➒ *Figure 40.62*

40.66 Method 66: Low-Definition Range Information

OBJECTIVE To obtain low-definition, 3-dimensional shape information about a widget, by simultaneously projecting a number of light stripes onto its surface.

TYPICAL APPLICATIONS Low tolerance shape-measurement applications. It is also useful in general mechanical manufacturing, for determining object type and posture. This technique is well suited to the food industry for checking the shapes/sizes of loaves, cakes, fruit, vegetables, etc.

EQUIPMENT Diode or other low-power laser, fitted with a holographic lens that generates a set of fan-shaped beams (When these are projected onto a plane, they generate a set of parallel light stripes).

CAMERA Array type.

MOTION Static. In many applications, the widget should be held in a fixed position relative to the camera.

REMARKS This is similar in concept to Method 68 (Also see Method 107). It is able to provide shape information simultaneously (i.e., within one video frame period) about the height profile within several cross-sections. This is achieved by projecting several stripes at once onto the widget. A holographic lens is able to generate a small number (typically up to 12) of parallel light stripes. Hence, it is possible measure the surface height at several positions, without moving the widget. Holographic lenses can also generate cross-lines, arrays of spots, grids and concentric squares or circles (Method 63). Data analysis can be straightforward, involving only a series of simple size checks, or more complicated, requiring the use of Pattern Recognition techniques. The inputs to a neural network, or other classifier could be derived by sampling each height profile at a number of fixed points. In some situations, it may be difficult to identify the different parts of "broken" stripes, in which case we may only be able to monitor deviations from the ideal 3D shape, rather than measuring surface height quantitatively. To resolve ambiguities that might arise when the projected arcs disintegrate and merge (➲ *Fig. 40.63b*), we can use two cameras (See Method 107).

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.63*

40.67 Method 67: Magnify One Image Axis

OBJECTIVES

- To make pixels square, so that rotating the image does not alter estimates of linear dimensions or areas, based on simple pixel counting.
- To make the best possible use of the available image resolution.
- To correct for oblique viewing by a camera placed off normal.
- To modify the image warping caused by anamorphic optics.
- To produce parallelogram warping, to make image processing easier. A parallelogram can be transformed into a rectangle, or a rectangle into a square.
- To adjust the virtual aspect-ratio of the photo-detectors in a line-scan sensor. Recall that the resolution across the web is determined by the camera geometry, while the web speed affects the down-web resolution. Cylindrical lenses can make the web speed appear to be greater/smaller, independently of the magnification applied across the web.

◘ Fig. 40.63

Low-definition range measurement using multiple laser stripes. (a) Optical layout. A low-power (diode) laser fitted with a holographic filter, projects a set of fan-shaped beams (typically 5–12) onto the widget. This should be placed in fixed position and orientation relative to the laser and camera. (b) Sample image (simulated using a single laser rotated to eight different angles in turn): automobile con-rod. *Left:* original image. The alignment of arc A with arcs B and C is accidental and is caused by the choice of projection-viewing angles; arc A is actually created by the same fan-beam as arcs D and E. This type of ambiguity places an upper limit on the number of stripes that can be accommodated by this technique. *Right:* Processed image, after filtering, thresholding and skeletonisation

TYPICAL APPLICATIONS

- To inspect long thin objects, such as nails, screws, needles, bottles, confectionary bars, machine parts, carrots, etc. where the aspect ratio may exceed 10:1.
- To correct the geometric distortion produced by a camera viewing a surface at some (known) angle other than 90°.

- To inspect print, paper, plastic film, steel sheet and other web products, as they are moving past a line-scan sensor.

EQUIPMENT One or more cylindrical lenses.

REMARKS A cylindrical lens system can be used to magnify any one axis of an image, relative to the orthogonal axis (This maps a square into a parallelogram, or a circle into an ellipse). Two lenses, mounted orthogonally to each other can magnify both axes independently, by different amounts. Notice that a cylindrical lens produces different focal planes for edges parallel to the stretched and non-stretched axes (Y- and X-axes in ➲ *Fig. 40.64a*). The reason is that rays in the XZ-plane are not deflected by the lens, while those in the YZ-plane are.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.64*

40.68 Method 68: Mapping Range by Projecting Multiple Stripes

OBJECTIVE To obtain low-definition 3-dimensional shape information, at high speed (one video frame period).

TYPICAL APPLICATIONS Low tolerance shape-measurement applications, particularly in the food industry. For example, analysing the shape of loaves, cakes, etc.

EQUIPMENT Ruggedised but otherwise standard slide projector. This projects a pattern consisting of a series of parallel stripes (Other patterns, such as arrays of spots, could be projected instead but images created using stripes are particularly easy to analyse). The transparency should be based on a rigid material (glass), rather than plastic or other material which is susceptible to warping.

CAMERA Array.

MOTION Static.

GEOMETRY Fairly smooth and uncomplicated, otherwise there will be some disintegration of the stripes which are difficult to “join together” again by image processing. As the angular separation between the slide projector and the camera is increased, the sensitivity becomes greater but the probability that the projected arcs will “break” also gets larger.

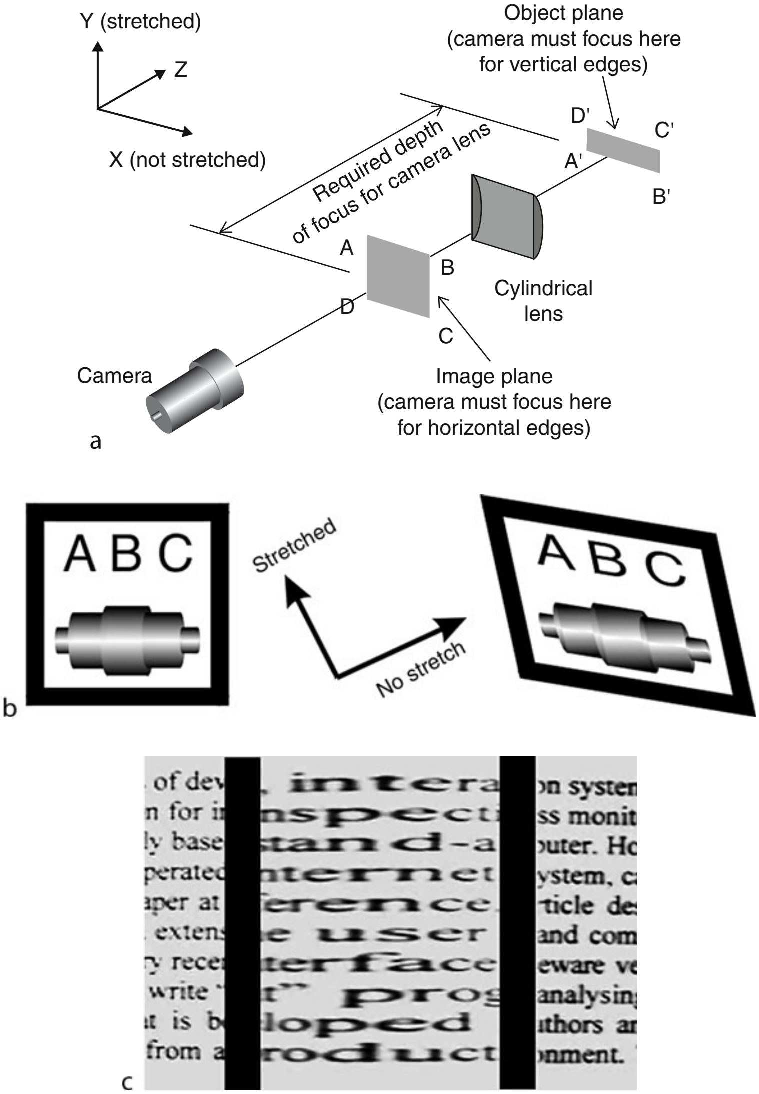
MATERIALS Matt, preferably not very strongly absorbing or reflecting.

REMARKS This is similar in concept to Method 107, but is able to provide shape information simultaneously about a number of cross-sections through the widget. This is achieved by projecting several stripes at once onto it. In some situations, it may be difficult to distinguish different stripes, in which case we may only be able to monitor deviations from the ideal 3D shape, rather than measuring surface height precisely. To avoid problems due to diffraction, the width of the stripes in the transparency must be many times the wavelength of the light used. To ensure that the projected arcs do not disintegrate or merge, due to occlusion, we can use two cameras. The system is then symmetrical about the projector’s optical axis.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.65*

40.69 Method 69: Mapping Range with Polychromatic Light

OBJECTIVE To obtain low-definition height information quickly, as a prelude to forming a range map (or depth map) from an object surface.



■ **Fig. 40.64**

Cylindrical lens. (a) Optical layout. Horizontal magnification = 1, (Hence [AB] = [A′B′]); Vertical magnification = M, where M = [AD]/[D′A′]. Notice that the vertical axis is inverted but the horizontal axis is not. (b) Parallelogram warping using a cylindrical lens. *Left:* Original. *Centre:* Two vectors are needed to characterise the magnification of a cylindrical lens. *Right:* Resulting image. Notice that the process is reversible, so these two images could be labelled in the reverse order. (c) Sample image: *Centre:* View of a printed page through a plastic Fresnel lens. *Sides:* Direct views

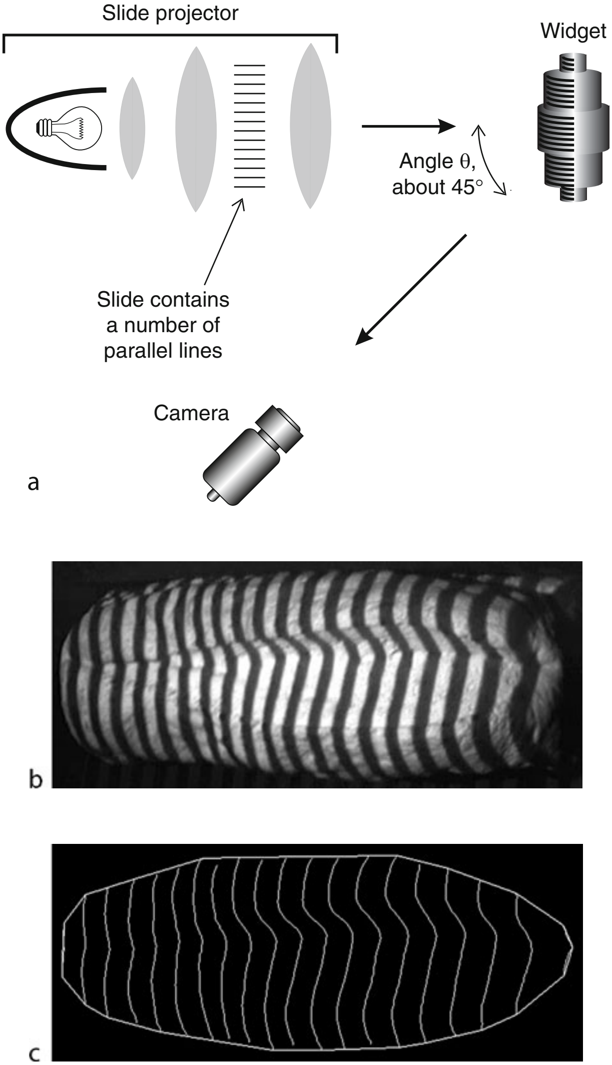


Fig. 40.65

Estimating surface height by projecting light stripes onto an object. (a) Optical arrangement. (b) Sample image: Loaf, original image. (c) Processed image. Each light stripe has been reduced to an arc one pixel wide. This makes subsequent analysis easier

TYPICAL APPLICATION Monitoring shape of loaves, cakes, etc.
EQUIPMENT Various options are available:

(a) Intense collimated source of white light, diffraction grating.
(b) Array of LEDs emitting at different wavelengths.
(c) Linear variable interference filter (At each point along the filter, it passes a narrow band of wavelengths. The wavelength at the centre of the pass-band varies across the face of the filter).

CAMERA RGB or HSI colour camera with array- or line-scan sensor geometry (An HSI camera is easier to use).
MOTION Static (array camera), or continuous linear motion (line-scan).
GEOMETRY Fairly simple; should not have steep-sided pits or cliffs.
MATERIALS Opaque, matt, preferably not strongly coloured, non-fluorescent. Surface, diffraction effects should be negligible.
REMARKS This method uses colour contours, instead of sharp illumination boundaries, in an otherwise conventional structured-lighting arrangement (Methods 107 and 68). If an RGB camera is used, its output signal is digitised and then passed through a look-up table to "calculate" hue. In the LUT, each [R,G,B] triple is associated with a single scalar quantity proportional to hue (H). If an HSI camera is used, its hue channel is used directly, while saturation (S) and intensity (I) are both ignored. By thresholding the hue at various levels, a range of contours can be produced, from which the height can be determined (See the inset in *Fig. 40.66a*). The geometry is the same as for Methods 107 and 68; colour contours simply replace the illumination edges.) The optical layout for a system based on an array-scan camera is shown in *Fig. 40.66a*. A "rainbow" is projected onto the widget surface. The *hue* of the light leaving a given point, P, on the object surface is not affected at all by the spectral-reflection characteristic at P, which is illuminated with only monochromatic light (Assuming that fluorescence effects are negligible, there is no light at P with any other wavelength). A standard slide projector, fitted with a variable-absorption filter (e.g., gelatine or coloured-glass) produces polychromic illumination. In this case, the measured values for hue, as well as the intensity, of the reflected light are affected by variations in the widgets' spectral reflectivity characteristic. The technique outlined in *Fig. 40.66a* requires a high-intensity light source and a highly sensitive camera, to obtain good accuracy. For this reason, it is unlikely to be suitable for inspecting large objects. An alternative scheme, based on a line-scan camera (*Fig. 40.66b*), makes more efficient use of the available light and hence is capable of being used on larger and darker objects. Among the techniques available for projecting a rainbow pattern are:

(a) A diffraction grating and an intense source of collimated white light that has a very small output aperture (*Fig. 40.66c*).
(b) An array of LEDs emitting light at different wavelengths spanning the VIS wave-band (*Fig. 40.66d*).
(c) Linear, variable band-pass interference filter, used in conjunction with a white-light projector (*Fig. 40.66e*).

TYPICAL APPLICATIONS
(a) Low-precision measurement and inspection.
(b) Measuring range for inspection and low-precision measurement.

EQUIPMENT Programmable spatial light modulator, such as:

(a) Liquid-crystal light valve.
(b) Digital Micromirror Device (DMD chip, or "mirror chip").

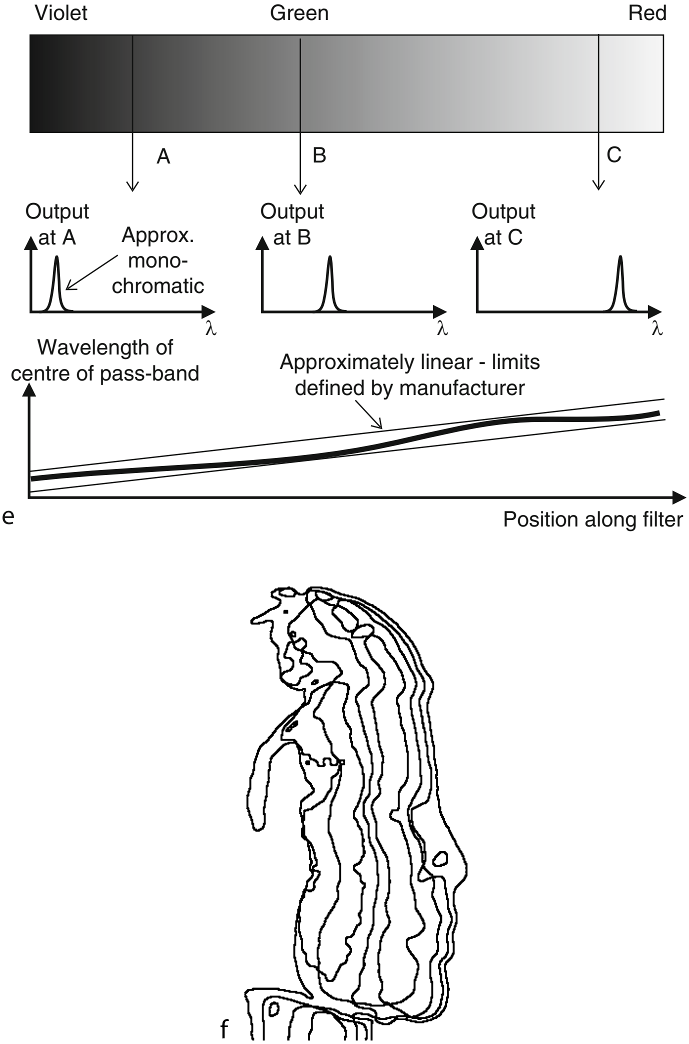

Fig. 40.66

Generating a range map by projecting a colour pattern. (a) Using an array-scan camera. While it was necessary to draw distinct fan-shaped beams and colour contours here, the projector actually produces a continuously variable coloured pyramid of light. Colour contours can provide information about range in the same way as the projected light stripes in Method 66. (b) Using a line-scan camera. (c) Using a diffraction grating to decompose white light. (d) Using an array of LEDs to create a ''rainbow'' pattern. (e) Variable band-pass pass filter. The central wave-length of the pass-band is a linear function of distance along the filter. (f) Sample image: Colour contours derived from a cardboard model of a human head. The ''rainbow'' was generated by a slide projector fitted with a single-stripe mask and a glass prism

CAMERA Array scan.
MOTION Static during several video frame periods (up to about eight).
REMARKS Liquid-crystal display projectors are now common-place in lecture rooms. However, it may be necessary to replace the lens, to accommodate small widgets and to reduce the working distance.

A DMD chip consists of an array of tiny mirrors (normally square and typically 13 × 13 μm^2 to 17 × 17 μm^2), each of which can be tilted through a small angle (10°–12°), thousands of times per second by applying a voltage pulse sequence. A typical DMD chip has a resolution of 1280 × 1024 pixels and the mirror array of mirrors is about 20 × 20 mm^2. An intense, continuous beam of white, coloured or monochromatic light is projected onto the mirror array. When one of the micromirrors is in the *on* state, light shone onto it is reflected towards the target (i.e., the widget) but in the *off* state, the light is reflected onto an absorbing surface, By switching the mirrors with a variable *on:off* ratio, a multi-level image can be projected. Temporal integration of the eye/camera is essential in creating an impression of shading. It is important, therefore, that the mirror's period of vibration is much smaller than the camera's light-integration period, to avoid strobing effects. The DMD chip is used in the manner shown in ➲ *Fig. 40.67b*. Projecting patterns of light onto a widget provides a useful means of inferring its 3D shape. In Methods 68 and 69, a fixed illumination pattern is used and a single image analysed, whereas the two schemes outlined in ➲ *Fig. 40.67* use dynamic, time-varying illumination and generate sequences of images.

To see how this facility can be used to measure range, consider a path *P* through the optical system so that it passes through the *(U, V)* pixel in the spatial light modulator (Notice that if we can identify *P*, we can also locate *(U, V)*). As time progresses, several rays are transmitted, in turn, along path P. The "intensities" of these rays will be denoted by $R_1, R_2, \ldots, R_n$; if ray *i* has zero intensity, then $R_i = 0$ (The spatial light modulator's *(U, V)*-pixel is switched *off*), while rays with non-zero intensity will be denoted thus: $R_i = 1$. The spatial light modulator allows us to generate a different binary sequence $(R_1, R_2, \ldots, R_n)$ for each optical path, thereby providing a unique identity for *P*. The camera observes the *sequence* of brightness values for each point in the image plane. Analysis of this bit pattern reveals the identify of the illumination path and hence *(U, V)*, thus providing the information needed to calculate the widget-sensor distance by applying formula given in Method 107. While this method relies on identifying the optical path digitally, Method 69 does so by varying the wavelength.

Program-controlled projection of patterned light. The spatial light modulator is a slightly modified form of computer display (a) Liquid crystal light valve. (b) Digital Micromirror Device

MOTION Static or linear motion.
MATERIALS Very thin transparent film, or coating overlaying a reflective surface.
REMARKS This method creates interference patterns similar to those visible on a film of petrol on a wet road. If monochromatic light is used, the interference fringes vary in brightness, rather than colour. The method can be adapted to visualise the surface height changes on optical quality surfaces. A thin film can be created by placing a glass plate, or lens, on a reference flat surface. Clear oil might be inserted between them. The air film thickness will vary with the undulations of the surface of the test surface. The interference fringes produced in this way represent contours of height difference.
LAYOUT DIAGRAM ➋ *Figure 40.68*

40.72 Method 72: Measuring Refractive Index of a Thin Film

OBJECTIVE Measure film thickness, or refractive index of a thin film.
EQUIPMENT Right-angle prism with a high refractive index.
CAMERA Line scan.

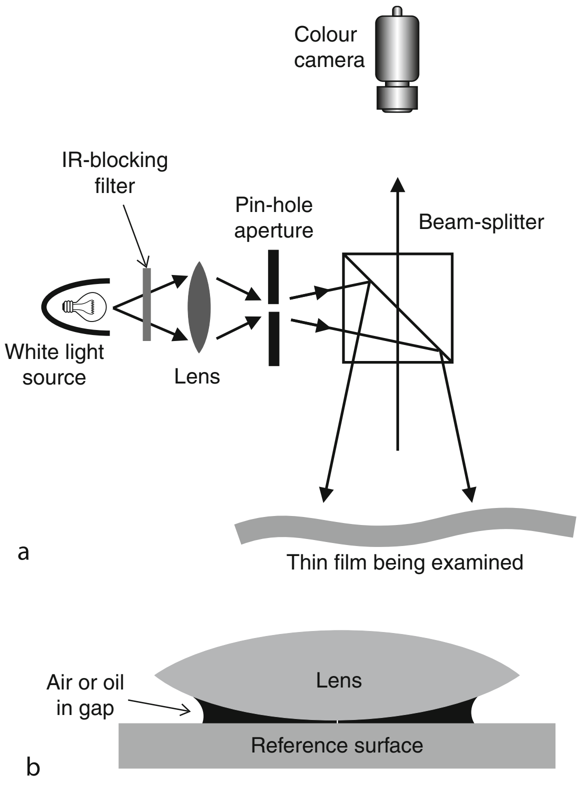

Fig. 40.68
Measuring the thickness of a thin transparent film or coating. (a) Optical arrangement. Produces coloured interference patterns. (b) Newton's rings, produced by a thin "film" of air between a flat surface and a spherical glass lens, can be used to measure the curvature of the test surface

LENS Short focus.
MOTION Static.
GEOMETRY Thin film.
MATERIALS Transparent.
REMARKS The prism is placed in direct contact with the film. Hence, its surface can become dirty and scratched. In some applications, a thin film of water, clear oil some other suitable liquid will help to maintain good optical coupling whilst providing a degree of lubrication. The displacement, *d* of a single ray of light travelling through a film of thickness *t*, with an angle of incidence equal to *A* is given by the formula:

$$t.sin(A).(1 - cos(A))$$

If the film thickness is known beforehand, the refractive index can be measured. Alternatively, if the refractive index is known, the thickness can be measured.
LAYOUT DIAGRAM ➔ *Figure 40.69*

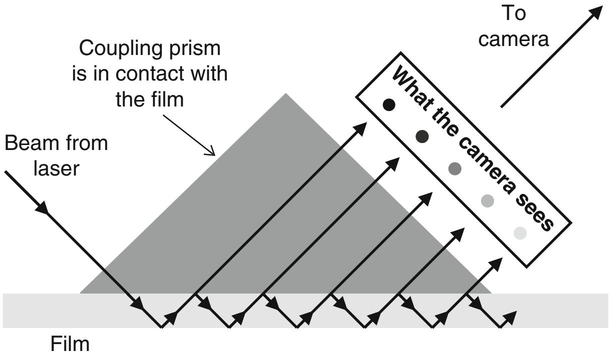

Fig. 40.69
Measuring the thickness of a thin film by observing multiple internal reflections

40.73 Method 73: Micro-Louvres Suppress Ambient Light

OBJECTIVE To prevent ambient light from affecting the image quality, whilst allowing a person to view the inspection area by eye.

TYPICAL APPLICATIONS Inspecting flexible and other awkward objects that are likely to jam the widget-transport mechanism. Using the arrangement shown in *Fig. 40.70b*, a person can visually monitor widgets moving, without disturbing the inspection process.

EQUIPMENT A light-proof enclosure with a window consisting of *Light-control Film* (product of the 3M Company). The structure and properties of this film are explained in *Fig. 40.70a*. The film is oriented so that it blocks light from the most prominent ambient source but allows a person to view inside the inspection cell.

REMARKS Light Control Film is often used to ensure privacy of viewing for confidential computer displays. People facing the screen directly can see the image unhindered, while an unauthorised person looking obliquely can only see a grey rectangle. Light-control film blocks light over a wide range of wavelengths, since it relies on physical barriers to light transmission: micro-louvres, consisting of parallel strips of opaque material embedded in clear acetate or polycarbonate. The action is similar to that of Venetian blinds. The film transmits all light rays whose angle of incidence, within the XZ-plane, is smaller than some critical angle, θ_c. A ray of light is transmitted if it falls within a wedge (See *Fig. 40.70a*). The light-pass volume becomes a pyramid, if we overlay two films with their (X, Y)-axes interchanged. Light-control film is normally placed in the illumination path, not in the camera's line of sight, since it reduces image quality significantly and can generate Moiré patterns with the camera's photo-detector matrix. Light-control film can be used to construct a collimator. Use a single sheet to collimate one axis only. Use two sheets, aligned orthogonally to one another, to collimate the beam in both axes.

40.74 Method 74: Microscopic Fourier Analysis of Transparent Film

OBJECTIVE To analyse a thin transparent film for microscopic surface defects, such as scratches.

TYPICAL APPLICATIONS Inspecting optical–quality transparent film, sheeting, etc. (e.g., acetate film used with overhead projectors, microfiche film, etc.).

EQUIPMENT Laser, beam expander. Converging lens.

LENS Macro lens, capable of close-up viewing of a small area.

CAMERA Array scan with a wide dynamic range.

MOTION Static.

MATERIALS Thin sheet of transparent material.

REMARKS Projecting a coherent beam of light though a transparent film generates the Fourier Transform of any surface defects, such as scratches. The Fourier transform is visible as the far-field interference pattern. To shorten the optical path, a simple lens can be used (See *Fig. 40.71*). This effect can be demonstrated simply, by shining the beam from a laser pointer through a sheet of OHP film. A similar result can be obtained using a fine fabric, a 50 mm slide, or the edge of a screw with a fine-pitch thread. Viewing distant street lights through a gauze curtain produces the same effect. Since the Fourier transform is generated optically in real-time, image processing software need only be applied to undemanding operations: sampling the intensity at a few pre-defined points, or simple fixed-position image comparison. Care must be taken to ensure that the prospective customer for a vision system understands that the Fourier Transform, not a direct image of the surface features, is generated by this method. He/she should appreciate, for example, that a series of equally spaced horizontal scratches generates a set of bright spots lying along a *vertical* line. The Fourier transform often generates an image with a very wide dynamic range, in excess of that accommodated by a standard video camera. For this reason, a camera with a logarithmic response characteristic is highly desirable.

Fig. 40.70

Light-control film. (a) A set of thin, opaque, parallel slats, placed very close together forms a crude, single-axis collimator. Any ray of light impinging on point P and originating within the grey wedge-shaped region (extended indefinitely along the Y- and Z-axes) will pass through the film, which covers the XY-plane. Other rays will be blocked. (b) Blocking ambient light from a single, fixed direction, whilst allowing viewing of the widget in situ. (c) Sample images: Zinc die-casting, black back-ground. Multi-source front lighting. *Top-left:* No additional lighting. *Top-right:* Brilliant ambient lighting, at a large angle of incidence, greatly reduces the image quality. *Bottom-left:* Light-control film blocks the ambient light, improving the image quality. The film does not provide an effective block at the *top* of the image, where the angle of incidence is less than the critical angle, θ_c (This can be avoided by altering the inspection cell geometry). If the film is rotated by 90°, it cannot block the unwanted rays

LAYOUT DIAGRAM *Figure 40.71*

40.75 Method 75: Motorised Filter Wheel

OBJECTIVE To provide a means of switching optical filters and polarisers under program control.

TYPICAL APPLICATIONS

- Flexible inspection cell.
- System prototyping.
- Working in an unpredictable optical environment.

EQUIPMENT Metal disc, fitted with various filters, such as:

- UV blocking filters.
- IR blocking filters.
- Colour-selection filters
- Neutral density filters.
- Polarisers.

REMARKS One commercial device allows the following filters to be fitted:

- 8 filters, size 1″, or

- 6 filters, size 1.25″, or
- 4 filters, size 1.5″

The unit is 6″ diameter, by 0.65″ deep. Another filter wheel, holds one of the following sets of filters:

- 16 filters, size 1″
- 12 filters, size 1.25″
- 8 filters, size 2″

This device is 10″ diameter by 1.3″ deep. It can hold square or round filters. Control is exercised by a USB or RS232 port. Since two units can be mounted back-to-back to combine filters. For example, it is possible to mount a series of low-pass filters on one wheel and high-pass filters on the other. This combination implements up to 64 band-pass filters that can be selected by computer. Also see Method 40.

40.76 Method 76: Multi-arm Image Conduit

OBJECTIVE To provide a split-image facility, so that several views of a complex object, or scene, can be combined into a single video frame. All sub-images are sampled at the same instant and may be rotated (by twisting the image conduit). In addition, the magnification may be different for each sub-image, which may be derived from an awkward viewing location, or a hostile environment.

TYPICAL APPLICATIONS Viewing complex objects and scenes in which there are several "interesting" areas, with large "uninteresting" areas that need not be examined.

EQUIPMENT Several lengths of fibre-optic image conduit. Flexible bundles may be used instead but this option is more expensive.

CAMERA Array.

LENS The main camera lens is replaced with the multi-arm conduit/bundle. Each conduit rod has its own objective lens.

MOTION Static.

REMARKS Since miniature cameras are cheap nowadays, this method is less important than it once was. The chief advantage is that the same camera is used to view all sub-images, thereby achieving accurate colour and intensity matching from one sub-image to another. If a frame-transfer camera is used, the sub-images are sampled at the same moment, thereby allowing accurate synchronisation of activity within the different sub-images.

LAYOUT DIAGRAM ➋ *Figure 40.72*

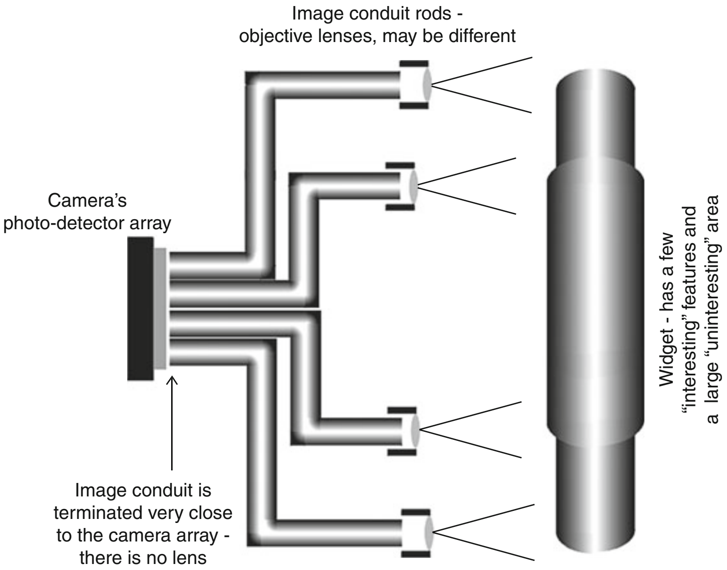

Fig. 40.72
Multi-arm fibre-optic image conduit, used to split the camera's field of view. The widget must be presented for inspection in fixed position and orientation

40.77 Method 77: Multi-Camera Specular and Near Specular Illumination

OBJECTIVES To highlight shallow surface features by providing oblique illumination, with oblique and normal viewing.

TYPICAL APPLICATIONS Inspecting nominally flat shiny surfaces, such as metal sheet, plastic film, sheet glass, etc. The surface to be inspected may be polished, painted or lacquered.

EQUIPMENT Up to four cameras, plus one of the following:

- Back light unit with slit mask placed in front
- Fluorescent tube, with a high frequency power source
- Fibre optic line illuminator
- Array of LEDs fitted with diffuser

CAMERA Line scan.

MOTION Linear motion.

GEOMETRY Nominally flat, smooth with minute pits, scratches, dimples, pimples, small particles of foreign material adhering to the surface.

MATERIALS Metal sheet, plastic film, glass, glossy paper/card, etc.

REMARKS Up to four cameras can be used simultaneously. These generate four images: "below specular" (BS in *Fig. 40.73b*), "specular" (S), "above specular" (AS) and "normal" (N). They are registered perfectly along the Y axis (i.e., along the web) and alignment along the

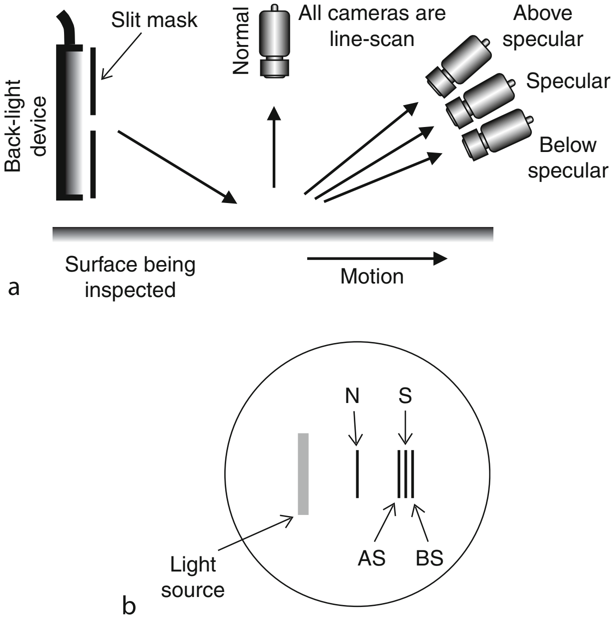

Fig. 40.73
Multi-camera grazing illumination. (a) Optical Layout. (b) Illumination diagrams. A - normal viewing; AS - above specular; S - specular; BS - below specular

Y axis (i.e., across the web) is straightforward. Hence, it is possible to obtain four well-registered images, which can be analysed individually or combined by suitable software. Highly sensitive discrimination of surface irregularities can be obtained by using a collimated light beam, in which all rays are parallel and lie within a narrow sheet. This can be achieved by projecting a collimated light beam through a slit aperture (The slit must be wide enough to avoid producing significant diffraction effects).
DIAGRAMS AND SAMPLE IMAGE ➋ *Figure 40.73*

40.78 Method 78: Multi-camera Structured Lighting

OBJECTIVE To obtain 3D shape information and generate an "all round" surface relief map, by simultaneously scanning the top and two sides of an object.
TYPICAL APPLICATION

- Analysing the shape of baked goods: loaves, pies, cakes, etc.
- "All round" inspection of extrusions, tubing, cables, etc.

EQUIPMENT Three or more lasers, fitted with holographic or cylindrical lenses, to generate fan-shaped beams.
CAMERA Three or more array cameras. To obtain precise shape measurements, digital cameras should be used (Vertical and horizontal video clocks should be locked to the scanning of the photo-detector array).
LENS Three or more lenses, probably with similar focal lengths.

MOTION Continuous linear motion.
GEOMETRY Should not be very complicated, to avoid occlusion and sub-sequent fragmentation of the range map.
MATERIALS Matt not reflective material, preferably not very dark.
REMARKS Aligning the lasers is straightforward: simply, rotate them by hand, until their beams coincide, projecting a single bright line onto any plane. The cameras view the widget from different vantage points. Hence, their images must be "warped," by applying simple geometric transformations, before they can be combined to create a composite cross-section contour of the widget. In order to align and register these images, careful calibration is necessary. This relies on a target consisting of a square board, with four high-contrast markers (e.g., LEDs), arranged at its corners (➋ *Fig. 40.74b*). The markers provide four reference points, from which we can calculate the appropriate geometric transformations. A different warping function is required for each vantage point. In each case, the objective is to map a trapezium into a square. The following image "warping" functions are needed:

(a) Linear rescaling and shifting of the horizontal axis (Cameras 2 and 3)
(b) Linear rescaling and shifting of the vertical axis (Camera 1)
(c) Trapezium-to-square mapping (Cameras 1–3)
(d) Non-linear stretching along one axis (Vertical axis for camera 1; Horizontal axis for cameras 2–3)

The last of these is only required if the cameras are placed close to the object. Once these functions have been performed, three "warped" images are obtained, each one containing a bright arc. These transformed images are then superimposed, with the markers aligned. This creates an image containing a single continuous bright curve, tracing the top and side edge contours of a vertical cross-section though the widget.
LAYOUT DIAGRAM ➋ *Figure 40.74*

40.79 Method 79: Multiple Views of a Widget

OBJECTIVE To combine several views of a widget, obtained under different lighting conditions thereby allowing features, or combinations of features, to be detected in a way that it is not possible from a single view.
EQUIPMENT Computer-controlled lighting system, with two or more sources, which may provide light of different colours and polarisation.
CAMERA Array.
MOTION NONE The widget must be absolutely stationary compared to the camera. Image acquisition requires two, or more, frame intervals.
REMARKS This method is suitable for viewing complex components and assemblies that have a non-homogenous surface finish (e.g., black rubber and polished metal). It is possible to combine edge contours and internal features (e.g., cracks, splits, pitting, etc.), which may be critical in certain parts of an object but not in others. The precise layout of the optical sub-system may vary from one application to another; the simple optical arrangement in ➋ *Fig. 40.75* is just one example that illustrates the general principle. Individual light sources can vary in position, polarisation and colour. Multi-lamp/multi-colour lighting systems are potentially very useful. Since the whole visible-light spectrum (VIS) can be covered by a series of LEDs whose wavelengths vary in 0.01 µm steps, it is possible to tailor a multi-colour lighting

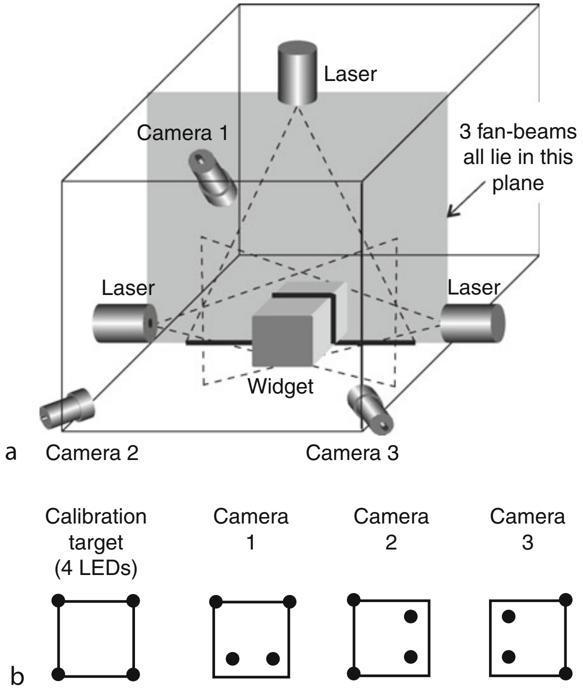

Fig. 40.74
Multi-camera Structured Lighting. (a) Optical layout. (b) Calibration target and images obtained by the three cameras

system to suit each individual application. A crude spectral analysis of a complex 2- or 3-dimensional scene can be performed using a series of switched LEDs. Holograms produce diffraction patterns which change their colour as the position of a white light source changes. This effect can be useful for authenticating holographic security tags. The general principle of combining two or more images, derived under different lighting conditions, has not been exploited to its full potential. There is considerable scope for further research in both the design of the lighting system and the processing of multi-view images.

LAYOUT DIAGRAM AND SAMPLE IMAGES *Figure 40.75*

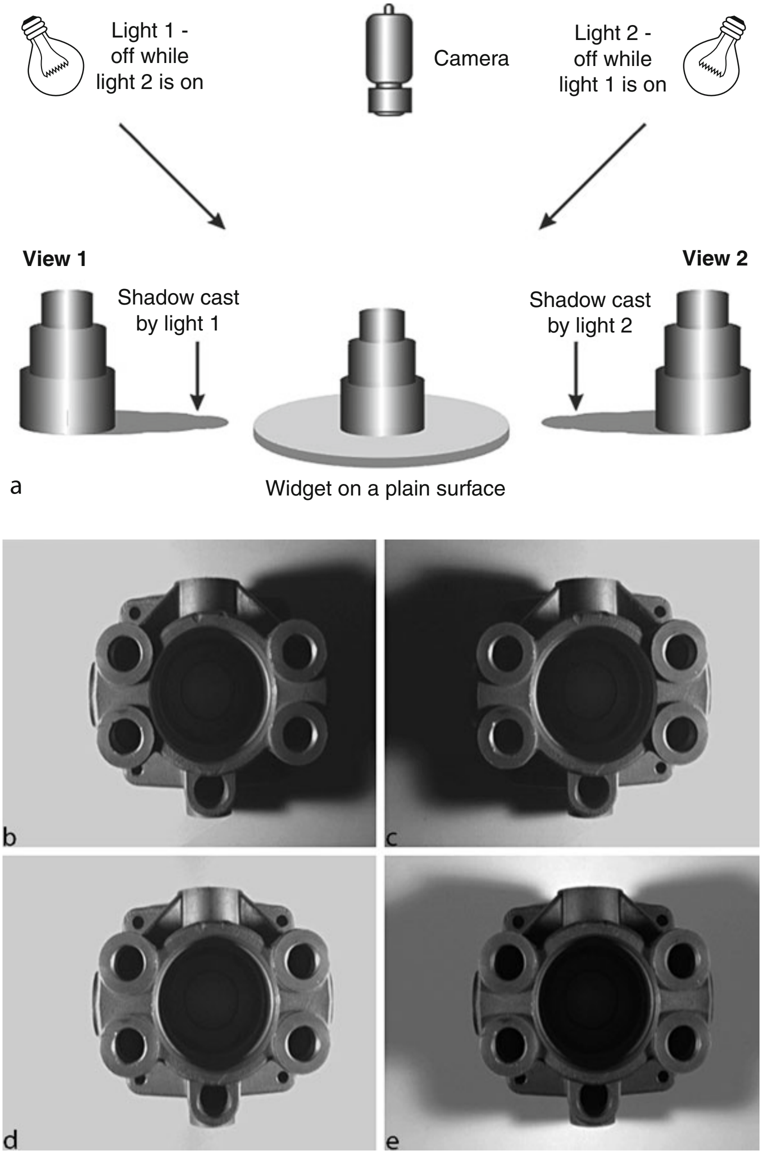
40.80 Method 80: Multi-spectral Image Sensing

OBJECTIVE To obtain images from a number of different spectral bands in the near-UV, VIS and near-IR. Performing a coarse spectral analysis at high speed.

TYPICAL APPLICATIONS Inspecting coloured packaging, printing and other multi-coloured objects.

EQUIPMENT Several matched image sensor arrays and filters, beam-splitters and mirrors or prisms.

REMARKS Three different optical arrangements are shown in *Fig. 40.76*. In each case, the optical system must be carefully aligned, to ensure that the images are properly registered.



■ **Fig. 40.75**
Images derived with lighting from different directions (a) Optical layout. (b) Sample image: hydraulics manifold, lit from the left. (c) The same component lit from the right. (d) Images (b) and (c) combined by computing the maximum intensity between corresponding pairs of pixels. (e) Lighting simultaneously from both sides casts shadows and produces an image that is far more difficult to analyse

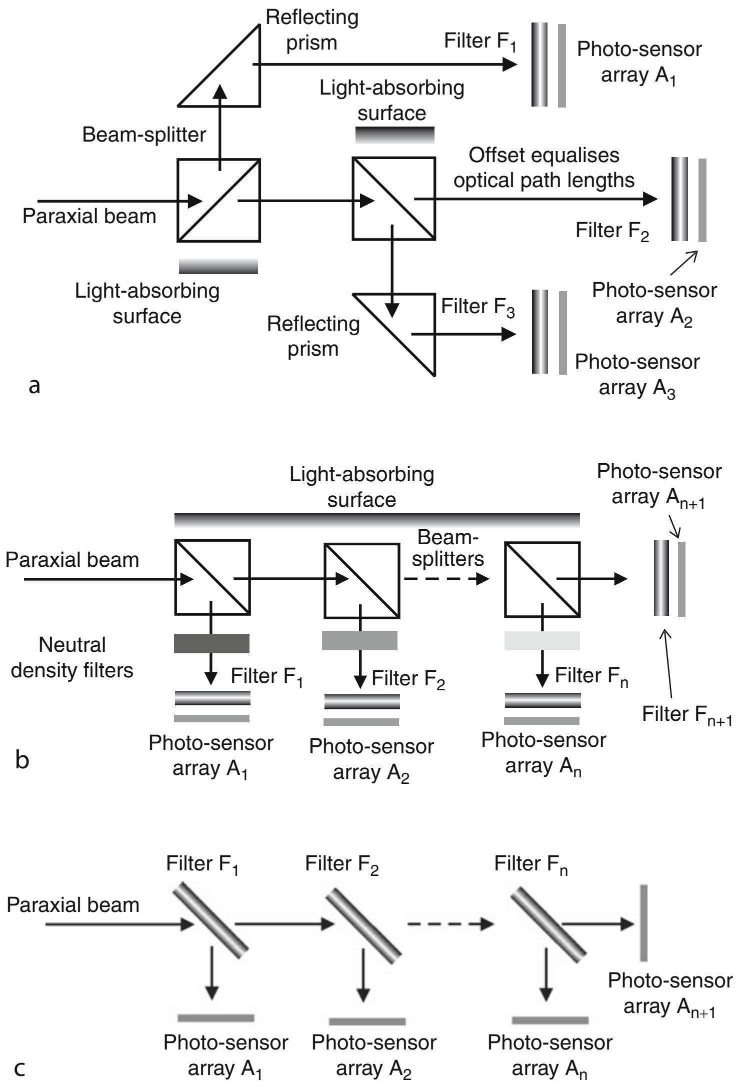


Fig. 40.76

Multi-spectral image sensing. These three diagrams are not drawn to scale; the path lengths should be equal, to ensure that the images will all be in focus and of the same size. (a) Using 50%/50% beam-splitters and filters that absorb, rather than reflect, ''unwanted'' light. The optical arrangement shown here can be extended to provide more than three colour-separation channels. Filter F_2 and sensor array A_2 are deliberately offset to equalise the optical magnification. (b) Alternative arrangement. Since each beam splitter has an (theoretical) insertion loss of 50%, the intensity decreases exponentially as the beam travels from left to right. This limits the overall length of the beam-splitter chain and can be corrected, for short chains, by the neutral density filters. (c) Using dichroic filter-mirrors. The order of the filters along the chain should be chosen to maximise the beam intensity. This does not suffer from the exponential loss of beam power that the previous arrangement does

These arrangements are theoretically capable of operating over a wide spectrum: near-UV, VIS and near-IR wave-band. However, bear in mind that solid-state sensors are most sensitive in the red/near-IR part of the spectrum and that they are much less so in the UV waveband. Also, remember that narrow band-pass filters do not transmit much light. As a result, high illumination intensity is often required. Using the optical arrangement in ➋ *Fig. 40.76b* or *c*, it is possible to examine a narrow spectral band (i.e., colour analysis) of a scene. For example, it is feasible to analyse up to about seven bands within a wave-length range of say 0.1 μm (Conventional colour cameras analyse just three channels over a much broader spectral range.). This is useful for precise measurement of colour variations, in natural products and food-stuffs, where subtle colour changes occur.
LAYOUT DIAGRAMS ➋ *Figure 40.76*

40.81 Method 81: Multi-View Stereo Imaging

OBJECTIVE To provide several views of an object, so that range data can be obtained.
TYPICAL APPLICATIONS Robot vision, automated assembly, automated vehicle guidance.
EQUIPMENT Two camera mounted on a rigid bar. The cameras' optical axes are arranged to converge at the desired working distance.
CAMERA Array.
MOTION Static.
GEOMETRY Preferably containing a number of step-like edges or holes.
REMARKS The analysis of range data from a pair of stereo images is a complex subject and the reader is referred to ➋ Chap. 15 for a more comprehensive discussion. Ideally, the scene being viewed should contain a large number of easily identifiable features that are visible to both cameras. These might be sharp "step" edges, holes, spots or linear features. They may be geometric (i.e., part of the 3D shape of the widget), or surface features (e.g., printed, etched, or punched), If few such features exist, it may be advantageous to project a pattern, such as a grid, an array of parallel lines, or spots onto the widget surface. Even a single point projected onto the widget by a diode laser (➋ *Fig. 40.77c*), can be useful in calibrating and aligning the optical system. Multiple lines or spots can be projected using a laser fitted with a diffraction lens. A projected "random" pattern might also be used. It is important, however, that we choose a projected pattern that allows easy alignment of the images from the various cameras; a truly random pattern might be difficult to analyse one that is more structured. The exact position of the projector is unimportant, as it is the disparity between the images derived from the various cameras that allows us to calculate the range. When we are inspecting a widget, we are normally trying to confirm that it conforms to the specification; For the purposes of *verification*, as distinct from *recognition*, we may use any convenient and easily analysed projected pattern.

LAYOUT DIAGRAMS ➋ *Figure 40.77*

40.82 Method 82: Normal Viewing of Spherical Surface

OBJECTIVE To view part of a spherical surface normally.
TYPICAL APPLICATIONS Inspecting surfaces of ball bearings.

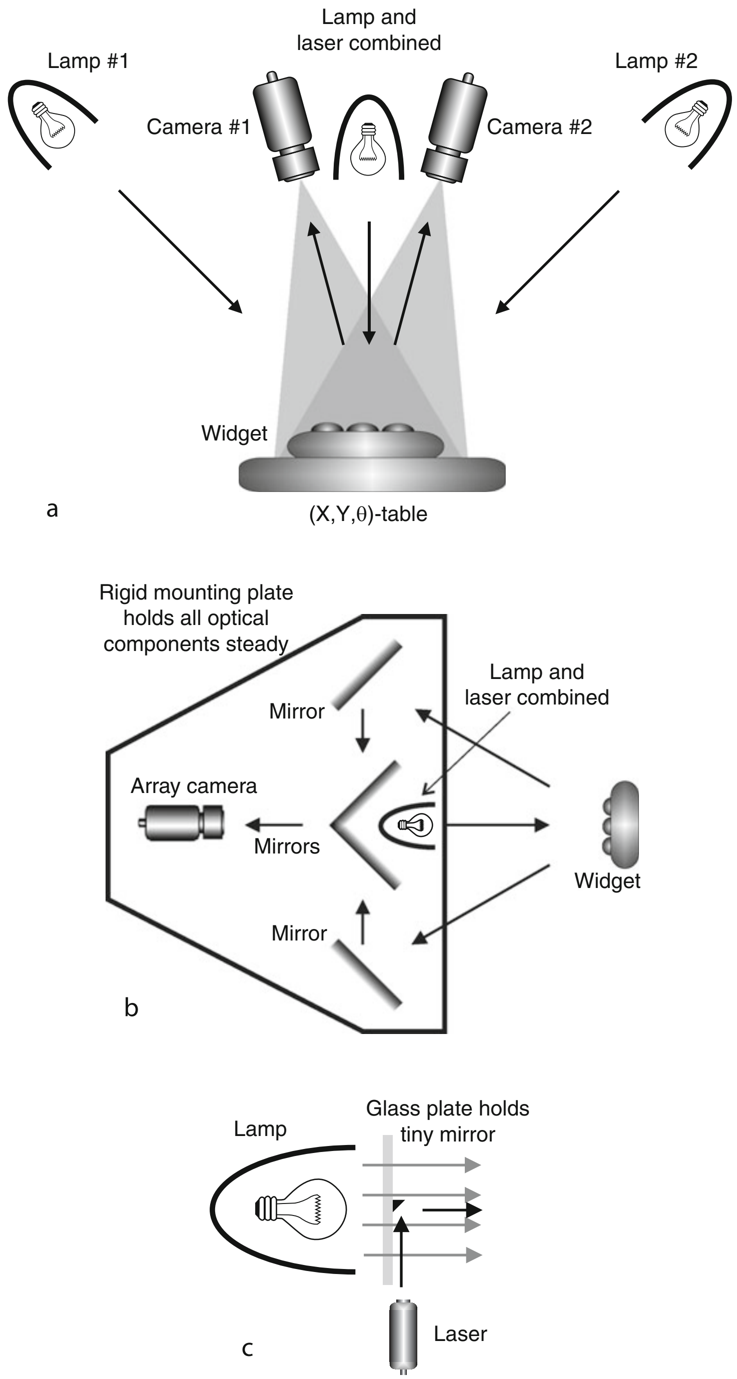

Fig. 40.77
Stereo imaging. (a) Using two cameras. (b) Using a single camera and image splitter. (c) Co-axial illumination by a lamp and laser

OPTICS
(1) Standard lens
(2) Two parabolic mirrors
(3) Elliptical mirror

CAMERA Array.

MOTION Static.

GEOMETRY Spherical.

MATERIALS Brightly polished (glinting).

REMARKS In the arrangements shown in ➲ *Fig. 40.78a* and *b*, the illumination and viewing are both normal to the widget surface. Hence, specular reflection is guaranteed over the whole field of view. Surface imperfections are therefore seen easily, if they alter either the angle or intensity of the reflected beam. Hence, imperfections of the spherical geometry and surface staining are both visible. The arrangement in ➲ *Fig. 40.78c* provides normal viewing but does not enable normal illumination to be achieved. Similar arrangements to these can be devised using cylindrical lenses and mirrors. A line-scan camera could then be used and the object rotated to scan all round the widget. None of these methods allows the whole surface to be viewed at the same time. They work best if the widget is small compared to the focal length of the lens/mirrors.

LAYOUT DIAGRAMS ➲ *Figure 40.78*

40.83 Method 83: Objects on a Conveyor

OBJECTIVE To inspect widgets transported past the camera on a continuously moving conveyor.

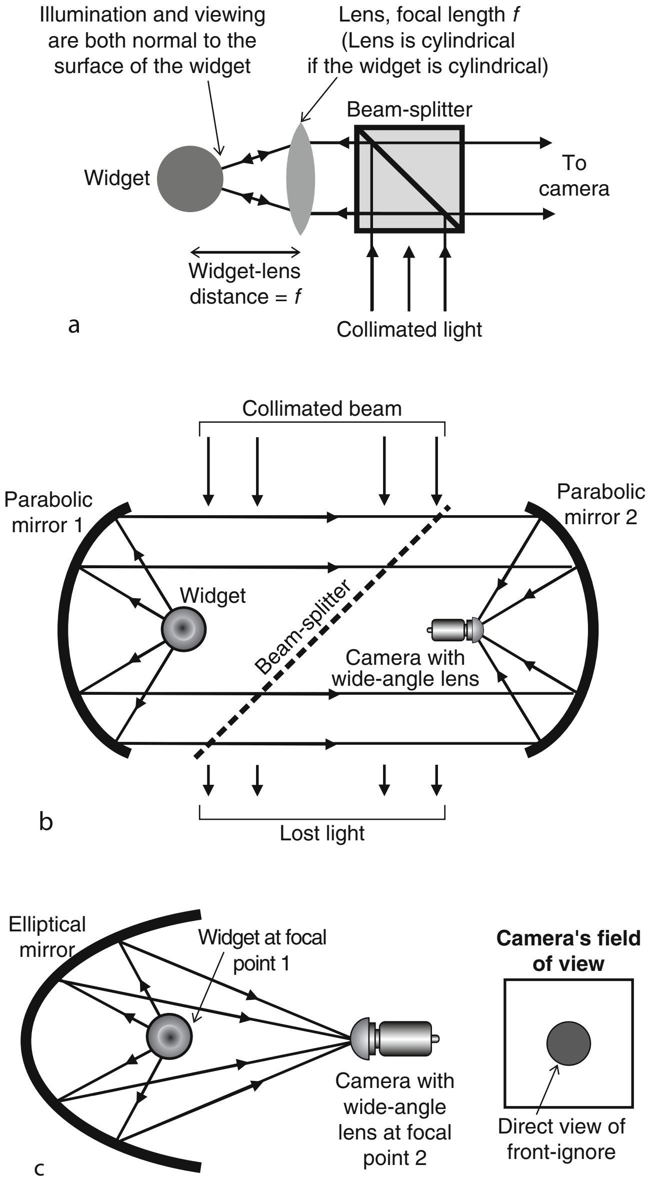
TYPICAL APPLICATIONS Inspecting discrete objects: piece parts and assemblies, one at a time.

EQUIPMENT Conveyor belt. Strobed lighting, or a camera fitted with a fast electronic shutter. Proximity sensor (Used to detect when a widget is in front of the camera). *Accept/reject* device (Used to deflect faulty widgets into a bin). A concurrent processor is ideally suited to this type of inspection application.

CAMERA Progressive scan, array type (Images can be digitised at any moment).

MOTION Continuous or indexed linear motion.

REMARKS The belt speed need not be known precisely. This method is not particularly sensitive to vibration. The camera can be mounted either above or beside the conveyor. Three cameras can used simultaneously, to inspect the top and sides of the widget. Strobed lighting can induce epileptic fits and migraine attacks, even in people who are not knowingly vulnerable. Moreover, moving objects can appear stationary under strobed lighting. Hence, care must be taken to stop bright flashing light, generated by the inspection system, from being visible to people standing nearby. A camera fitted with a fast electronic shutter is intrinsically safer but it requires continuous, high intensity lighting, often creating excessive heat. A LED-photo-transistor proximity sensor can be used to signal the arrival of widgets, as they reach the camera. However, it is important that the light source associated with the proximity sensor (often an IR LED) does not spoil the image (➲ *Fig. 40.78b*). A concurrent processor is ideal for inspecting objects on a conveyor, since it can simultaneously analyse images derived from several widgets, as they travel from the camera towards the *accept/reject* device. Such a system can have a high *throughput rate* (i.e., number of widgets inspected per unit time), even though



Illumination and viewing are both normal to the surface of the widget

Fig. 40.78
Viewing a spherical surface normally. (a) Optical layout using a single lens. In practice, a compound lens would probably be used, to obtain a greater coverage of the surface, by providing a wider viewing angle. (b) Optical layout using two parabolic mirrors. The widget and camera are placed at the focal points of the mirrors. The symmetrical reflectors do not introduce any geometric distortion. Some rays reflected from mirror 1 are blocked by the widget on their way towards mirror 2. Hence, there is a small ''dead'' region in the centre of the image, (c) Optical layout using an elliptical mirror. This arrangement does not preserve the geometry of the widget. Obtaining uniform normal lighting is problematical

Fig. 40.79
Inspecting objects on a continuously moving conveyor. If strobed lighting is used, the region immediately around the camera and lamps must be enclosed within a light-proof screen (not shown). IR light from the proximity sensor can cause reflections. Solutions: Make main lights brighter; use an optical filter to block IR entering the camera; switch off the IR LED during image capture

its *latency* is high (Latency is the time taken for a widget to travel along the conveyor, from the camera to the *accept/reject* mechanism). During the latency period, the conveyor belt effectively “stores” widgets until the *accept/reject* decision has been computed. This method can be slightly modified, to examine web materials that have a strongly defined pattern (e.g., high-contrast printed materials). Image capture is synchronised by a simple non-imaging sensor observing registration features (fiduciary marks) on the edge of the web.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.79*

40.84 Method 84: Observing Bubbles in Clear Liquid

OBJECTIVES To view small air bubbles rising in a clear liquid, such as water, oil, etc.

TYPICAL APPLICATIONS

- Checking for air leaks in pipes, bellows. joints, etc.
- Visual determination of f in carbonated liquids (lemonade, mineral water, beer, champagne), etc.

- Measuring liquid viscosity, by deliberately producing bubbles that rise naturally due to gravity and then measuring their sizes and terminal velocities.

EQUIPMENT Water/oil bath with transparent walls or optical windows.

CAMERA Array or line scan.

MOTION

- Array scan: static
- Line-scan: scanning relies on bubble motion

GEOMETRY Bubbles.

MATERIALS Liquid in the bath should not be cloudy or absorb too much light.

REMARKS ➲ *Figure 40.80* shows several possible lighting-viewing methods including dark-field and back-illumination, for array-scan and line-scan sensors. Clearly, it is necessary to choose the best combination for each application, in order to achieve the greatest possible image contrast. When using a line-scan camera, the bubbles should be allowed to reach terminal velocity before they are examined (This will probably require thermostatic control of the bath temperature to limit viscosity variations). Notice that the technique can be used to measure viscosity. When an array-scan camera is used, it may be necessary to use stroboscopic illumination, to "freeze" bubble motion. It may also be necessary to use multiple strobe flashes within a single video frame, or digitise multiple images, to measure terminal velocity.

Mirror

Fig. 40.80

Observing air bubbles moving in a clear liquid. The top lamps provide flood lighting and are used in conjunction with the mirror at the bottom. The fibre-optic bundle can be arranged to produce very precise projection of the light beam for side or dark-field illumination. The ring light produces front illumination, while the optical background may be bright, dark, or bright with a black patch (for dark-field illumination)

40.85 Method 85: Omni-Directional Illumination

OBJECTIVES

- To provide uniform, all-round (omni-directional) illumination
- To eliminate shadows
- To reduce the effects of glinting
- To see inside deep blind holes

TYPICAL APPLICATIONS

- Viewing complex parts and assemblies, fibrous surfaces, etc. without casting shadows.
- Viewing bright reflecting surfaces without glinting.

EQUIPMENT Circular illumination source: circular fluorescent tube (driven by a high-frequency supply to avoid strobing), fibre-optic ring light, circular array of small bulbs, or LEDs. Hemispherical diffuser, painted matt white or stippled inside, with small viewing aperture at the centre. A cylindrical baffle prevents direct illumination of the widget.

CAMERA Array.

MOTION Static.

GEOMETRY Complicated shapes. Deep holes.

MATERIALS Brightly polished metal, shiny plastic, porous, fibrous.

REMARKS The omni-directional light source is similar to the "light tent" that has been used by photographers for many years when recording images from shiny objects, such as polished silver hollow-ware. Since there are no shadows, step-like features produce very little contrast. It is possible to see inside quite deep holes that would appear dark with standard (oblique) illumination. The effects of specular reflection are slight. (Glinting occurs but does not cause problems, because the hemispherical diffusing surface is of nearly uniform brightness.) Changes in the reflectance and colour of an object with a diffusing surface are clearly visible. The cloudy day illuminator is a proprietry omni-directional source with an adjustable secondary light source and beam-splitter, which compensate for the dark viewing orifice.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.81*

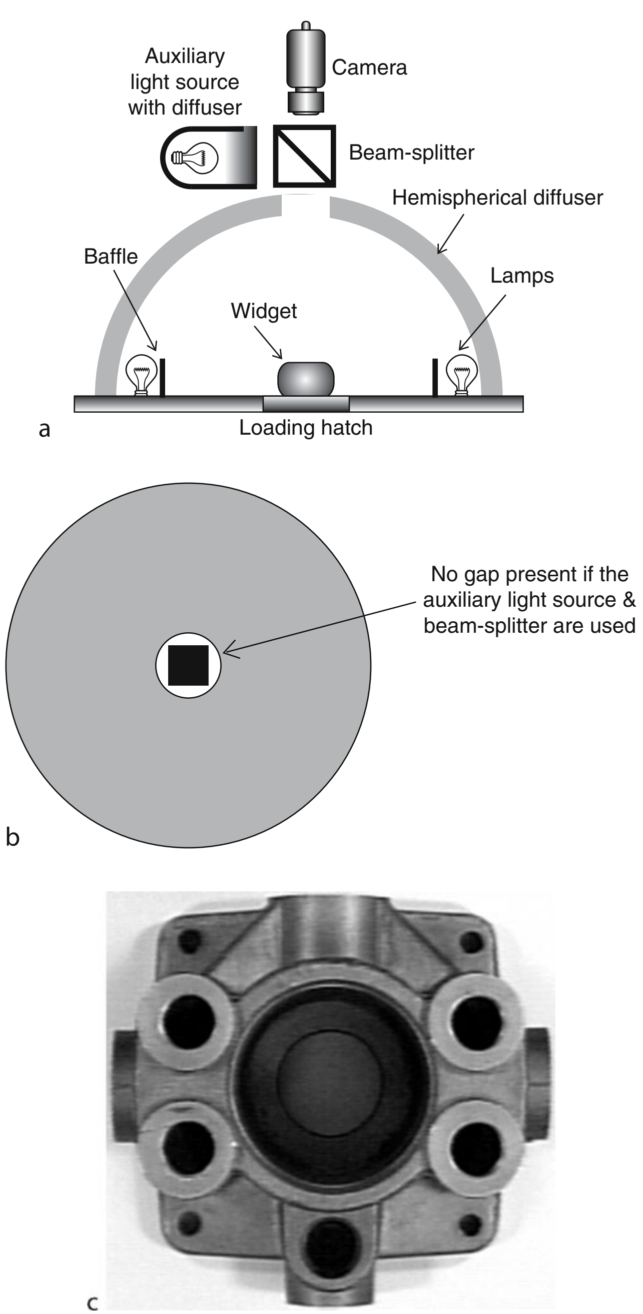
40.86 Method 86: Optically Tooled Bowl Feeder

OBJECTIVE To examine objects as they leave a vibratory bowl feeder, determining their orientation and performing a simple, non-dimensional, check on shape.

TYPICAL APPLICATIONS Parts recognition, determining orientation of parts prior to assembly, handling small components with flexible parts (e.g., brushes used in small electric motors/generators. Since these consist of a graphite block with a copper wire "tail," they are difficult to handle).

EQUIPMENT Vibratory bowl feeder. Illumination can be provided in one of several ways:

(a) Fibre optic device,
(b) Linear LED array or



◘ Fig. 40.81
Omni-directional lighting. (a) Optical set-up of the cloudy day illuminator (cross-section) The omni-directional light source was originally described without the auxiliary light source and beam-splitter. (b) Illumination diagram. (c) Sample image: light-grey aluminium casting, about 120 × 120 mm^2. Step-like features (82 mm) do not cast significant shadows and hence are barely visible. The large circular well is 78 mm deep and its diameter is 56 mm

(c) Laser fitted with a cylindrical lens, generating a fan-shaped beam,

(d) Using a collimator and slit aperture, as shown below. Image acquisition, achieved using a fibre optic ribbon or conduit, allows the camera to be located out of harm's way.

CAMERA Line scan.

LENS None needed – uses fibre optic image conduit instead.

MOTION Motion is provided as parts leave the bowl feeder. Movement is obtained using bowl feeder, slide-way (outside bowl), or using a special pusher.

GEOMETRY Only simple non-interlocking shapes can be separated by a bowl feeder.

MATERIALS Hard metal and plastic parts that are smooth and non-sticky and will not be damaged by the action of the bowl feeder.

REMARKS Vibratory bowl feeders are used to feed small machine parts. As the widgets arrive at the top of the bowl, they reach a slide-way and slip downwards, accelerated by gravity, past the sensing head illustrated in ➋ *Fig. 40.80*. A bowl feeder is not always able to separate widgets in different poses (e.g., travelling "head first" or "tail first") Simple guide rails can achieve some success but they are prone to jamming and are not able to separate widgets in different postures if the differences are subtle. This is precisely the type of situation in which the optically tooled bowl feeder is useful. It may be necessary to use active handling methods (e.g., a pick-and-place robot) to normalise the posture. Alternatively, widgets that are travelling "tail first" might simply be returned to the bowl feeder for recycling. In this case, only widgets travelling "head first" are machined or assembled. Since the speed of travel along the slide-way is uncertain it is not possible to use this method for precise dimensional measurement of widget length (i.e., measured along the slide-way). However, this optical arrangement is also useful for inspecting objects on a conveyor belt, in which case the speed may be known quite precisely.

LAYOUT DIAGRAM ➋ *Figure 40.82*

40.87 Method 87: Passive De-speckling of Laser

OBJECTIVES To remove, or reduce, the speckle seen in an image when using a laser as a source of high-purity monochromatic illumination.

TYPICAL APPLICATIONS Any application in which laser light is useful for illumination but where image averaging, or active de-speckling, is undesirable.

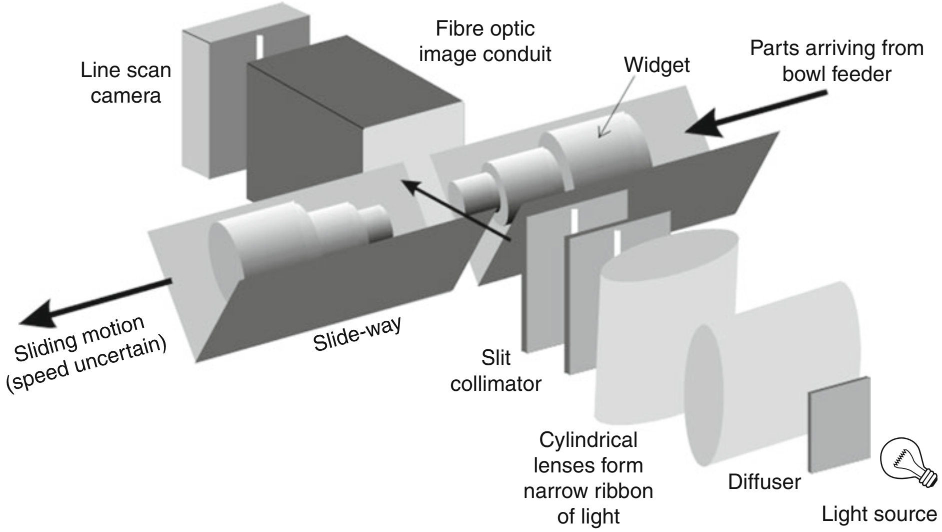
EQUIPMENT One of the following:

- Integrating sphere
- Hollow sphere cut from a suitable diffusing material
- Metal/plastic sphere coated internally with a diffusing paint
- Table-tennis ball painted externally with a matt white paint to improve diffusion (This is a cheap alternative that may suffice for non demanding applications and initial testing purposes)

CAMERA Any.

LENS Any.

REMARKS Light enters the sphere via a small hole and undergoes multiple reflections before leaving through the exit port. The latter should be located at 90° to the input port. These reflections greatly reduce the spatial coherence of the beam and hence diminishes the interference



Line scan camera
Fibre optic image conduit
Widget
Parts arriving from bowl feeder
Sliding motion (speed uncertain)
Slide-way
Slit collimator
Cylindrical lenses form narrow ribbon of light
Diffuser
Light source

Fig. 40.82
Inspecting small objects on a slide-way leading from a bowl feeder. Lighting is provided by a single lamp and diffuser. Two cylindrical (rod) lenses and several narrow slits aligned with each other form a collimated "ribbon" of light aligned vertically and traversing the slide-way. A short length of image conduit receives the light and feeds it directly onto the camera array; there is no imaging lens. This keeps the camera away from danger and provides a small robust imaging system

effects that produce speckle. This method works well with sources that have a short coherence length, such as diode lasers. It works less well with long-coherence length devices such as gas lasers. The efficiency of an integrating sphere is low; it is proportional to the ratio of the area of the output port to that of the sphere. On the other hand, a small aperture ensures effective de-speckling. Thus, for a given port size the sphere should be as small as possible. As this ratio increases, however, the de-speckling effect decreases. Alternative methods for de-speckling rely on physical movement of a diffuser or beam deflector. Deliberate high-frequency variation of the laser drive current can be used to reduce speckle further, by causing mode hopping. Artefacts due to laser speckle can also be attenuated by averaging several video frames (The widget must, of course, be stationary and the laser light level constant throughout image acquisition).

LAYOUT DIAGRAM ➜ *Figure 40.83*

40.88 Method 88: Pipe or Hollow Cone of Light

OBJECTIVES To provide a "thick-walled" pipe or cone of light.

TYPICAL APPLICATIONS Inspecting deep circular holes, objects with circular symmetry: rims of bottles, jars, other containers.

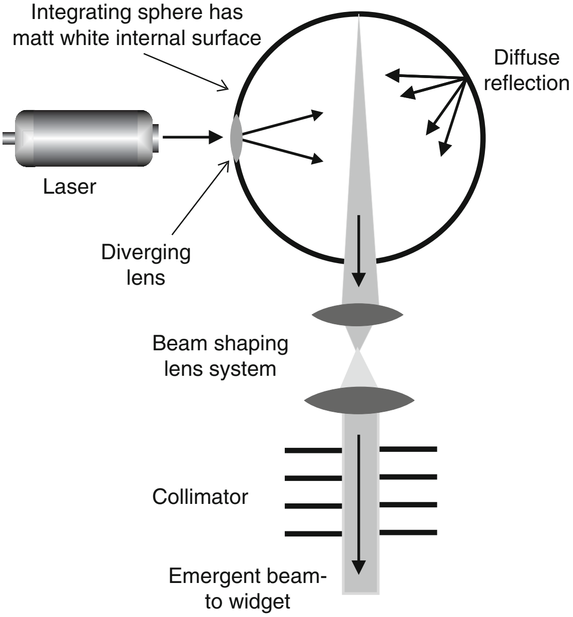

Fig. 40.83
Passive de-speckling of laser radiation

EQUIPMENT

- For a pipe of light: Two “axicons” (An axicon is a conical lens, i.e., a shallow cone of transparent material. It has one plane and one curved surface)
- For a hollow cone of light: One axicon and one lens

CAMERA Array or circular scan.

MOTION Static.

GEOMETRY Object with spherical, circular or radial symmetry.

REMARKS The optical arrangement in *Fig. 40.84a* generates a “pipe” of light. If it is set up properly, this produces a hollow “pipe” of light, with parallel sides. The arrangement in *Fig. 40.84b* produces a hollow “cone” of light. In front of the “focal point,” the cone is converging. It diverges thereafter. When projected onto a plane surface, these two methods generate a bright annulus, with a dark centre. Using one or two axicons makes more efficient use of the available light than merely applying a circular mask to a collimated beam.

LAYOUT DIAGRAM *Figure 40.84*

40.89 Method 89: Polar-Coordinate Scan of Annulus

OBJECTIVE To provide a high-resolution view of an annular target. The central disc is ignored and a polar-coordinate map of the intensities within the annulus is created.

TYPICAL APPLICATIONS Inspecting ring-shaped objects, such as

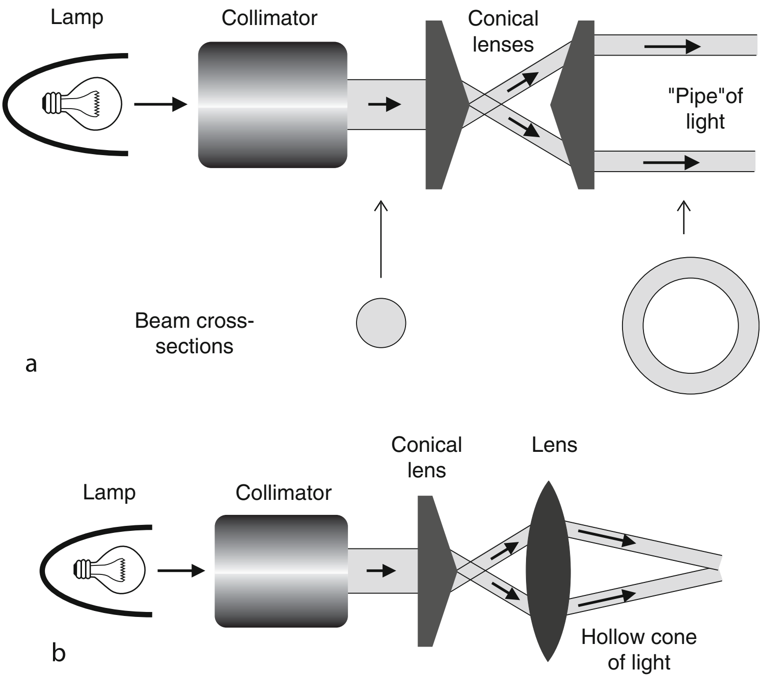

Fig. 40.84

Pipe and cone of light. (a) Two axicons generating a pipe of light. (b) One axicon and a lens produce a hollow cone of light

- Rims of bottles/jars and their lids
- O-rings
- Wheels
- Rims of holes and cylindrical objects

EQUIPMENT Dove prism, plus a simple assembly consisting of two mirrors mounted rigidly together. The latter is rotated at twice the speed of the Dove prism in the opposite direction (A 3-mirror assembly can perform the same function as a Dove prism and does not introduce spherical and chromatic aberrations *Fig. 40.85b*).

CAMERA Line scan.

LENS Telecentric lens (The 3-mirror assembly does not introduce aberrations to the same extent as the Dove prism and does not require a telecentric lens).

MOTION The widget and camera are both stationary. The prism and two-mirror assembly are rotated mechanically.

REMARKS The opto-mechanical scanner illustrated in *Fig. 40.85a* effectively performs a polar-to-Cartesian coordinate mapping of the widget surface; rotation of the two-mirror assembly scans an annulus, while the Dove Prism maintains constant image orientation. An added benefit of using a telecentric lens is that the distance between the mirrors can be adjusted without changing the magnification or focus. This allows a simple variable-radius scanner to be built. While the Dove prism is mechanically stable and easy to mount on a rotating shaft, it

LAYOUT DIAGRAM ➋ *Figure 40.85*

40.90 Method 90: Projected Array of Spots

OBJECTIVE To obtain qualitative, low-precision information about the geometry of an object surface.

TYPICAL APPLICATIONS

- 3-dimensional shape analysis of machine parts, plastic mouldings, die castings, food products (e.g., loaves, cakes, meat pies, etc.)
- Metal and plastic extrusions

EQUIPMENT Industrial (i.e., ruggedised) slide projector. This projects light through a transparency having a regular or irregular, 1- or 2-dimensional array of spots.
CAMERA Array-scan or line-scan.
MOTION Static (for array-scan camera) or linear motion (line-scan camera).
GEOMETRY Arbitrary but known.
MATERIALS Matt, non reflective (Small local areas which are brightly reflecting can be tolerated).
REMARKS When this method was originally developed, a slide containing a regular array of bright spots of light was projected onto the widget (➲ *Fig. 40.86*). This creates a regular array of spots on a plane, although on general, non-planar surfaces, it produces a non-periodic array. The resulting digital image may be difficult to analyse, particularly if there are steep-sided cliff-like features present. The can cause some spots to be become "lost" due to occlusion. This may be acceptable, if the ideal form of the widget is fixed and is known with some precision. In this case, the inspection procedure consists of simply checking that there is a spot present in each position where a spot has been encountered before and that there are no spots visible elsewhere. However, when it is possible to anticipate the shape of the widget, it is usually preferable to arrange the spots so that the camera sees a regular pattern of bright points on the surface of a well-formed widget (➲ *Fig. 40.86b*). The resulting image is easier to analyse. A 1-dimensional version of this optical arrangement, based on a line-scan camera, can be used to good effect, when inspecting extrusions.

LAYOUT DIAGRAMS ➲ *Figure 40.86*

40.91 Method 91: Protecting the Camera Using a Periscope

OBJECTIVE To fold the optical path, so that the camera can be situated in a convenient, safe position, well away from the widget.
TYPICAL APPLICATIONS

- Monitoring operations such as casting, grinding, cutting, welding, etc. that create a lot of flying debris
- Inspecting very hot, steaming, or spluttering widgets
- Inspecting objects within an explosive, toxic or radioactive atmosphere, where people cannot work safely
- Placing the camera in a convenient position, where it is easy to service or adjust
- Inspecting objects that are immersed in water, oil, etc. (➲ *Fig. 40.87b*)

EQUIPMENT Plane mirrors, preferably front silvered. Notice that 45°/45°/90° prisms may be used in lieu of mirrors.
CAMERA Array or line-scan.
MOTION Static (array-scan camera) or linear motion (line-scan camera).

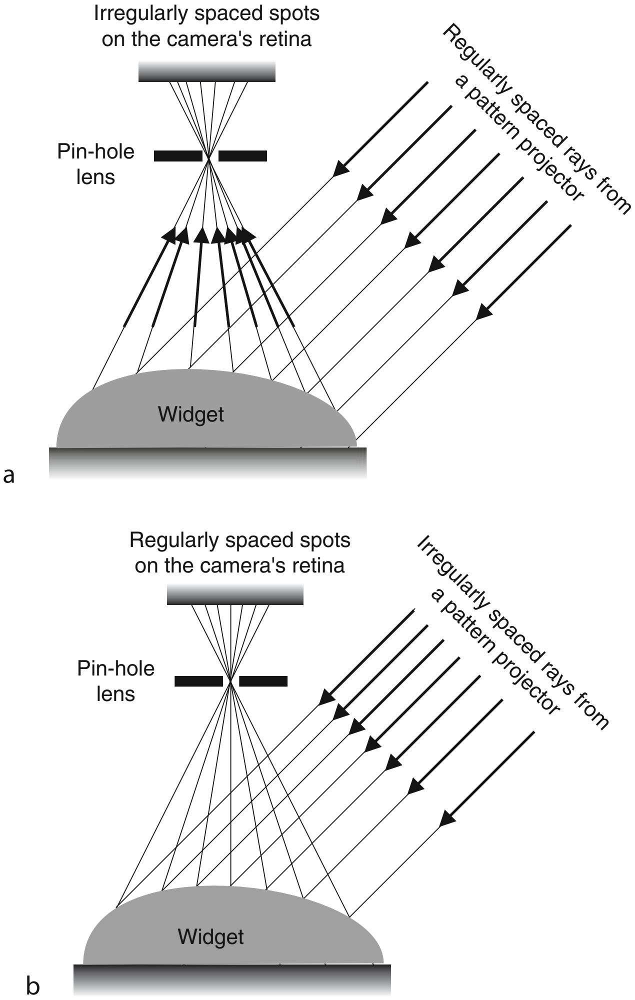

Fig. 40.86

Projecting an array of spots. (a) A regular array produces a non-periodic pattern of bright points on the camera's retina. A pin-hole lens is shown here for simplicity of illustration. In practice, a normal glass or plastic lens would be used. (b) If the form of the surface is known, an irregular array of projected spots can be used to create a periodic pattern of bright points on the object surface. The idea implicit in these two diagrams can be extended into 2-dimensions

REMARKS The periscope is a versatile device. By adding extra mirrors, it can be used to examine objects that are displaced both vertically and horizontally. It can allow viewing within a confined space, where access for servicing/adjusting the camera would be impossible.

Periscope. (a) Optical arrangement. (b) Examining an object within a plating bath. The lighting arrangement shown here avoids immersion and is suitable for bulky high-voltage lamps. This is just one of many possibilities; LEDs and fibre optics, located within the periscope, could be used instead

40.92 Method 92: Protecting the Camera with Fibre Optics

OBJECTIVE To remove a camera from a dangerous environment, by transmitting the image along a coherent fibre optic image bundle directly onto the camera. The fibre optic bundle may be flexible, or rigid bundle (called *image conduit*), or in the form of a flexible ribbon.

TYPICAL APPLICATIONS Inspecting objects in a hazardous environment, which may be very hot, very cold, corrosive, explosive, toxic, biologically contaminated, radioactive, or in an intense x-ray, UV or microwave beam, or be at a high electrical potential.
EQUIPMENT Fibre optic ribbon, flexible fibre optic bundle, or image conduit.
CAMERA Line-scan, or array-scan.
MOTION Static, or continuous linear/rotary movement.
REMARKS Optical fibre ribbon can be purchased, or made in the laboratory, using the following process. Wind a neat coil of optical fibre onto a large drum. Secure the fibre to the drum at two points, by placing two lengths of adhesive tape along the coil and close together. Cut the coil between these points. The ribbon can then be removed from the drum. The ends are then encapsulated in epoxy resin, machined flat and polished. A flexible fibre-optic bundle can be used with an array camera. If flexibility is not important, image conduit may be used instead (This is a rigid rod-like assembly of optical fibres that preserves image integrity. It can be bent to shape after heating in a gas flame.). Specialised fibre-optic devices are available commercially and perform a variety of useful functions, including quarter-twist, 90° bend, change of image size (magnification/minification), change of aspect ratio. The sensor array may be interfaced directly to the fibre bundle, as in ➲ *Fig. 40.88*, or an intermediate lens may be added. Care must be taken to avoid creating Moiré effects, by matching the pitch of the fibre matrix to that of the camera array.

LAYOUT DIAGRAMS ➲ *Figure 40.88*

40.93 Method 93: Protecting the Camera

OBJECTIVE To protect the camera and lens from damage due to

- Hot/cold air
- Condensation
- Infra-red radiation
- Fine airborne pollution (dust, mist, fumes, smoke, aerosols, paint, coating and cleaning chemicals, etc.)
- Flying particulate debris (saw-dust, swarf, grinding sparks, etc.)
- Flying droplets (water, oil, coolant, adhesive, paint, etc.)
- Scheduled cleaning (particularly in food and pharmaceutical factories)
- Tampering, theft, sabotage
- Impact (both accidental and deliberate)
- Blast from explosive processes
- X-rays and nuclear radiation

TYPICAL APPLICATIONS

- Inspecting hot steel slabs and sheet, loaves and cakes in the baking oven, etc.
- Controlling/monitoring the cutting of timber and metal, injection moulding

- Measuring aerosol spray cone
- Controlling painting, spraying, etc.
- Remote visual control in areas providing radiation, toxic or biological hazards

EQUIPMENT *General* Rugged box with a tough optical-quality window at the front end and providing a broad range of environmental protection measures. Internal surfaces of the enclosure should be matt black. Not all of the features shown in ➲ *Fig. 40.89a* are needed in every application.

Radiation Lead box. Radiation resistant optics are needed.

CAMERA

- Array- or line-scan camera
- Tube camera and valve electronics may be needed in very radio-active areas, as solid-state devices are quickly damages

REMARKS Heat dissipation by the camera electronics should be considered when designing an enclosure, to avoid overheating. Similar environmental protection techniques are appropriate for protecting small illumination sources (e.g., LEDs) Notice too that the product must also be protected from the camera and lights, to ensure parts (e.g., glass lenses, screws, etc.) do not fall off and contaminate critical products (e.g., food/pharmaceuticals). In very radio-active areas, a tube camera may be required, since solid-state electronics is susceptible to radiation damage. Special types of glass and insulation may be needed.

LAYOUT DIAGRAM ➲ *Figure 40.89*

40.94 Method 94: Range Measurement Using Talbot Fringes

OBJECTIVE To measure 3D surface shape by projecting Talbot fringes onto the widget surface.

TYPICAL APPLICATIONS Inspecting small objects which have a simple geometry.

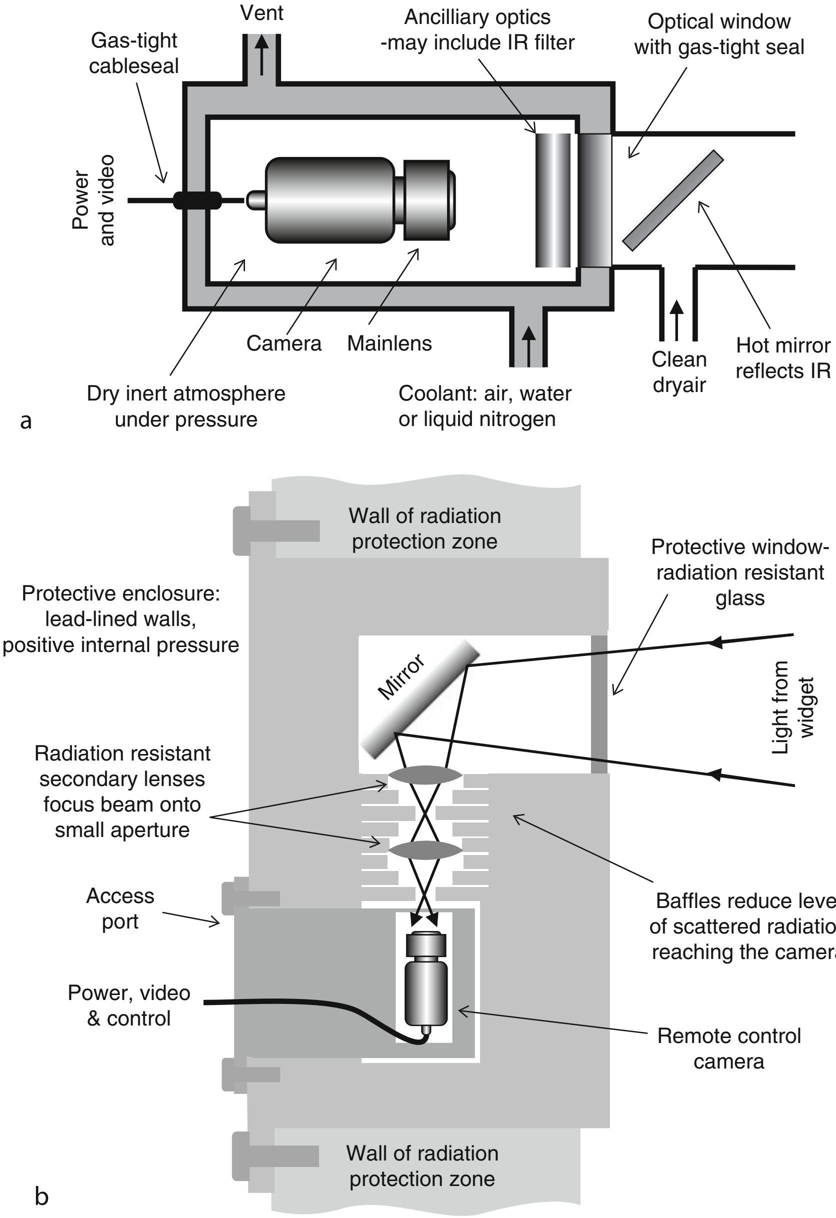
EQUIPMENT Laser, optical grating.

CAMERA Array.

MOTION Static.

MATERIALS The widget must have uniform reflectivity. To achieve this, it may be necessary to coat it. The developer spray used for dye-penetrant crack detection is ideal, as it can be applied as an aerosol spray. Talc ($Mg_3Si_4O_{10}(OH)_2$) or ammonium chloride (NH_4Cl) may be used for this purpose.

REMARKS When a coherent beam of light is transmitted through a coarse grating, a series of sharply focussed images of the grating (*Talbot images*) is generated at regular intervals along the optical axis. This effect was first reported in 1836 by Henry Fox Talbot but was then forgotten until it was rediscovered by Lord Rayleigh in 1881. The spacing between these images, the so-called *Talbot period*, is given by A2/λ, where A is the slit spacing of the grating and λ is the wavelength of the light. This is based on the assumption that A >> λ. For red light with a wavelength of 632.8 nm (the wavelength of light produced by a HeNe laser) and a grating with 50 slits per inch (a = 0.508 mm) the Talbot period is 407.8 mm. See ➲ *Fig. 40.90*. For accurate range measurement, the object should be uniformly reflective over its whole surface. The range is measured by estimating the local contrast in the digital image captured from the camera. Large objects in which the variation in height exceeds the Talbot period cannot be measured directly, since adjacent fringes become confused.



▪ Fig. 40.89

(a) Combination of techniques for protecting the camera and lens. Even if no air purge is used, a long thin tube around/in front of the lens provides an effective dust trap (However, this may affect both camera placement and cause vignetting). (b) Protecting the camera from nuclear radiation and x-rays

40.95 Method 95: Reading Printing in Photo-Chromic Ink

OBJECTIVE To obtain an image of text or a data code (e.g., bar code, or dot matrix code) printed with photo-chromic (PC) ink.

TYPICAL APPLICATIONS There are numerous potential applications in security and document/product authentification.

EQUIPMENT

- Ultra-violet flash lamp (to switch the colour of the PC ink)
- Visible (VIS) flash lamp (to switch the ink back to its original colour)
- Low intensity visible lamp (for viewing)

CAMERA Colour array scan.

MOTION Static.

MATERIALS Avoid red/pink surfaces for red-transparent PC ink.

REMARKS Photo-chromic ink changes colour when it is irradiated. Typical changes are as follows:

- Ultra-violet – colour changes to pink-red
- Visible light (VIS) – colour changes to transparent

Other colour combinations are possible. In its transparent state, PC ink is difficult, but not impossible, to see by eye. Switching between colour states is very fast and can easily be accomplished during the inter-line scan interval of a video signal. (Rapid colour switching occurs as a result of a change in the *geometry* of an organic ring-shaped molecule; there is no chemical change. The reader should not confuse the PC ink being described here with the more familiar photo-chromic spectacles, in which the colour change is much slower. Moreover, PC ink has two stable colour states, unlike PC spectacles, which have one stable state and one quasi-stable state.) To isolate photo-chromic ink from normal ink, we might use the following procedure:

(a) Flash the UV lamp. Digitise an image (Call this *I1*.)
(b) Flash the high-intensity VIS lamp. Digitise an image (Call this *I2*.)
(c) Subtract images *I1* and *I2*
(d) Threshold the difference image

This is effective in highlighting the PC ink and obscuring the normal ink. PC ink can be applied using a variety of printing methods, including ink-jet printers. It can therefore be applied under program control. When programmable PC printing is combined with high-level encryption and optical character recognition (OCR) software, it is possible to provide a message, or product, with a high degree of security. The PC ink effectively authenticates the document, while its message is protected by the encryption process. People must be protected during colour switching, by the use of appropriate shielding. (Ultra-violet light can damage eyes and skin, while a high intensity VIS flash can induce epileptic fits and migraine episodes.)

REMARKS The technique works best if the widget is held so that its flat surface is horizontal and in a fixed vertical position. Commercially available low-angle ring lights are sometimes described as "dark field lights."
LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.93*

40.98 Method 98: Rotate Image Using a Dove Prism

OBJECTIVE To rotate an image by a fixed amount, to make subsequent image analysis easier.
TYPICAL APPLICATIONS Looking for lines of known orientation. Analysing texture, where the pattern has a known form, with dominant features at fixed angles. If θ is the orientation of the prism, this method will emphasise linear features at angles 2.θ and 90° + 2θ.
EQUIPMENT Dove prism. A conventional 45°/45°/90° prism will suffice but this is larger and heavier than a Dove prism.
CAMERA Array or line-scan camera, as appropriate for the application.
LENS Standard lens fitted to camera. It may be necessary to fit an extra lens in front of the prism.
MOTION Static or moving, as appropriate for the application.
REMARKS Optical image rotation is usually preferred to software, for the following reasons:

- The optical system does not degrade the image significantly, whereas rotating a digital image produces ragged edges, due to quantisation effects
- Optical systems have a far higher resolution
- There is no increase in the computational load. This makes the optical system faster than one based on software

- The optical system has minimal running costs
- The rotation can be altered by simply turning the prism by hand. This allows easy real-time interaction during the initial alignment and calibration of the system

Notice that the image is rotated by an angle 2.θ where θ is the orientation of the Dove prism. The advent of miniature cameras makes this method less important than hitherto.

A variable angle of rotation can be achieved, using a motorised Dove prism. Hence, polar-coordinate raster scanning can be implemented, by rotating the Dove prism continuously and using a line-scan camera ➋ *Fig. 40.94c*. This is particularly useful for viewing objects that possess several concentric circular features, are radially symmetric or have a "wheel-spoke" appearance. A fused fibre optic bundle (image conduit) can also rotate an image. Image conduit is made with various standard rotations: ±90° and 180°. Other values can be made on request. The conduit can be bent into an L- S-, or U-shape and is a very robust means of transmitting an image. It is also able to function in a smoky or fume-laden atmosphere. The image rotation can be performed by a 3-mirror arrangement, sometimes called an Abbe K-mirror.

LAYOUT DIAGRAM ➋ *Figure 40.94*

40.99 Method 99: Silhouette from Multiple Shadows

OBJECTIVE To obtain a high-contrast silhouette of an object by combining several views, obtained using lighting from different directions.

TYPICAL APPLICATIONS This method can be useful for inspection applications, where there is limited rear access and there is little or no contrast between the widget and its background.

EQUIPMENT Computer controlled lights.

CAMERA Array.

MOTION Static over several video frames. Vibration cannot be tolerated.

MATERIALS Virtually any opaque material.

REMARKS This method is suitable for use in those situations where back-lighting is impossible and there is little, or no contrast, between the widget and its back-ground. If oblique lighting is used from a single point source, the widget casts a shadow that is offset to one side. This increases the contrast around just part of the edge. However, that part of the edge nearer the light source still has low contrast. If the light source is now moved around the widget, a different part of the silhouette will be well defined. In practice, it may be necessary to provide illumination from several different directions (at least four) in turn. For each lighting direction, a digital image is captured. These images are then combined using a simple image processing algorithm: Let *a(i,j,k)* be the intensity at the point *[i,j]* in image *k*. Then, we generate an image *{b(i,j)}* by computing

$$b(i,j) = MIN(a(i,j,1), a(i,j,2), a(i,j,3), \ldots)$$

for all *[i,j]*. In this way, it is often possible to create a continuous high-contrast edge in the combined image, *{b(i,j)}*, that no single view could achieve. Notice that the inclined lighting causes errors in estimating the position of the outer edge of the widget (➋ *Fig. 40.95b*). Their

extent depends upon the 3D shape of the widget near the edge. For example, chamfers could cause an under-estimate of the size of the widget. For this reason, it may be necessary to place the lamps close to the camera, to ensure that the lighting is nearly normal.
LAYOUT DIAGRAM ➜ *Figure 40.95*

40.100 Method 100: Silhouette in Restricted Space

OBJECTIVES To view an opaque, object in silhouette, in situations where there is limited rear access.
TYPICAL APPLICATIONS In-process inspection of objects as they are being machined.

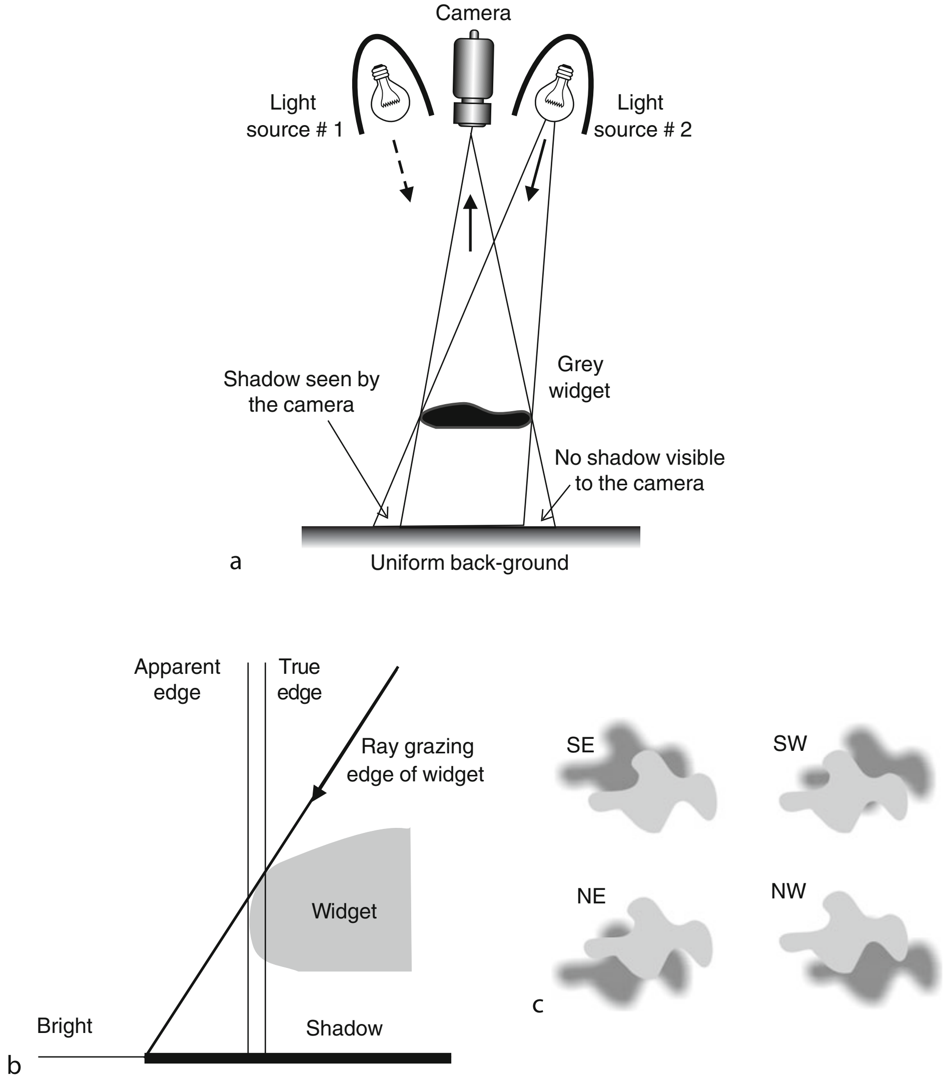

Fig. 40.95
Obtaining a silhouette of an opaque widget by creating multiple shadows, in sequence. (a) Optical layout. Only one lamp is lit at any given moment. (b) Inclined lighting causes errors in estimating the position of the outer edge of the widget. (c) Individual shadows increase the contrast around only part of the outer edge. These images are combined by simple image processing to produce a high-contrast edge all round the widget

EQUIPMENT Diffusing filter, beam-splitter, retro-reflective film.
CAMERA Array- or line-scan.
MOTION Static or linear/circular motion.
MATERIALS Matt, non-shiny.

REMARKS In normal room lighting, a retro-reflector appears to be light grey in colour. However, when a source of light is placed very close to the line between the eye and the retro-reflector, it shines brilliantly: far brighter than a sheet of white paper. Hence, in this optical arrangement, the retro-reflector provides a bright background for the widget. To obtain an accurate silhouette of the widget, the primary illumination should be from a diffuse source; an accurately collimated beam may miss the camera entirely after it has been reflected. If the widget is close to the retro-reflector during dirty operations, such as milling, spraying, etc. there is a danger that it will quickly become dirty, thereby reducing its effectiveness. In this case, the retro-reflector should be protected behind a clear glass screen that can easily be wiped clean. (Retro-reflective film cannot be cleaned so easily, without damaging its surface.) Retro-reflective material can be purchased from automobile spares retailers. Flat panel units with LED or cold cathode illumination are alternatives.

LAYOUT DIAGRAM ➋ *Figure 40.96*

40.101 Method 101: Size Measurement in Free Fall

OBJECTIVE To measure size and shape parameters of a small object, such a drop of fluid, in free fall.

TYPICAL APPLICATIONS

(a) Measuring and counting wall/oil drops emerging from a nozzle

(b) Calibrating fluid control valves

(c) Checking/measuring the flow of cutting fluid during the machining of metal components

EQUIPMENT

- Optical proximity sensor, to indicate when the object is in front of the camera
- Strobed light box, with a dark patch at its centre, to provide dark-field illumination

CAMERA Asynchronous (progressive scan) camera, capable of digitising an image immediately, the trigger signal is received from the proximity sensor.

MOTION Free fall.

MATERIALS Opaque or transparent solid. Clear or opaque fluid.

REMARKS The secondary (LED) light source, within the proximity sensor, must not be allowed to reduce image contrast, by illuminating the drop of oil/water during image capture. Hence, it may be necessary to place an IR-blocking filter immediately in front of the camera lens. Alternatively the LED may be switched off during image acquisition, just before the back-light strobe is triggered. Strobing is needed, because the drops are travelling quite fast: a small drop of oil/water that has previously been in free fall, through a distance of 100 mm, is travelling at about 1.5 ms^{-1} and hence travels about 60 mm during a CCIR video frame-period. Compare this with the movement during the strobe flash (typically, 0.01–0.1 ms). During this time interval, the drop falls by about 0.015–0.15 mm. This motion effectively limits the vertical resolution that can be achieved by this method. If possible, the drop should have reached its terminal velocity before it arrives within the camera's field of view. This ensures that the drop is in standard, known position, thereby allowing the maximum possible spatial resolution to be achieved.

LAYOUT DIAGRAM ➋ *Figure 40.97*

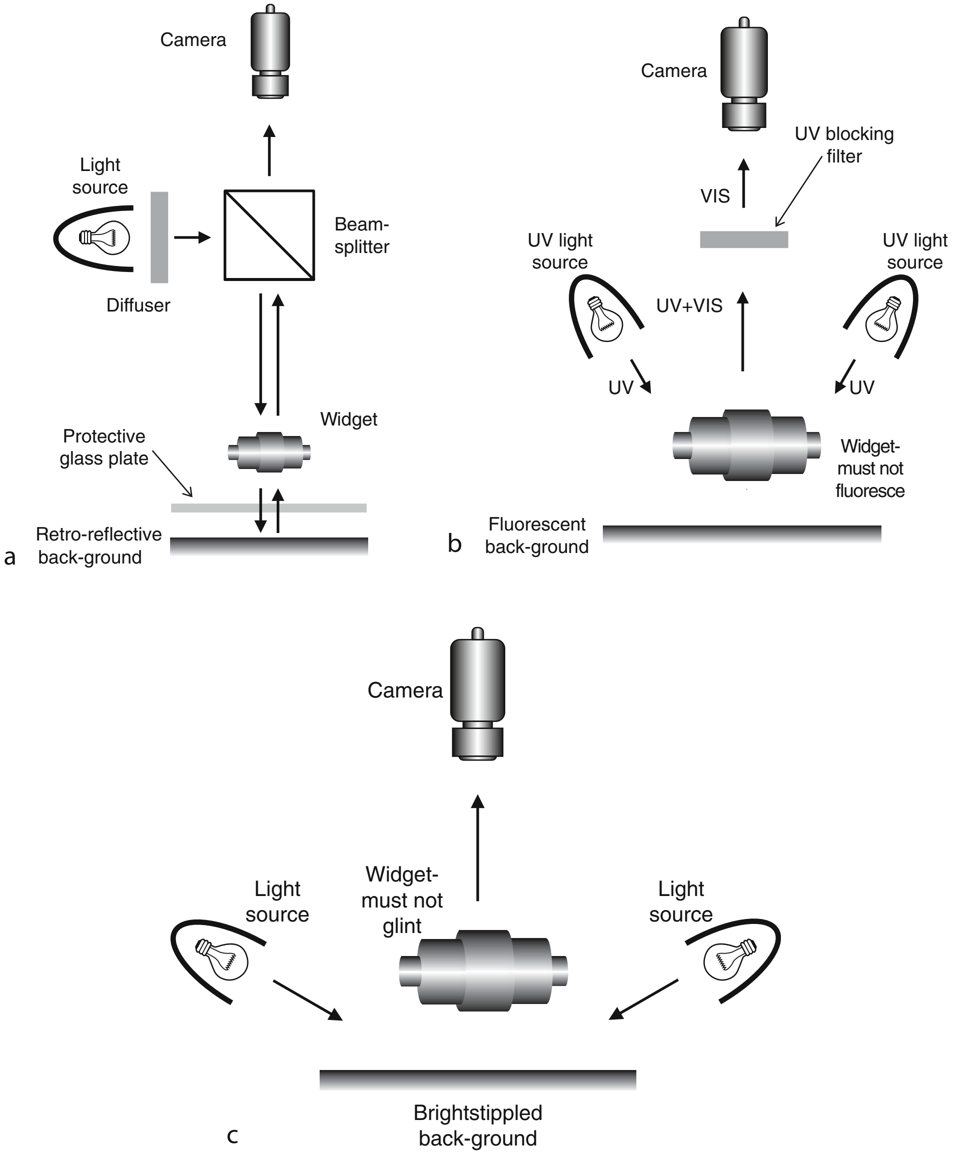

Fig. 40.96
(Continued)

40.102 Method 102: Split Field Lighting and Viewing

OBJECTIVES To obtain two or more views of an object, using a single camera. For example we may view the front and back of an simultaneously, or the ends of a long-thin object.
TYPICAL APPLICATIONS

- Inspecting complex objects

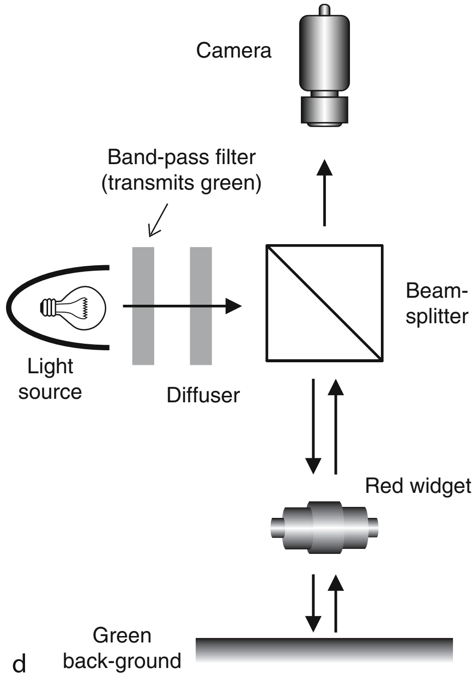

Fig. 40.96
Inspecting an object silhouette in a restricted space (a) Retro-reflective back-ground. (b) Fluoresent back-groud. (c) Stippled glinting back-ground with low-angle illumination. (d) Coloured illumination and background

- Inspecting long thin objects
- Robot vision (viewing front and back of an object before picking it up)

EQUIPMENT

- Front-silvered (first-surface) plane mirrors. (Prisms could be used instead.)
- Colour filters
- Beam splitter

CAMERA Array.

MOTION Static.

REMARKS Mirrors provide a low-cost method of splitting the camera's field of view. Using the optical arrangement in *Fig. 40.98*, the field of view is split into two. However, illumination can be difficult, since a lighting arrangement that optimises image quality for one half-field may reduce the contrast in the other. Two possible illumination methods are shown *Fig. 40.98*, while omni-directional lighting offers another option. Since video cameras are cheap nowadays, it may be preferable to use two separate cameras instead of the split-field method illustrated shown here. The video images can be combined electronically, or in software.

40.103 Method 103: Stabilised Lighting

OBJECTIVE To provide high-stability lighting that remains nearly constant despite changes in lamp efficiency. Changes in brightness may occur as a result of ageing, power-line voltage fluctuations, and tarnishing/contamination of optical surfaces.

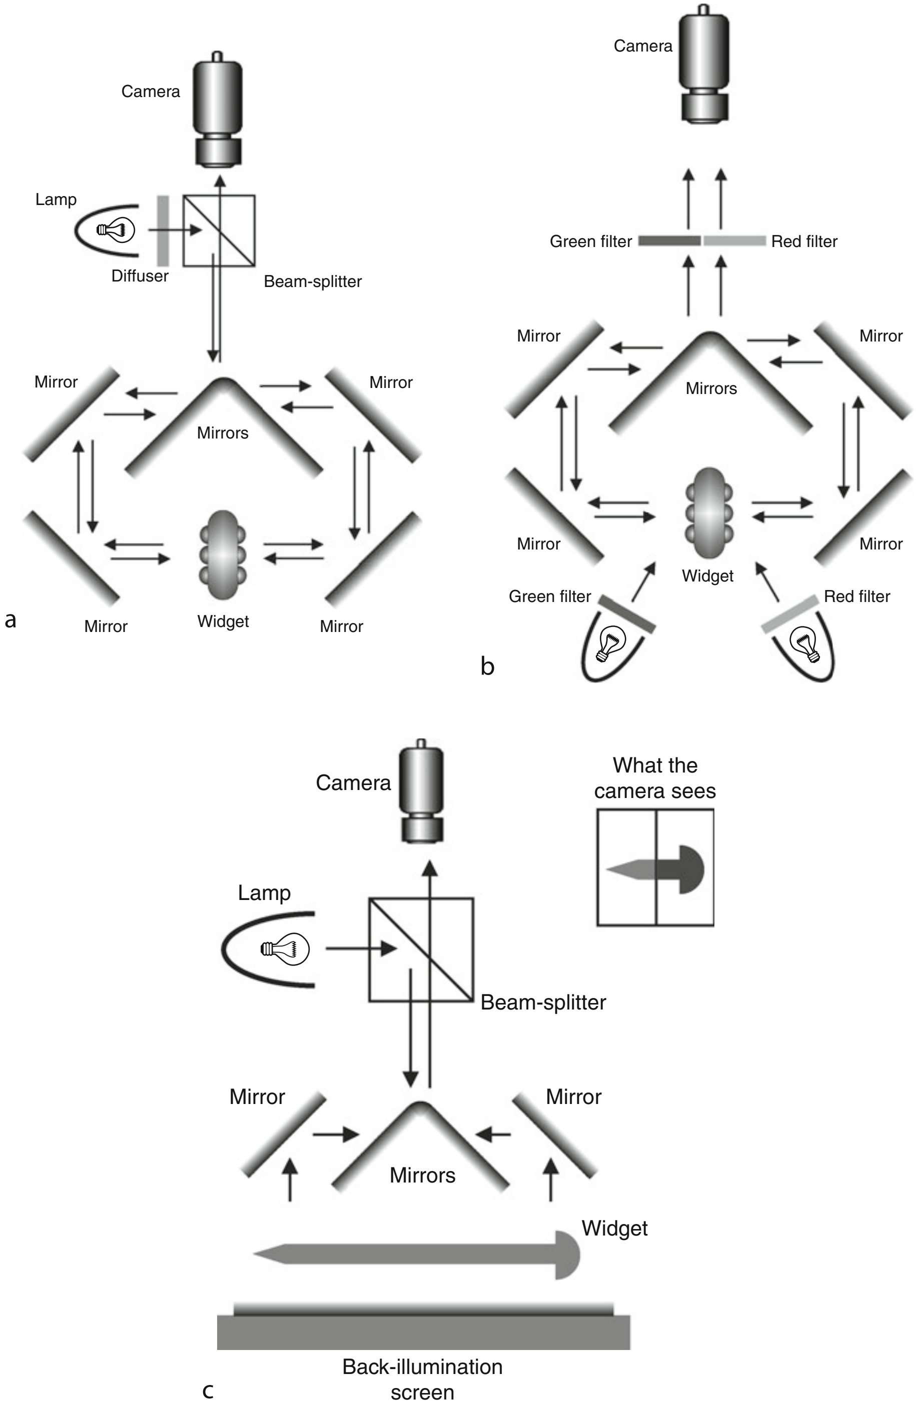
TYPICAL APPLICATIONS

- Nearly all applications benefit from the use of well-controlled lighting, since it is possible then to make the best possible use of the camera's limited dynamic range
- High-resolution print and web inspection, where simple thresholding is used at the beginning of the processing cycle, to reduce the image to binary form and thereby achieve the highest possible throughput rate
- Measuring the sizes of opaque objects using simple thresholding and pixel counting. (This is a standard arrangement for simple, low-cost vision systems.)

EQUIPMENT This depends upon which of the methods described below is used.

- Photo-sensor, capable of measuring light levels accurately
- Feedback control amplifier
- Voltage controlled power amplifier
- Filament lamps, or LED array

REMARKS Many proprietary lighting modules now incorporate some form of feed-back control. Normally, the output light level is measured just before the luminaire aperture. (Method A in *Fig. 40.99*) However, this does not directly control the light level received by the camera, which is the critical parameter. Hence, it is usually better to monitor the light levels



◘ Fig. 40.98
(Continued)

falling on the widget or its back-ground. Several methods for controlling the light level are possible:

1. Sensor is placed close to the light source, possibly within the luminaire, and measures the light output from the lamps
2. Sensor is placed close to the background and measures light scattered by it
3. A sensor is embedded within the back-ground and measures light received directly from the lamps
4. Sensor observes the back-ground from afar and measures light scattered by it
5. Feed-back signal is derived from the optical image received by the camera, which may be viewing either of the following:
   (a) A standard calibration pattern, occasionally placed in the camera's field of view
   (b) A calibration pattern permanently attached to the back-ground. This might, for example, be a simple "chess-board" target

These all have different merits. The final choice about which method is best for a given application depends upon the level of contamination (dust and fumes) that exists around the inspection area, the precision expected of the inspection process and the availability of staff to perform regular calibration checks. 5(b) is closest to the ideal calibration method, since it is available continuously and monitors what is most important: the light reaching the camera. Standard incandescent lamps change colour when the filament temperature varies. LED brightness can be varied using pulse-width modulation but this requires careful synchronisation with the camera, to avoid producing hum bars. Discharge and fluorescent lamps are rather difficult to control.

LAYOUT DIAGRAM ➋ *Figure 40.99*

40.104 Method 104: Steerable Image Sensor

OBJECTIVES

- To perform rapid pan-and-tilt sampling of a large/complex scene
- To observe a moving widget without introducing significant motion blur
- To view a static widget using a stationary line-scan sensor

TYPICAL APPLICATIONS

- Situations where a single expensive camera (e.g., low-light, IR or UV sensor) must be used for more than one function
- Surveillance, using a single static camera to monitor activity within a large scene
- Tracking individual widgets as they are transported along a conveyor line
- Motion analysis

Fig. 40.98

Viewing the front and back of an object at the same time. (a) Coaxial illumination and viewing. The right-hand side of the optical system provides back-illumination for the widget as it appears in the left half-field and front-illumination for the right-hand field. This method is only effective if the reflectivity of the widget is high. (b) Colour filters stop this back-illumination effect. This method is not effective for vividly coloured objects; the widget should have neutral shading (i.e., grey). (c) Viewing the ends of a long thin object

Fig. 40.99
Methods for monitoring and adjusting lamp brightness

- Eliminating motion blur
- Monitoring the motion of a robotic vehicle
- Monitoring a long thin scene (e.g., checking a walk-way for debris)
- Warehousing: checking rows of items on shelves

EQUIPMENT One or two small first-surface mirrors mounted on galvanometers.

CAMERA Array or line-scan, depending on the application.

MOTION Static or continuous linear motion, depending on the application.

REMARKS A galvanometer mechanism, fitted with a small first-surface mirror, provides a convenient facility for “random access” viewing of large and/or complex scenes. By effectively panning the camera at the same speed as a moving object, it is also possible to “freeze” its movement, thereby eliminating motion blur without resorting to stroboscopic illumination. For example, in one project, an IR camera was used to inspect red-hot glass-ware on a continuous-motion conveyor. Without the scanning mirror, the images would have been severely blurred. Two types of galvanometer are available. One kind allows the mirror to be *positioned* precisely. (➋ *Fig. 40.100a*) On the other hand, by using a resonant galvanometer, the mirror *motion* can be predicted accurately. (➋ *Fig. 40.100b*) While a modern light-weight camera could be mounted on a scanning mechanism, its connecting lead would be flexed continuously, making operation unreliable. A wire-less power and video link would, of course, circumvent this problem but would increase the load on the galvanometer and reduce its resonant frequency.

LAYOUT DIAGRAMS ➋ *Figure 40.100*

40.105 Method 105: Steering a Laser Beam in Two Directions

OBJECTIVES To establish the 3D structure of a complex scene, using a software-controlled, 2-axis flying-spot scanner.
TYPICAL APPLICATIONS Active stereo for robot vision, or automated vehicle guidance.
EQUIPMENT Laser, plus two galvanometer movements mounted with small mirrors. The latter are driven, via digital-to-analogue converters, from the image processing computer. The laser can also be switched on/off under software control. Standard lighting is also used.
CAMERA One or two array-scan cameras. If high-speed operation is required, two line-scan cameras may be used to locate the laser spot.
MOTION Static.
REMARKS The laser-deflection system is explained in ➜ *Fig. 40.101a* and is intended to be used in a triangulation arrangement, such as that shown in ➜ *Fig. 40.101b*. The laser beam can be steered independently along the x- and y-axes. We could, for example, scan the scene, creating a coarse raster scan, jumping about at random, or following a contour derived from the visual image(s). Since only one range measurement can be obtained during a video field period, this method is far too slow for generating a full-resolution depth map. This remark applies specifically to a system based on array-scan cameras. Specialist analogue, spot-position sensors are available and can greatly increase the speed. However, this does require a more complicated optical set-up. Another fast arrangement for spot location is shown in ➜ *Fig. 40.101c* and uses two line-scan sensors. If a separate range-measurement sensor is used, we must ensure that the camera(s) and spot locator are properly aligned. The rangefinder is typically used to interrogate the visual scene at a relatively small number of points chosen by analysing the image. First, we first switch the laser off and the main lights on. This allows us to obtain a standard visual image (or two, if two cameras are used), which is then processed and a few key points identified. (These might, for example, be points where the

magnitude of the intensity gradient is high.) We then switch the main lights off and the laser on. We then measure the range at these key points, to distinguish between foreground and background surfaces. To do this, we might apply an edge-detection operator to the visual image, to identify a contour of high intensity gradient. We can then use the range finder to establish whether this contour corresponds to a physical edge; we could, for example, distinguish between the leg of a table and its shadow on the wall behind it.

LAYOUT DIAGRAM ➋ *Figure 40.101*

40.106 Method 106: Stroboscopic Illumination

OBJECTIVE To "freeze" fast continuous motion, using a very short flash of light.

TYPICAL APPLICATIONS Inspecting continuously moving

- Machinery (The motion may be linear or rotary.)
- Discrete parts on a conveyor, slide-way or in free-fall
- Webs (e.g., printing, fabric, sheet materials), extrusions, wire, cable, tubing, ribbon, etc.

EQUIPMENT Strobed light source, synchronised to the camera. A discharge tube or LED array may be used. The strobe does not have to flash for every video frame but it must be triggered at a fixed point in the video cycle. Screening is particularly important to avoid stray light from reaching people nearby. Fibre optics is useful for directing light from a large/remote source onto the surface, whilst eliminating stray light.

CAMERA Array-scan. A progressive scan camera is useful, as it can be triggered by the strobe or an external signal.

MOTION Fast continuous linear, or rotary motion.

REMARKS Stroboscopic lighting is potentially dangerous as it can trigger migraine and epileptic fits. It can also make rotating machinery appear to be stationary. It is therefore imperative that all stray light be eliminated. Stroboscopic lighting, with viewing by eye, has

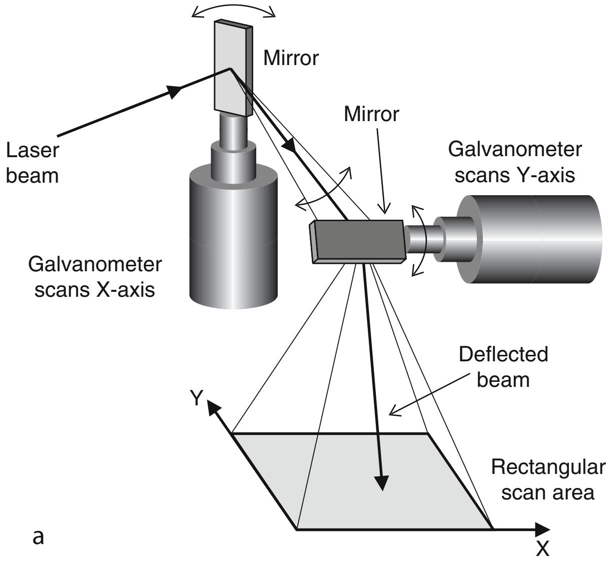

Fig. 40.101
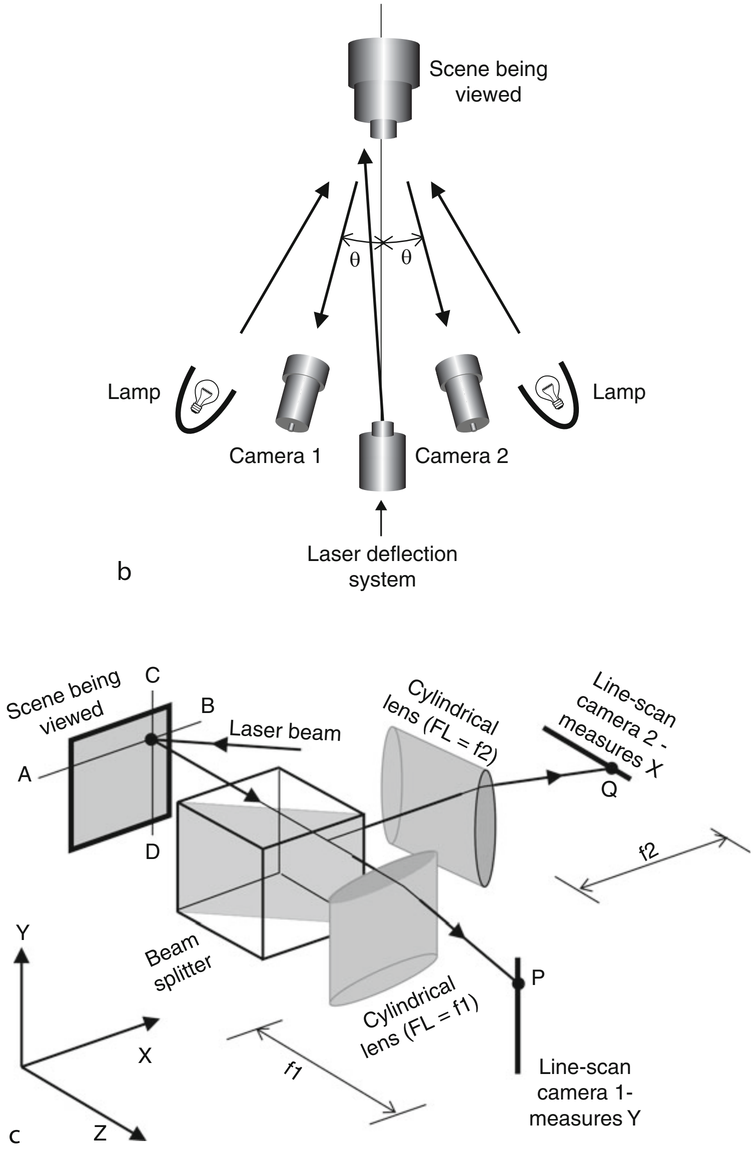
(Continued)



◘ Fig. 40.101

Twin-axis laser flying-spot scanner. (a) Beam-steering sub-system. The galvanometers are from a computer. (b) 2-camera triangulation scheme. Using two cameras reduces the effects of occlusion due to parallax and enables stereo image pairs to be correlated. (c) Using two line-scan cameras to locate a laser spot. All points along the line AB are focussed onto a single point, P, on camera 1. Similarly, all points along the line CD are focussed onto a single point, Q, on camera 2. The main lights are assumed to be off, or at least, very much darker than the laser spot

long been used for inspecting rotating machinery and continuously moving webs that have repeated patterns (e.g., printing). By providing image storage, it is also possible to examine non-periodic, transient events, provided that there is some signal to herald the event of interest. The use of stroboscopic illumination for Machine Vision requires careful consideration of timing; the camera, strobe unit and image processor must all be synchronised to external (factory) machines. The following analysis relates to a non-interlaced array-scan camera synchronised to the strobe.

Web speed:	S metres/second
Video frame rate:	F frames/second
Strobe rate:	F/N pulses/second, where $N \in [1,2,3,\ldots]$
Strobe intensity:	I photons/second *(unusual units to simplify calc.)*
Flash duration:	T seconds (Ensure that $T < < 1/F$)
Surface reflectance:	R $(0 \leq R \leq 1)$
Web movement during scan:	S/F metres
Web movement during flash:	S.T metres
Integration time:	Q/F seconds, where $0 \leq Q < 1$. (Acknowledges that the integration time is less than the clock period. Normally, $Q/F. >> T$).
Light energy at camera:	$R.I.T$ photons/frame. *(Must be large compared to swamp noise but avoid saturating the camera.)*
Minimum pixel size:	S.T metres (along the direction of travel)
Smallest detectable spot:	2.S.T metres
Maximum image resolution:	1/(F.T) pixels (along the direction of travel)

The light source(s) may be placed anywhere, as most effective. For example, we may use paraxial, back, dark-field or grazing illumination. Multiple light sources must be synchronised to each other. A proximity sensor (e.g., LED-phototransistor) may be useful for detecting the arrival of a widget in front of the camera. Webs may be made with special features (e.g., fiducial marks, punched holes) on the edge, to trigger the strobe.

40.107 Method 107: Structured Lighting (Triangulation)

OBJECTIVE To obtain 3-dimensional shape information, generating a *depth map* (also called a *range map*).

TYPICAL APPLICATIONS Measuring machine parts, plastic mouldings, die castings, extrusions, food products (e.g., cakes and loaves), piles of granular material, etc.

EQUIPMENT Laser fitted with cylindrical, or holographic, lens to generate a fan-shaped beam. Linear or rotational transport mechanism.

CAMERA Array.

LENS Analysis given below applies to a narrow-angle of view. Wide-angle lens requires separate calibration procedure.

MOTION Linear or rotary, slow continuous, or indexed.

GEOMETRY Moderate complexity. Occlusion occurs with complex shapes.

MATERIALS Opaque, matt, non-reflective, neither glinting nor very dark.

REMARKS Three methods are described below.

1. **Inferior system** The notation is explained in *Fig. 40.102a*
   (a) The height of the widget surface above the reference plane, at the point where the laser beam impinges upon it, is H
   (b) The camera is placed at height L above the reference plane
   (c) The camera photo-detector spacing is d
   (d) The bright spot projected onto the photo-detector array is off-set by N rows
   (e) The lens has a minification (inverse of magnification) equal to M at a working distance equal to L
   (f) The central axis of the laser beam is inclined at an angle A relative to the vertical. (Usually A is about 45°.)

Generating a range map by triangulation, using structured lighting (a) Inferior method. (b) Superior method. (c) Sample images: Grey toroidal alloy component, scanned on a turn-table. Diameter 200 mm. *Top-left:* Oblique view in natural illumination, with light stripe superimposed *Top-right:* Depth map; intensity is proportional to surface height. Edges have a sinusoidal form because the component was not centred on the turn-table. Black regions indicate areas of occlusion. *Bottom-left:* Cartesian-to-polar co-ordinate transformation. *Bottom-right:* After noise reduction. Centre of the image (black cross, corresponds to the centre of the turntable) and centroid of the hole in the middle (white cross) (d) Using two cameras to reduce the effects of occlusion. (e) Using orthogonal cameras to reduce the effects of occlusion. This set-up and that shown in (d) can be combined to reduce occlusion still further. (f) Illumination pattern for (e). While red-green illumination is shown here for illustrative purposes, other pairs of easily-distinguished wavelengths might be used, if the widget does not scatter both red and green light

The height of the widget surface at the point of illumination (H) is given by

$$H = L.N.d.M/[L.\tan(A) + N.d.M)]$$

If L.tan(A) >> N.d.M, then

$$H \approx N.d.M.\cot(A).$$

Notice however, that the object surface is illuminated at a point located a distance H.tan(A) from the camera axis. Although we have located a point on the object surface, the data is difficult to use. We cannot, for example, easily construct a range map. If we ignore the off-set along the horizontal axis, objects in the depth map appear to lean over. The layout diagram shown in *Fig. 40.102a* is often shown in books and papers on Machine Vision, even though this technique is usually not so useful as that described next.

2. **Superior system** This time, the camera's optical axis is inclined at an angle A relative to the vertical. (Usually about 45°. See ➜ *Fig. 40.102b*.) Then:

$$H = N.L.d.M/[L.\sin(A) + N.d.M.\cos^2(A)]$$

   H is a ratio of two linear functions of N, which is the parameter measured experimentally. All other terms in this equation are constant. If L >> [N.D.M], H reduces to a linear function of N:

$$H \approx N.d.M.\mathrm{cosec}(A).$$

   This assumes that the lens does not have a wide-angle view. Since the laser beam is vertical, the illuminated point on the widget is always in the same horizontal position, whatever the value of H. This is not the case for the inferior method described above, which has been commonly shown in books and papers on Machine Vision.
3. **Using two cameras to avoid occlusion** (➜ *Fig. 40.102d*) This is essentially the same as that just described, except that two cameras are used, instead of one. This allows a greater part of the object surface to be mapped, as it is less susceptible to occlusion. To merge the images from the two cameras, we use the following algorithm. Let L(i,j) denote the (i,j)th pixel in the image from the left-hand camera and R(i,j) be the (i,j)th pixel in the image from the right-hand camera. Then M(i,j), the (i,j)th pixel in the merged output image, is given by

$$M(i,j) = \begin{cases} L(i,j), \text{if } R(i,j) = 0 \text{ (occluded from right camera) and } L(i,j) > 0 \\ R(i,j), \text{if } L(i,j) = 0 \text{ (occluded from left camera) and } R(i,j) > 0 \\ [L(i,j) + R(i,j)]/2, \text{if } L(i,j) > 0 \text{ and } R(i,j) > 0 \\ 0, \text{ otherwise.} \end{cases}$$

LAYOUT DIAGRAMS AND SAMPLE IMAGES ➜ *Figure 40.102*

40.108 Method 108: Switched-Colour Light Source

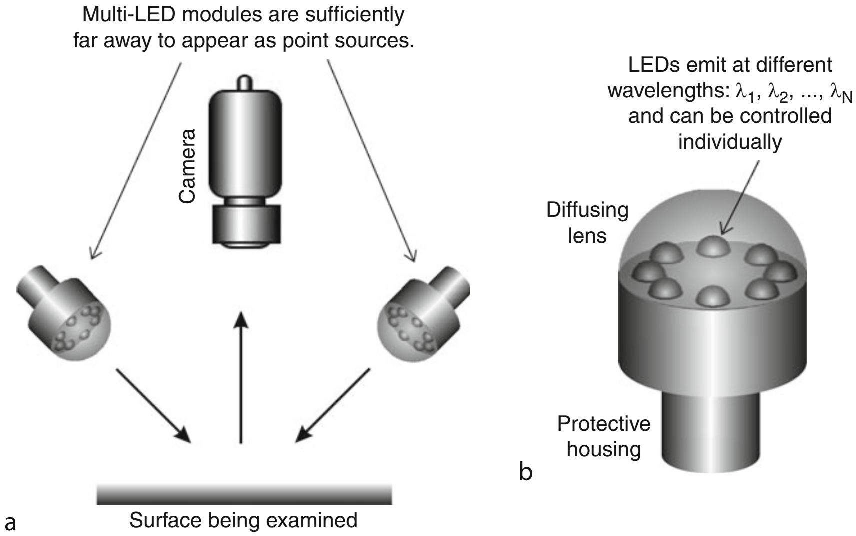
OBJECTIVE To obtain images from a number of different spectral bands in the near-UV, VIS and near-IR.

TYPICAL APPLICATIONS

- Inspecting printing, labels, packaging, etc.
- Inspecting woven textiles and printed fabrics
- Reading resistor colour codes
- Inspecting holograms

EQUIPMENT Switched LED modules (➜ *Fig. 40.103b*). Monochrome camera whose spectral response has previously been calibrated.

REMARKS Obtaining multi-spectral data is made much easier through the use of switched LED sources. Several images are digitised in quick succession, using closely-spaced LEDs, operating at different wave-lengths. 3-colour LED modules are available commercially. These usually contain red, green and blue LEDs, although other combinations are also available. It is possible to span the entire VIS spectrum (0.4–0.7 μm) with LEDs whose wave-lengths vary in increments of 0.01 μm. The emission spectrum from an individual LED is narrow,



Multi-LED modules are sufficiently far away to appear as point sources.
Camera
Surface being examined
a
LEDs emit at different wavelengths: $\lambda_1, \lambda_2, ..., \lambda_N$ and can be controlled individually

approximately monochromatic. Hence, we can examine a narrow spectral band in detail (e.g., up to ten samples within a wave-length range of 0.1 µm), or obtain multiple samples (up to about 30), spaced uniformly across the VIS spectrum. (Recall that conventional colour cameras analyse only three channels over the range 0.4–0.7 µm.) This provides a low-cost, versatile and relatively precise method for analysing colours of small objects, including natural products, food-stuffs and food-products, where subtle colour changes occur.
DIAGRAMS ➲ *Figure 40.103*

40.109 Method 109: Telecentric Lens

OBJECTIVE To view objects as if they were at an infinite distance from the camera, thereby eliminating parallax distortion.
TYPICAL APPLICATIONS Metrology. A number of other lighting-viewing methods rely on the use of telecentric lenses.
EQUIPMENT Telecentric imaging system, consisting of a large lens (possibly Fresnel type, if a large objective element is required) and a smaller standard lens. Pinhole aperture.
REMARKS The magnification of a telecentric imaging system is determined by the ratio of the focal lengths of the individual elements: f_2/f_1. The optimal image quality is obtained with a very small pin-hole aperture, although this introduces a high optical loss. In this case, the widget must be brightly illuminated. Notice that the objective element must be at least as large as the widget. Telecentric lenses of diameter up to 475 mm are available commercially. To obtain an even larger field of view (up to 2 m diameter), plastic Fresnel lenses may be used. (It may be

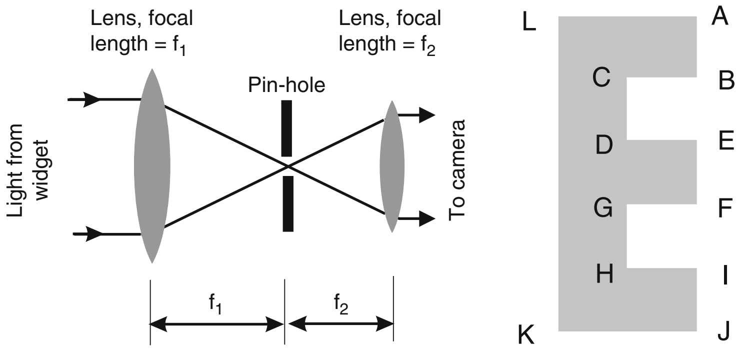

Fig. 40.104
Telecentric imaging. (a) Optical layout. The system has a magnification of f_2/f_1. A large aperture increases the image brightness but allows rays that are not truly parallel to the optical axis to pass through, resulting in a system producing images of degraded quality. (b) If an opaque object with this geometry were viewed from the right using a standard lens. K, L, D and G would be obscured. If the widget were transparent, the features would be aligned in order A, L, B, C, E, D, G, F, H, K, J. However, if a telecentric lens is used, points are aligned in pairs as follows: L with A, C with B, D with E, G with F, H with I, and K with J

necessary to use monochromatic light, to eliminate “rainbows” around high-contrast edges,.) Fresnel lenses (30 cm diameter) intended for overhead projectors can be used. to produce a low-cost telecentric system. Cylindrical-telecentric lenses are also available for line-scan cameras.

LAYOUT DIAGRAM ➲ *Figure 40.104*

40.110 Method 110: Using Mirrors to View Front and Back

OBJECTIVE To view the front and two side-rear faces of a widget.
TYPICAL APPLICATIONS This technique was originally developed for inspecting corks, which were held in place by feeding them through a glass tube.
EQUIPMENT Plane mirrors.
CAMERA Array.
LENS Must be able to focus from the front of the direct view to the rear-most visible point on the virtual images.
MOTION Static.
LIGHTING Matt, non shiny objects are best inspected in this way as there is a limited number of options for lighting.
REMARKS This technique could, in theory, be extended to provide all round inspection of the widget, although it would not then be possible to move it past the camera. The advent of

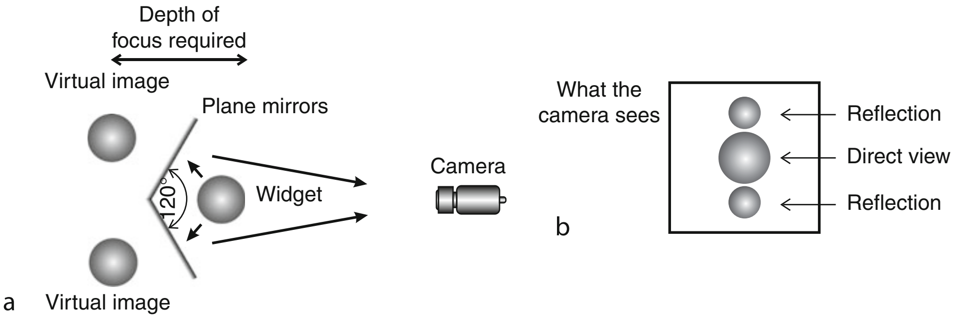

Fig. 40.105
Combining front and two side-view images of a widget using two plane mirrors. (a) Optical layout. (b) What the camera sees. Notice that the two reflected images are smaller than the direct view

low-cost cameras and lenses makes this method less useful than it once was. Notice the change of size of the direct and reflected views and the requirement for a large depth of focus.
LAYOUT DIAGRAM ➋ *Figure 40.105*

40.111 Method 111: Very Large Membrane Mirror

OBJECTIVE To provide a very large mirror, which may be part of an anamorphic or paraxial imaging system.
TYPICAL APPLICATIONS Viewing whole car body, manufacturing plant, robot work space, etc.
EQUIPMENT A large air-tight box is evacuated continuously by a vacuum pump. The front face of this box is perforated and is shaped to the desired form of the mirror. (Very high tolerance machining is not necessary.) A "silvered" (aluminised) Mylar film is stretched over the front face and takes up the shape of the front face. Minor variations in the shape of its reflecting surface are eliminated by the elasticity of the film.
LENS A standard-size wide angle lens is used in conjunction with very large mirror. The mirror optics should be adjusted to correct for geometric distortion introduced by the lens.
REMARKS Concave mirrors can be built most easily in this way; convex mirrors require more precise machining of (parts of) the front face of the vacuum box. Membrane mirrors as large as 4 × 4 m have been used in flight simulators. Membrane mirrors may be anamorphic. and a large paraxial imaging system can be built at moderate cost. The membrane mirror shape should be adjusted to correct for geometric distortion introduced by the wide-angle lens. The vacuum pump should be either a continuous flow type, or be buffered, to prevent oscillations in air pressure from affecting the shape of the mirror.

40.112 Method 112: Vibration Analysis: Speckle Pattern Interferometry

OBJECTIVES To analyse vibration patterns in real time using electronic speckle pattern interferometry (ESPI).

TYPICAL APPLICATIONS Inspecting/testing loudspeakers, musical instruments (strings and percussion), panels covering vibrating machines (e.g., car, domestic white goods, pumps, etc.)

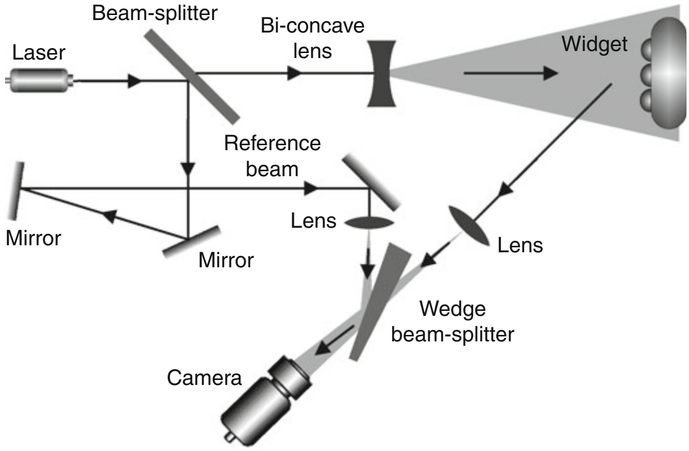

Fig. 40.107
Vibration analysis using speckle pattern interferometry

EQUIPMENT Pulsed laser, various small optical devices.
CAMERA Array.
MOTION Widget is stationary but is vibrating.
GEOMETRY Fairly smooth surfaces.
MATERIALS Low contrast, preferably coated in fine white powder. The spray-on developer used for crack detection is ideal.
REMARKS Notice that the object may be vibrating naturally. It is also possible to excite vibration in panels used in applications such as car bodies, using a loudspeaker mechanism, or piezo-electric device. ESPI is a highly specialised area and requires considerable expertise in optical engineering, for two reasons: (a) to maintain safe operation of high-power laser equipment (b) to keep optical equipment working reliably in a factory environment.

LAYOUT DIAGRAM ➲ *Figure 40.107*

40.113 Method 113: View Annulus, Ignoring Central Disc

OBJECTIVE To view an annular region of a scene in high definition, while ignoring the central disc.
TYPICAL APPLICATIONS Inspecting circular objects, such as

- Tops of cans, jars and bottles

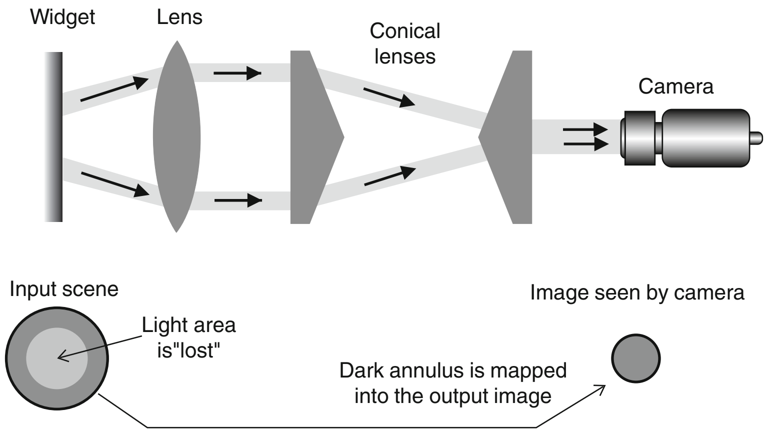

Fig. 40.108
View an annulus, ignoring the central disc

- Rims of holes
- Ends of rods, screws, etc. that are to be inserted into a hole

EQUIPMENT Two axicon lenses. (An axicon is a cone of transparent material.)
CAMERA Array.
MOTION Static.
GEOMETRY Circular, annulus.
REMARKS Using the optical arrangement shown in *Fig. 40.108*, it is possible to avoid storing and processing pixels that are not needed for the inspection process.
REFERENCES Optics for Research, Caldwell. http://www.ofr.com. Accessed 6 Sep 2011
LAYOUT DIAGRAM *Figure 40.108*

40.114 Method 114: View Flat Surface Without Glinting

OBJECTIVE To view a mirror-like surface that is very nearly flat, without observing reflections of the light source.
TYPICAL APPLICATIONS Inspecting glossy and mirror-like surfaces for stains, rust, etc. For example, glossy paper and card, DVDs, flat glass plates, smooth plastic sheet, ceramic tiles, magnetic tape, automobile and refrigerator body panels, etc.
EQUIPMENT Two, four or more flood lamps, or a ring-light (fibre-optic, LED array or circular fluorescent tube).
CAMERA Array or line-scan.
MOTION Static (array camera) or moving (line-scan).
GEOMETRY Nominally flat.
MATERIALS Smooth plastic, glass, ceramics, metal, etc. Lacquered/painted surfaces.
REMARKS This technique is closely related to the popular method used by photographers when recording images on glossy paper or card. Light from each of the lamps is reflected in a direction well away from the camera, which therefore receives only light that has been scattered by diffuse reflection and specular reflections from scratches, embossing, pimples,

pits, etc. A ring-light may be used to provide illumination through 360°, around the widget. Commercially available low-angle ring lights are sometimes described as "dark field lights."
DIAGRAMS AND SAMPLE IMAGE ➋ *Figure 40.109*

40.115 Method 115: View Orthogonally Polarised Images

OBJECTIVE To separate the horizontal and vertical polarisation components of an optical beam, so that they can be viewed simultaneously, using different cameras.
TYPICAL APPLICATIONS Inspecting.

- Surfaces coated with paint, lacquer, varnish, etc.
- Plastics, ceramics, glass, perspex (plexiglass), rubber and other non-metallic materials that have a smooth shiny surface
- Shiny, wet/oily objects
- Analysing stress in glassware and clear plastic materials

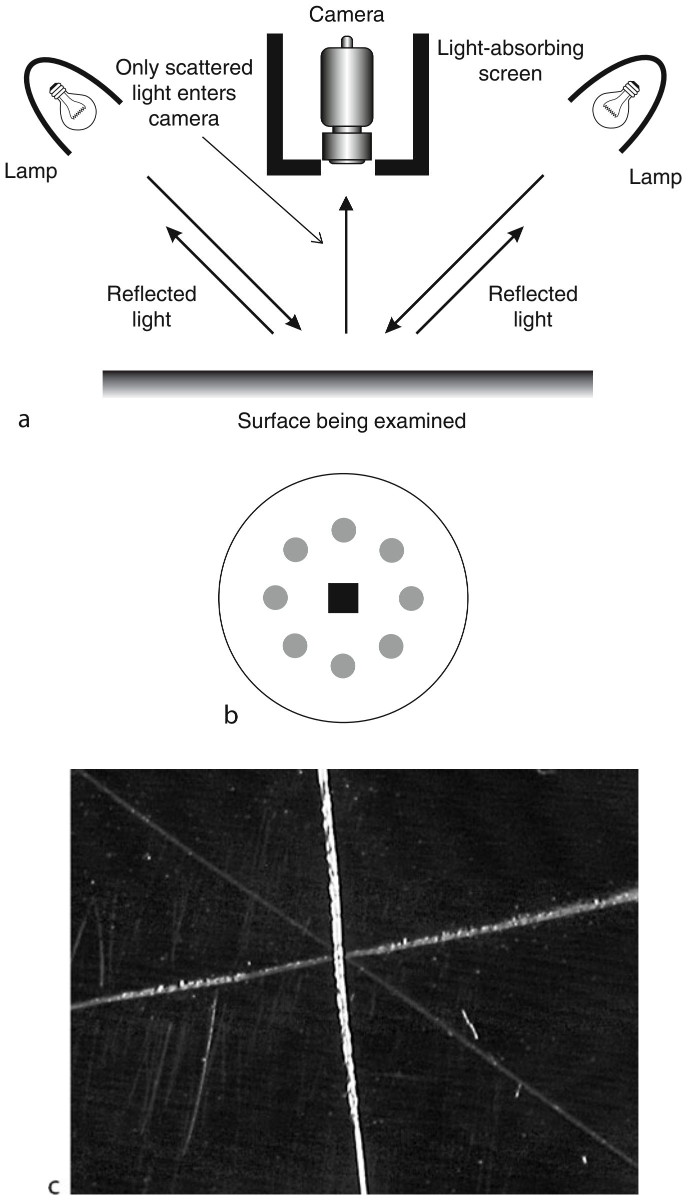
EQUIPMENT One of the following:

- Polarising prism. (This resembles a cube beam-splitter but has a multi-layer dielectric film coating on the interface surface between them.)
- Wollaston prism, made of calcite, or some other bi-refringent material. Other possibilities exist: Rochon, Ahrens, Sénarmont, Foster, Glan Thompson, Feussner, Bertrand
- A conventional beam-splitter and two linearly polarising sheets could be used instead

MATERIALS

- Non-metals, such as plastics, ceramics, glass, perspex (plexiplass), rubber, coated paper/card, etc.
- Painted/lacquered/varnished surfaces
- Surfaces with oil/moisture or other contamination

REMARKS Dielectric surfaces often produce reflections that are more strongly polarised in one direction than the other. (➋ *Fig. 40.110b*) Viewing a wet road, or the paint-work on a car body produces polarisation patterns, which are readily visible through polarising sun-glasses. If a ray of light impinges on a horizontal non-conducting (i.e., non-metal) surface at angle θ, then the ray reflected (angle $-\theta$) has a strong horizontally polarised component. (➋ *Fig. 40.110b*) A vertically polarising filter placed in the optical path strongly attenuates the horizontally polarised component, but leaves the vertically polarised component unchanged. (➋ *Fig. 40.110c*) Using the optical arrangements shown in ➋ *Fig. 40.110a* and *d*, it is possible to visualise defects in surface condition (e.g., breaks in coating, oil, water or other contamination), since these alter the relative strengths of the polarisation. components. A Wollaston prism consists of two prisms made of calcite, or some other bi-refringent material, cemented together. (➋ *Fig. 40.110d*) Both beams travel together (i.e., co-linearly) through the first prism although they experience different refractive indices. At the interface, one beam experiences an increase in refractive index, while the other observes a decrease. At this point, the beam paths diverge. The angular separation between their paths is increased as the beams emerge from the second prism. The Wollaston prism produces nearly symmetrical deviations of the light path, while others (e.g., the Rochon prism) produces asymmetric deviations. Several other types of bi-refringent polariser exist: Ahrens, Senarmont, Foster, Glan Thompson, Feussner, Bertrand. All of these are able to generate two images, so that the polarisation components can be viewed separately and simultaneously. It may, of course, be possible to enhance the differences between



◘ Fig. 40.109

Viewing a mirror-like surface without seeing the light source. (a) Optical layout. (b) Illumination diagram for an array of eight lamps. (c) Sample image: Scratches on a mirror. Light was projected from just one source (*top left*). This highlights some scratches but not others, emphasising the importance of multi-directional lighting

these images by using polarised lighting; we project the illuminating beam through a polarising sheet. Prisms made of calcite have a wide spectral range, extending from UV into the IR waveband: roughly 0.19–2.50 µm. To ensure good separation of the polarisation components, the incoming beam should contain only parallel rays. For this reason, a telecentric lens system, should be used. (Method 107) Stress can be visualised in glass and clear plastic by separating the horizontal and vertical polarisation components. (Method 122).

LAYOUT DIAGRAMS AND SAMPLE IMAGE ➋ *Figure 40.110*

40.116 Method 116: Viewing Side Walls of a Bore

OBJECTIVES To view all round the side wall of a blind hole.

TYPICAL APPLICATIONS

- Inspecting internal (female) screw threads
- Examining bores for debris, scratches, cracks, pitting, pitting, corrosion, etc.

EQUIPMENT One or two convex conical mirrors. A double cone may be needed to ensure that the illumination strikes the bore surface at the correct angle. A plane mirror with a hole in its centre and collimator are also needed.

CAMERA Array.

LENS Standard.

MOTION Static.

GEOMETRY Blind (i.e., single ended) hole, large enough to insert probe.

MATERIALS Bright shiny materials may give some problems due to glinting.

REMARKS A collimated annulus of light is projected onto the illumination cone. From there, it is reflected onto the wall of the bore. The illumination cone angle must be chosen carefully, to ensure good illumination. In some situations, it is possible to use the imaging cone for illumination. In this case, the illumination is normal to the bore surface. The conical mirror maps (fixed-diameter) cylindrical coordinates (X,θ) into polar coordinates. The image formed by the conical mirror is sampled by the camera, using a Cartesian coordinate system. Let (U, V) be the position of a point in the digital image derived from the camera and (U_0, V_0) be the apparent position of the apex of the cone in that image. Hence, assuming that the imaging cone mirror has a half-angle of 45°

$$\theta = \tan^{-1}((V - V_0)/(U - U_0))$$
$$X = X_0 + \sqrt{[(U - U_0)^2 + (V - V_0)^2]}$$

where X_0 is the X-coordinate of the apex of the cone mirror along the bore axis. The conical mirror provides an example of anamorphic imaging: paraxial lines on the bore wall generate radial lines; circles around the circumference are mapped to concentric circles; a helical screw thread forms an Archimedes spiral in the output image. (Its radius varies linearly with angle, θ.) To avoid blurring, the camera lens should have a high *f*-number.

40.117 Method 117: Viewing Aerosol Spray

OBJECTIVES

- To analyse the overall shape of an aerosol spray cone
- To examine the internal structure splitting of the cone and identify jets and flying drops of liquid

TYPICAL APPLICATIONS Inspection of

- Domestic, commercial and industrial aerosol sprays
- Fuel sprays for internal combustion engines, oil-fired heaters, etc.
- Coating and painting, sprays

EQUIPMENT Environmental protection enclosure is used to confine the spray and avoid contamination of optical equipment. This enclosure is fitted with two separate windows for illumination and viewing the spray cone. The internal surfaces of these windows must be kept clean, possibly using air purges. At the end of each inspection cycle, the atmosphere within the enclosure should be purged by a current of air.

LIGHTING The lighting sub-system may use fibre optics, an array of LEDs or fluorescent tubes, to ensure uniform, cold (IR-free) illumination of the spray cone. Care must be taken to eliminate UV, to avoid fluorescence. The lighting unit(s) must not be allowed to raise the temperature within the environmental protection enclosure, as this may alter the nature of the aerosol spray.

CAMERA Array.

LENS Standard.

MOTION Static.

REMARKS The importance of keeping the windows clean within the environmental protection enclosure cannot be over-emphasised. Similar lighting techniques can be used to obtain images of smoke plumes. A fine jet of smoke is often deliberately introduced into wind-tunnels, so that the air-flow pattern can be visualised. The jet may be illuminated in the same way, using Dark Field Illumination (Method 27), or a combination of the two.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.112*

40.118 Method 118: Viewing Inside an Irregular Transparent Object

OBJECTIVE To observe internal detail within a piece of material of known refractive index, and irregular shape.

TYPICAL APPLICATIONS

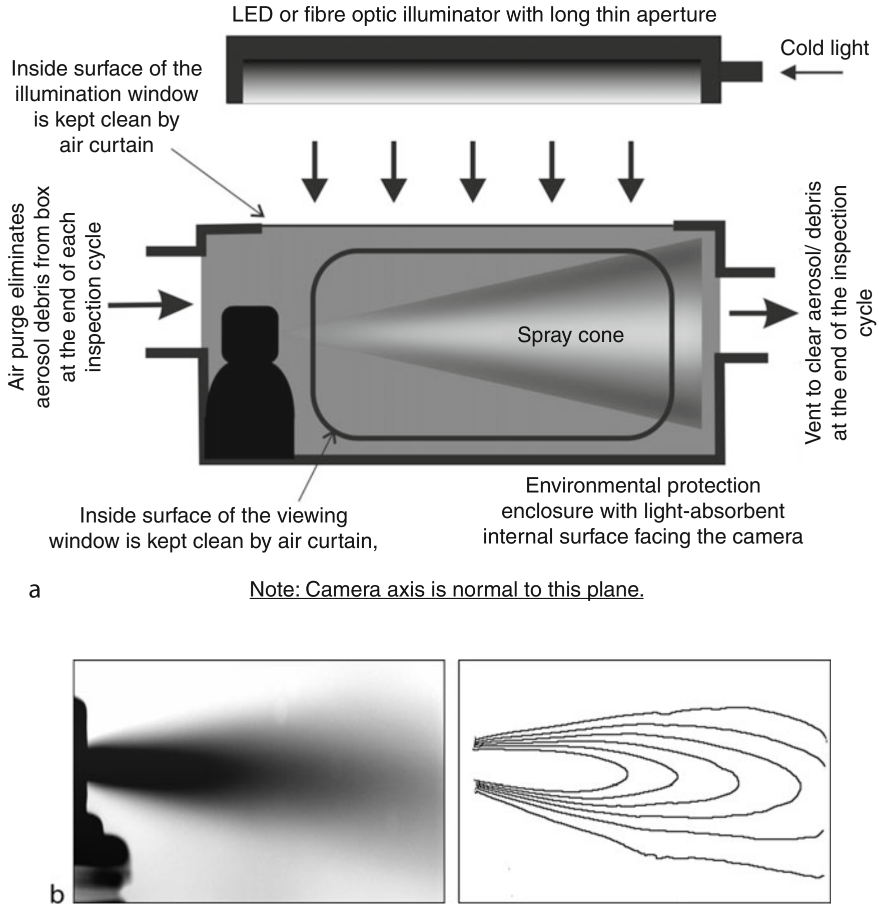
- Detecting foreign material, air bubbles, fractures, etc. in crystals, such as gems
- Examining cut glass objects for air bubbles and inclusions

EQUIPMENT Bath of water, oil, or other liquid, having approximately the same refractive index as the material being inspected.

GEOMETRY Complex and/or irregular. May not be known.

MATERIALS Transparent, plastics and other transparent materials. The refractive index must be fixed and known. Diamond and other materials with very high refractive index cannot be viewed in this way, because it is not possible to obtain a transparent liquid with a matching high refractive index.

REMARKS If the difference in the refractive indices of the solid material (μ_s) and liquid (μ_l) are exactly equal, the outer edge of the crystal is totally invisible. If μ_s and μ_l are nearly equal, the outer edge can be seen but with some difficulty. (Recall that ice cubes floating in water are nearly invisible. Only trapped air bubbles are clearly seen.) This assumes the surface of the solid material is clean and does not have air bubbles adhering to it. It is possible, therefore, to use



LED or fibre optic illuminator with long thin aperture
Cold light
Inside surface of the illumination window is kept clean by air curtain
Air purge eliminates aerosol debris from box at the end of each inspection cycle
Spray cone
Vent to clear aerosol/ debris at the end of the inspection cycle

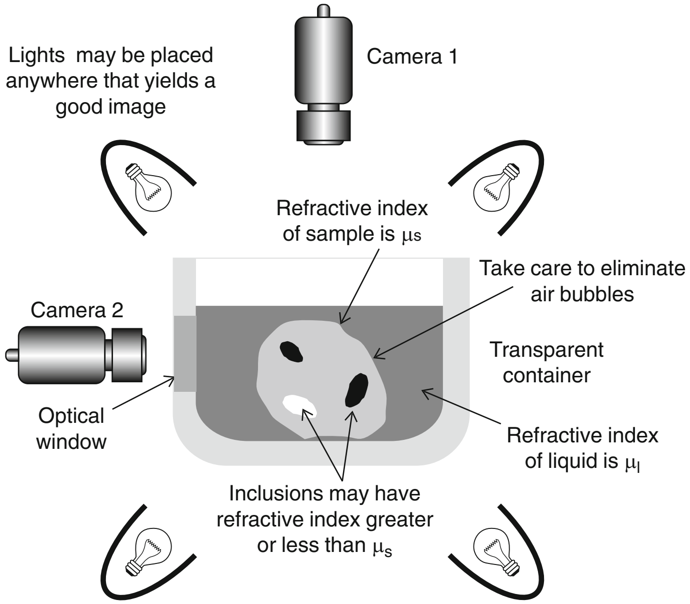
Inspecting aerosol sprays. (a) Optical layout. The inside surface of the environmental protection enclosure should be cleaned regularly and the atmosphere purged after each inspection cycle. (b) Sample image: domestic furniture polish. *Left:* The negative of the original image is shown here to increase clarity. *Right*: Isophotes (intensity contours) indicate the density of the aerosol

water (μ = 1.3) to provide an approximate match for glass (μ = 1.5). Some liquids of organic origin have a high refractive index can be used to view inside gems such as sapphire and ruby. However, such liquids are often expensive and may be toxic. It is better to view the sample through an optical window set in the side-wall of the container (camera 2 in *Fig. 40.113*), rather using an overhead camera (camera 1). This avoid image distortion due to ripples on the surface of the liquid and, hence, makes the optical system more tolerant of vibration. It also eliminates highlights, due to reflections on the liquid surface.

LAYOUT DIAGRAMS *Figure 40.113*



Lights may be placed anywhere that yields a good image

40.119 Method 119: Viewing Small Objects (Short Focus Lens Attachment)

OBJECTIVE To view small objects using a standard zoom lens.
TYPICAL APPLICATIONS Experimental work for prototype development, when viewing objects of approximate size 5–50 mm.
EQUIPMENT Short focus lens attachments, screwed onto a standard zoom lens.
REMARKS The combination of a standard zoom lens and a set of short-focus lenses provides a convenient macro zoom lens that is ideal for prototype development. Short-focus lens attachments produce slightly inferior picture quality, compared to extension tubes. However, they are rather more convenient to use, since they are easier and quicker to change. Short-focus lenses are available in a range of powers. Chromatic aberration can be problematical with lens attachments. For this reason, monochromatic or narrow-band lighting is preferred. A useful set of lenses for experimentation consists of a standard zoom lens, used in conjunction with +1,+2 and +4 dioptre short-focus attachments. (The power of a lens, measured in dioptres, is the reciprocal of its focal length in metres.) The effect of adding two or more short-focus lenses is additive. The corners of the picture may be distorted and blurred when large-power short-focus lenses are fitted. In addition, some vignetting may occur. The short-focus/zoom lens combination is best used for experimental application analysis. Once a good image has been obtained in the laboratory, it may be possible to select an equivalent a macro lens for use in the target system.

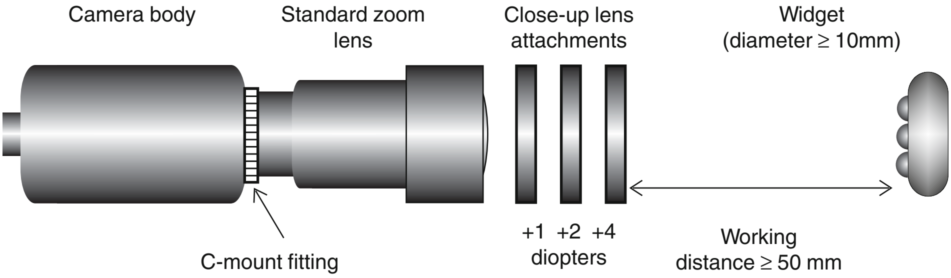

Fig. 40.114
Short-focus attachment lenses screw onto the main lens. They can be cascaded, if necessary, to reduce the focal length further

Table 40.2
Focal lengths for a standard lens fitted with a short-focus attachment. All distances are in millimetres

Short-focus attachment	Nominal setting, main lens			
	∞	3,000	1,000	500
1 dioptres	100	75	50	33
2 dioptres	50	43	33	25
3 dioptres	33	30	25	20
5 dioptres	20	19	16	14
10 dioptres	10	10	9	8

LAYOUT DIAGRAM ❯ *Figure 40.114*
FOCAL LENGTH CALCULATION See ❯ *Table 40.2*

40.120 Method 120: Viewing Small Objects/Features

OBJECTIVE To view objects/features of microscopic size.
TYPICAL APPLICATIONS Inspecting the following objects and surfaces:

- Bearing surfaces (wear damage)
- Metallurgical samples
- Micro-electronic devices
- CDs/DVDs
- Printing (fine structure of colour printing)
- Electrical switch contacts
- Surgical/razor blades (cutting edge)
- Metal-working tools (cutting edge)
- Abrasives
- Gems

- Internal structure of materials (viewing cross sections of industrial foams, baked dough and other food products)
- Textile fibres

EQUIPMENT Either of the following:

- Microscope, fitted with a suitable adaptor for a video camera (e.g., C-, CS-mount, etc.). Many modern microscopes allow the user to view the optical image simultaneously with image capture/recording by a video or film camera
- Video microprobe. This is a shortened variant of the endoscope that has been designed to provide high optical magnification. Light can be projected onto the widget from an in-built a ring light, surrounding the objective lens element. A microprobe has no mounting, or translation stage, for the sample being examined

CAMERA Array, monochrome or colour.

LENS The microscope/microprobe is fitted in lieu of a standard lens.

MOTION Static – avoid vibration.

GEOMETRY Features larger than about 20 μm can usually be examined optically. Objects smaller than this usually require the use of an electron microscope.

MATERIALS Provided suitable lighting is used, any solid material, which may be opaque, translucent or transparent.

REMARKS There are many possible lighting methods available for use with for microscopes including: front, inclined, grazing, side, back, dark-field, phase contrast, fluorescence, polarised, coloured, ultra-violet, infra-red, etc. Etching/staining can be used to enhance image contrast.

40.121 Method 121: Viewing Small Objects (Extension Tubes)

OBJECTIVE To view small objects using a standard lens.
TYPICAL APPLICATIONS Experimental work for prototype development, when viewing objects of approximate size 5–50 mm.
EQUIPMENT Extension tubes fitted to standard lens.
REMARKS The combination of a standard lens and an extension tube provides a convenient alternative to a macro lens that is suitable for prototype development in the laboratory. Extension tubes produce slightly superior picture quality, compared to short focus lens attachments but are more difficult to use. Extension tubes lenses are available in a range of powers. For the standard C-mount lens fitting, a useful set of tubes for experimental purposes consists of 20 mm, 10 mm, 5 mm and a set of washers of various thicknesses. The effect of adding two or more extension tubes lenses is additive. When using extension tubes, care are should be taken to avoid vignetting. Extension tubes are well suited for experimental problem analysis; once a good image has been obtained in the laboratory, it may be possible to substitute an equivalent macro lens for the factory-floor system.
LAYOUT DIAGRAM ➋ *Figure 40.116*

40.122 Method 122: Viewing Stress in a Transparent Sheet

OBJECTIVE To display stress patterns in glassware and transparent sheet materials.
TYPICAL APPLICATION

- Checking annealing of glass-plastic hollow-ware (bottles, jars and other containers)
- Visualising stress in experimental components test structures and components. (The structure to be tested is modelled in glass or perspex.)

EQUIPMENT Two linear polarisers. An infra-red (IR) blocking filter may also be needed. The light source should not emit significant amounts of infra–red. (For this reason, filament lamps should be avoided.)
CAMERA Array.
LENS Standard.
MOTION Static.
MATERIALS Clear glass, perspex (plexiglass), plastic, polycarbonate, celluloid, acetate film, etc.

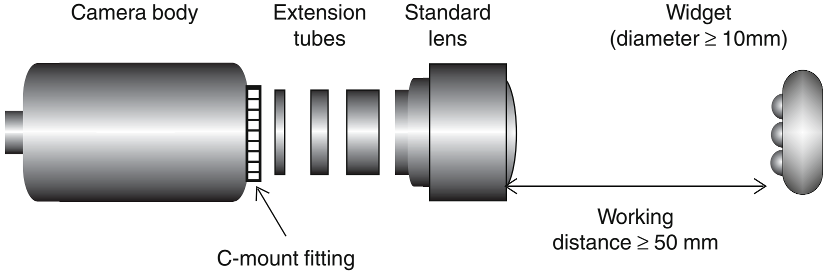

Fig. 40.116
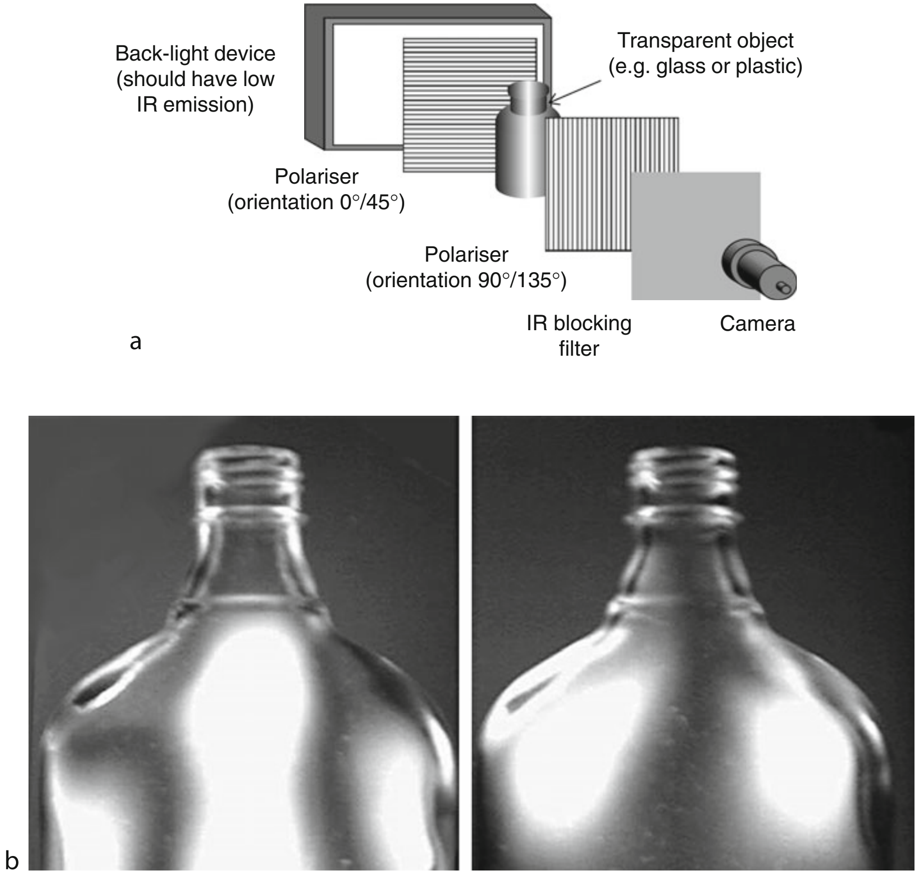
Extension tubes fit between the camera and its main lens

REMARKS Stress is a vector quantity, which varies in magnitude and direction, from point to point. In a sheet of glass, only those components of the stress vector that are normal to the optical path (i.e., parallel to its plane sides) are visible. Some polarisers do not function in the near infra-red region of the electro-magnetic spectrum, while many solid-state cameras have a significant response to IR. As a result, images obtained without the IR-blocking filter shown in ➋ *Fig. 40.117a* may have a low contrast. In some cases, the stress patterns are not visible at all to a camera, even though they can clearly be seen by eye. An optical filter which absorbs infra-red will greatly improve the contrast. The light source should not emit strongly in the IR wave-band; filament lamps are not recommended. The optical set-up in ➋ *Fig. 40.117a* is the classical arrangement shown in school-level text books. However, it is clear from ➋ *Fig. 40.117b* that the



■ Fig. 40.117
Viewing stress patterns using two crossed linear polarisers. (a) Optical arrangement. (b) Sample images: stress patterns in a glass "hip flask" (a flattened bottle). *Left:* polarisers at 0° and 90°. *Right:* polarisers at 45° and 135°. The effects of the front and back walls of the bottle are superimposed

image seen with polarisers at one orientation (e.g., 0°/90°) does not highlight the stress patterns completely, as stresses in some directions are not made visible. It is necessary to rotate the polarisers by 45° (to 45°/135°) to obtain a second image. These two images are then added to obtain a measure of the total stress in the plane of the sheet. In order to avoid stress direction dependence, a pair of circular polarizers may be used instead of two linear polarisers. Notice that circular polarisers should be used with monochromatic light whose wavelength matches that of the polariser design.

REFERENCE Large sheets of polarising laminated film is available from a number of suppliers, for example, Edmund Optics, http://www.edmundoptics.com/. Accessed 6 Sep 2011

OPTICAL LAYOUT AND SAMPLE IMAGES ➋ *Figure 40.117*

40.123 Method 123: Viewing Through a Small Aperture

OBJECTIVE To view inside a tube or vessel that has only a small viewing aperture, without entering it.

TYPICAL APPLICATIONS Inspecting pipes, tubes, internal threads, engine cylinders, hydraulics cylinders, tanks.

EQUIPMENT Hypercentric lens with small spacer between it and the camera, ring light.

CAMERA Array camera.

MOTION Static.

GEOMETRY Typically hollow cylinder.

MATERIALS Not critical.

REMARKS Other options for lighting are available, including coaxial illumination and viewing.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➋ *Figure 40.118*

40.124 Method 124: Visual Sensor On Robot

OBJECTIVE To provide the following facilities:

- Camera, with accompanying lights, mounted on a robot arm
- Range finder, mounted on a robot arm
- Image sensor and range finder, mounted on an autonomously guided vehicle

TYPICAL APPLICATIONS Inspecting an array of components held on a large tray, large panels, (e.g., refrigerator, cooker, automobile/aircraft body panels, etc.), complex assemblies of components, checking machining, assembly, stacking, painting, spraying, etc. Agricultural/horticultural robotics: harvesting, milking, pruning, potting plants, etc. Robotic trimming of natural products: trimming vegetables, fruit, timber, butchery, etc.

EQUIPMENT Rugged camera head containing super-bright LEDs and diode laser light-stripe generator.

CAMERA Miniature array camera.

LENS Short focus, wide angle lens.

Fig. 40.118
Hypercentric lens used as a borescope (a) Layout (b) Interior of a car oil filter, viewed through an 18 mm hole [Image kindly supplied by Spencer Luster, Light Works. http://www.lw4u.com]

REMARKS An earlier design used fibre optic bundles for both illumination and imaging. However, this is not robust, as the continued flexing of a fibre optic bundle is likely to cause a small proportion of the optical fibres within it to break. This results in uneven illumination of the widget/assembly being examined, and black spots in the image. Moreover, the robot has to cope with the additional load placed on it by the stiffness of two ruggedised bundles with tough cladding. The design in *Fig. 40.119a* is generally superior. The advent of very small cameras and very bright, efficient LEDs makes it possible to build a unit like this within a small volume 50×50×50 mm^3. The video signal can be conveyed to the image processing system via a fine, flexible (and cheap) cable, or a short-range radio transmitter. Of course, radio/IR control of the laser and LEDs is also possible using *Bluetooth* technology. The camera-lighting head can be fixed to the robot *in lieu* of the gripper. Alternatively, it may be fitted to the wrist of the robot, alongside the gripper, within the gripper unit. It can even be held in a cradle beside the base of the robot until needed, then picked up and held in its gripper, during the inspection process. An air purge can be built into the camera-lighting head, to keep the optics clean in smoky, dusty and aerosol-laden atmospheres. (See Method 93) A large depth of field can be achieved by using a wide-angle lens, with a small aperture. The range finder (❯ *Fig. 40.119a*) helps in keeping the working distance nearly optimal and compensating for changes of magnification as working distance varies. It should be appreciated that there are significant algorithmic/computational problems involved in safely manoeuvring a camera round any object of complex form These are exacerbated if the scene being examined is of unknown form and size.

40.125 Method 125: Visualise Changes in Refractive Index

OBJECTIVE To highlight changes in refractive index in a transparent medium, such as air, or water.

TYPICAL APPLICATIONS

- Visualising gas, air/fluid flow
- Visualising convection patterns in air/liquid
- Detecting shards of clear glass/plastic in water
- Visualising fluid in glass/plastic container
- Analysing emulsions of clear liquids
- Studying aerodynamic flow and convection currents

EQUIPMENT

- *Schlieren Imaging*: Intense source of nearly monochromatic light such as a laser, filter, two high-precision parabolic mirrors. A specially constructed test cell is needed for studying fluid flow. This must have precision optical windows
- *Phase Contrast Imaging*: Three lenses. Two masks. Sample is in the form of a thin transmissive film, labelled "Transparency" in ➲ *Fig. 40.120c*

CAMERA Array.

MOTION Static, or slow enough for motion to be "frozen" by strobing camera or lights.

REMARKS Two methods are described: Schlieren Imaging (➲ *Fig. 40.120a*) and Phase Contrast Imaging (➲ *Fig. 40.120b*). Both of these employ optical interference to highlight small-scale changes in refractive index in a transmissive medium. These may be caused by local pressure, or temperature, gradients. Schlieren Imaging was developed by A. Toepler in 1864. Its name is derived from the German word meaning "streak." Phase contrast imaging is familiar in microscopy, where it is used extensively to obtain images of transparent micro-organisms and to increase contrast in images obtained from tissue samples. Both methods are highly sensitive to changes in refractive index and optical path length. The "Transparency" in ➲ *Fig. 40.120c* might consist of a thin test cell, with parallel walls, made of optical-quality glass and containing a clear fluid. A telecentric lens with a high f-number and a collimated light source can produce good Schlieren images.

LAYOUT DIAGRAM AND SAMPLE IMAGE ➲ *Figure 40.120*

40.126 Method 126: Visualising Heat Distribution

OBJECTIVE To visualise heat distribution, without using an expensive thermal imaging camera.

TYPICAL APPLICATIONS

- Prototype development of low-volume printed circuit boards, where the high cost of dedicated thermal imaging equipment cannot be justified
- Remote monitoring for over-heating in bearings, motors, engines, pumps, pipe-work, etc.
- Crack detection
- Checking structural integrity of adhesive joints

EQUIPMENT Thermo-chromic (liquid crystal) paint (TC-paint), or thin plastic film coated with such paint. TC-paint can be made to detect changes (i.e., change colour) over a narrow, well-defined range of operating temperatures. (These materials are used in disposable clinical

thermometers.) The illumination must be "cold" (i.e., containing no significant amount of infra-red.) For this reason, an incandescent filament lamp is *not* suitable; a VIS LED array is ideal.

CAMERA Standard array-scan colour camera. A monochrome camera may be used in conjunction with an optical filter, to obtain good colour (i.e., thermal) differentiation.

MATERIALS Metals, plastics, ceramics, and other materials. The surface must be clean, non-absorbent, relatively smooth and able to accept the TC-paint without damage. Alternatively, thermo-chromic film may be attached by adhesive, applied uniformly to ensure good and consistent thermal contact.

REMARKS Thermo-chromic materials reversibly change colour as the temperature changes. They can be made as semi-conductor compounds, from liquid crystals, or using metal compounds. Some older forms of TC-paint are based on mercury compounds and are poisonous. The change in colour occurs at a well-defined temperature, which can be varied by doping the material. They can be supplied in liquid form, applied to a thin film, or mixed into moulding, or casting materials. This method can be applied to check crazing, cracking, adhesive joints, plating and other coatings, and to check for integrity in honeycomb and lattice structures. Heat may be deliberately applied at one end of a structure and the temperature changes observed over time along its length. In this way, it is possible to detect cracks, which impede thermal conduction and therefore alter the temperature-time profile. Using TC-paint provides the basis for a low-cost, low-precision inspection method. It is capable of providing only qualitative results, albeit at a well defined temperature threshold. It is well suited to detecting "hot spots" on printed circuit boards, or monitoring bearings for overheating. This

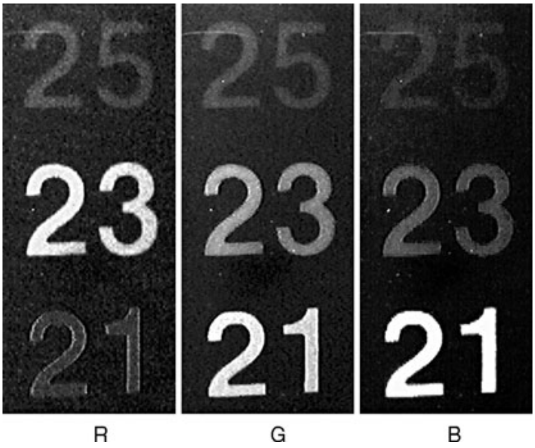

Fig. 40.121
Image derived from a thermo-chromic room thermometer. The picture shows the RGB colour channels for a thermometer. Numbers denote degrees Celsius. "Cold" near-white light was provided by an LED array

technique was developed for medical applications: using thermo-chromic film in good thermal contact with the skin, it is sometimes possible to detect hot-spots overlying breast tumours. Thermo-chromic materials have also been applied to small batteries providing an integral charge tester and to decorate T-shirts, coffee mugs, etc.
SAMPLE IMAGE ➔ *Figure 40.121*

40.127 Method 127: Wireless Image Acquisition

OBJECTIVE To provide a wireless connection between the camera and lights on the one hand and the control/image processing computer on the other. There are several factors to be considered:

(a) Power for the lighting module(s), camera and possibly the lens
(b) Control signals for the lighting module(s)
(c) Control signals for the cameras
(d) Control signals for the lens

TYPICAL APPLICATIONS

- Working in awkward locations where it is difficult to install cables
- Installing a camera on moving machinery (e.g., a lathe, hoist, robot, autonomic guided vehicle)

EQUIPMENT Various methods are described below, using

- Magnetically coupled coils, located close to each other on opposite sides of the wall of a container, forming a simple transformer
- Wireless (radio or IR) video link
- Cell phone video link
- Bluetooth

REMARKS There are numerous and varied circumstances where it is useful to operate a video camera and/or lights without providing direct electrical contacts:

- Autonomously guided vehicle (AGV). The wireless link avoids the use of a long, unwieldy and unreliable “umbilical” cable
- It may simply be more convenient (i.e., cheaper) to use a wireless data link, rather than installing cables, particularly if the inspection equipment is expected to be in situ for only a short time. This might typically apply to prototype systems, or short-run inspection applications

LAYOUT DIAGRAMS ➲ *Figure 40.122*

40.128 Method 128: X-Ray Imaging

OBJECTIVE To examine and measure internal features that are not be visible on the surface of an object or assembly.

TYPICAL APPLICATIONS

- Detecting foreign bodies in food, pharmaceuticals and toiletries. (The most important categories of mis-placed items are manufacturing waste, and natural contaminants. This includes articles such as false teeth, hair clips, contact lenses, screws, shards of glass, metal swarf, plastic splinters, bones, nut shells, rodents, insects, stones, twigs, etc.)
- To identify missing parts and mis-alignment in complex, multi-component products and assemblies
- Examining internal detail, correctness of assembly and internal alignment in safety-critical assemblies, such as munitions and electrical equipment

EQUIPMENT X-ray source and sensor, enclosed within a secure cabinet fitted with a range of safety devices. Widgets must be transported automatically through the x-ray beam.

CAMERA Array or line-scan detector. A high sensitivity camera is normally needed as the fluorescence generated by the x-ray beam is often weak.

REMARKS Care should be taken to choose a long-life x-ray tube, or one which can be fitted easily and quickly with a new filament. Safety is obviously of crucial importance when operating x-rays. However, with careful system design of the cabinet, there is no fundamental reason why x-ray inspection systems cannot be used perfectly safely in a factory. The maintenance and regular servicing of x-ray systems are crucial for safe and effective operation. Key points to note are:

(1) Fit micro-switches which turn off the power to the x-ray source when a door on the cabinet is opened
(2) Design the equipment so that no part of the body can be irradiated by the x-ray beam. For example, long entrance and exit tunnels can prevent operators from placing their hands within in the beam.
(3) Fit opto-electronic switches which turn the tube beam current *ON*, only when an object of the correct size is in place for inspection. Turn the current *OFF* again immediately afterwards
(4) Make the x-ray beam as narrow as possible. For an array sensor, use a pencil-shaped beam, if possible. When using a line-scan camera, mask unwanted rays, to create a thin fan-shaped beam

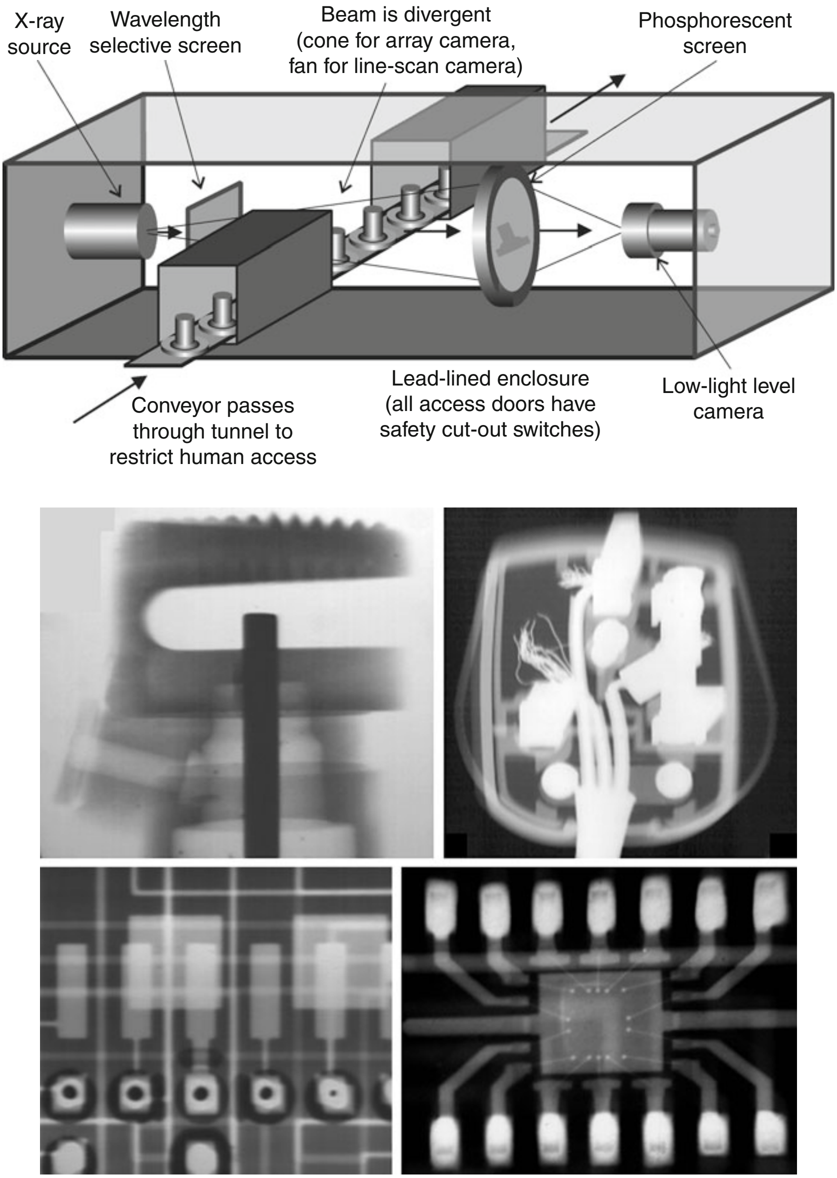
Two juxtaposed coils form a simple transformer, able to transmit power for multi-LED lighting modules and a camera. A radio link transmits the video signal from the camera to the image processor (not shown). (b) Inspect the internal surface of a large-diameter extruded tube. (c) Inspecting all round a solid rod using a wireless video link. Power might be supplied by slip-rings. (d) Network configuration for wireless video transmission via cellular 'phone and/or short-range radio link

(5) Use appropriate shielding to attenuate all unwanted x-rays. Pay attention to scattered x-rays
(6) Service the machine regularly
(7) Unauthorised and untrained personnel should not be able to gain access to the interior of the cabinet to make modifications to the machine. The cabinet should be lockable and secure fixings used to prevent side panels from being removed with standard tools, such as a screw-driver
(8) All personnel who work near the x-ray system should wear radiation detector (film) badges. These must be checked regularly

Contrary to some people's misplaced fears, x-rays do not damage food, or make it radioactive and there is no residual radioactivity. The x-ray dose is minimal. The energy levels are minute,



X-ray source

Varying magnification by changing the widget-to-camera distance. (a) Optical layout. In practice, the camera might be mounted on a robot arm, or a motorised slide-way. (b) Sample images: hydraulics manifold moving relative to the camera. The life-size sculptured head is at a fixed distance (same as the manifold in the image on the right). Notice that the focus is maintained despite the large proportional change in position (about 2:1). The number of pixels across the hydraulics manifold is reduced in the image on the right (Lens: focal: length 8 mm, *f*-number: 1.3.)

compared to those used, for example, during nuclear radiation sterilisation. Damage to large organic molecules (e.g., proteins in food products) does occur with very high x-ray doses but the effect is minute with the beam energy and exposure time normally used for inspection. Similar x-ray inspection methods are used for inspecting food materials, e.g., detecting bone in chicken, parasitic worms in fish, insect infestation in plant material, etc.

LAYOUT DIAGRAM AND SAMPLE IMAGES ➜ *Figure 40.123*

40.129 Method 129: Zooming By Movement

OBJECTIVE To vary the magnification of an optical system by varying the widget-to-camera distance.

TYPICAL APPLICATION Robot vision: using a camera with a fixed-focus lens, mounted on a robot arm, it is possible to perform a zoom function.

CAMERA Array.

LENS It is important that the lens is able to provide a large depth of field. A pin-hole lens, a wide-angle lens, or a standard lens with large *f*-number, may be used.

MOTION The position of the camera relative to the widget is controlled by a robotic device. Either the camera or the widget can be moved by the robot.

REMARKS The lens must be able to maintain sharp focus as the widget-to-camera distance varies over a wide range. Since the magnification is linearly related to the widget-to-camera distance, the distance between the camera and widget must be known accurately. It is important to realise that the spatial resolution varies as the magnification changes.

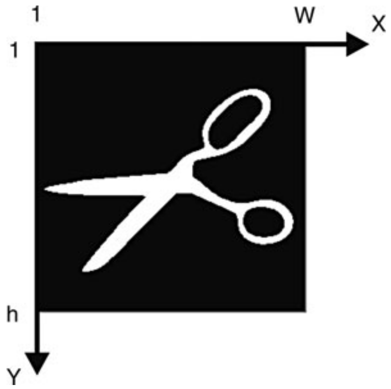
41 QT Image Processing Functions

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_41,

41.1 Notation

Coordinate axes



Input image 1 (associated with QT's Current Image)	*A = {A(x,y)}, [x,y] ∈ [1,w] × [1,h]*
Input image 2 (associated with QT's Alternate Image)	*B = {B(x,y)}, [x,y] ∈ [1,w] × [1,h*]
Result of image processing operation (replaces QT's Current Image)	*C = {C(x,y}, [x,y] ∈ [1,w] × [1,h]*

Intensity scale

$0 \le A(x,y) \le W, [x,y] \in [1,w] \times [1,h]$

$0 \le B(x,y) \le W, [x,y] \in [1,w] \times [1,h]$

Normalisation of the intensity scale is applied to ensure that

$0 \le C(x,y) \le W, [x,y] \in [1,w] \times [1,h]$

The operator ⇐ denotes a repeated assignment, performed on all pixels, $[x,y] \in [1,w] \times [1,h]$

The following assignments are equivalent

$\{C(x,y) \leftarrow \{\mathrm{f}(A(x,y), B(x,y))\}, [x,y] \in [1,w] \times [1,h]$

and

$C \Leftarrow f(A, B)$

Example (QT operator *adi*)

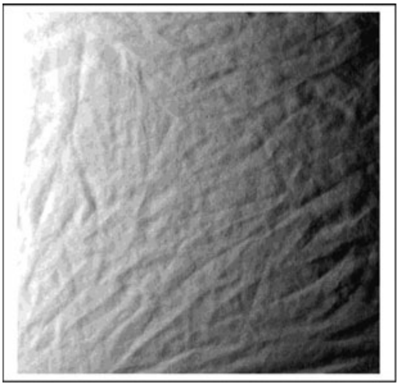
$C = (A+B)/2$ % Adds corresponding pixels in image arrays *A* and *B* and then divides by 2

"*Switch images*" indicates that the Current Image has been an altered by the function (*f*), following which the Alternate Image displays the previous Current Image

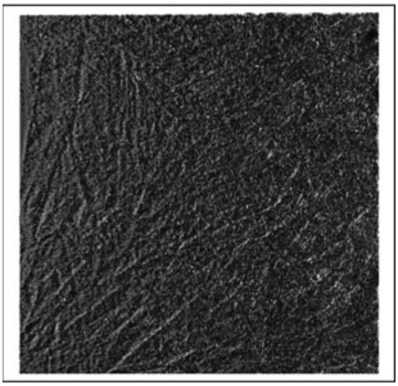
41.2 abd

Format	*abd*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Absolute value of difference in intensities between current and alternate images
Definition	$C \Leftarrow \|(A - B)\|$
Switch images	Yes
Typical uses	Emphasising local differences between images, irrespective of which is brighter/darker
Remarks	*abd* is most commonly used as a component within more complex algorithms, such as filters which high-light texture, or detect bright/dark intensity anomalies
Illustration	
Input images	Creased fabric and blurred version of same (*caf*)
File number	28
Command	*caf*, *abd*, *enc*

Left: original (Other image is output of *caf*)



Right: after processing



41.3 abv

Format *abv*

Arguments None

Defaults Not applicable

Output values None

Image type Grey

Type Monadic

Function Fold the intensity scale about the mid-grey value. (White and black are both mapped to the same value: white.) This function calculates the 'absolute value' of the image intensity, referred to mid-grey. If {a(i, j)} and {b(i, j)} are two images of the same size, then the output is {c(i, j)}, where

$$c(i, j) \Leftarrow |\,(W + a(i, j) - b(i, j))|/2$$

This is repeated for all *points*, $[i, j]$, in the input images

Switch images Yes

Typical uses In conjunction with various filters (e.g., high-pass), so that dark and bright intensity anomalies are treated in a similar way

Remarks The function *abv* 'folds' the intensity scale about the mid-grey value, so that white and black are both mapped to the same value (i.e. white)

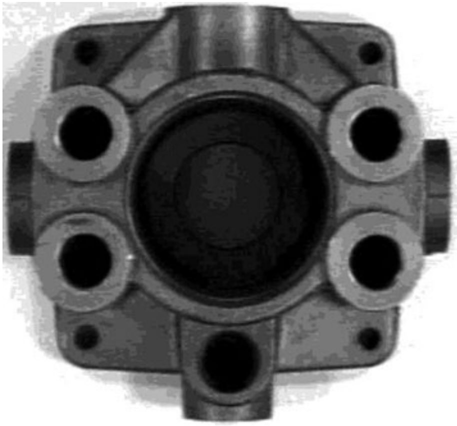
Illustration

Input image Hydraulics component

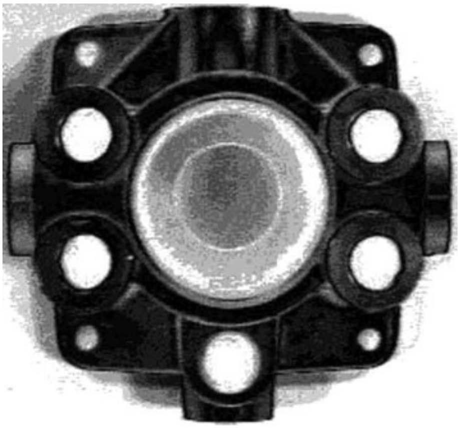
File number 37

Command *abv*

Left: original



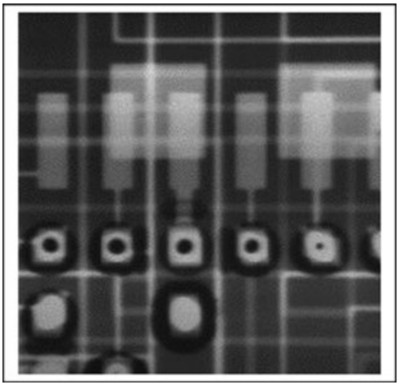
Right: after processing



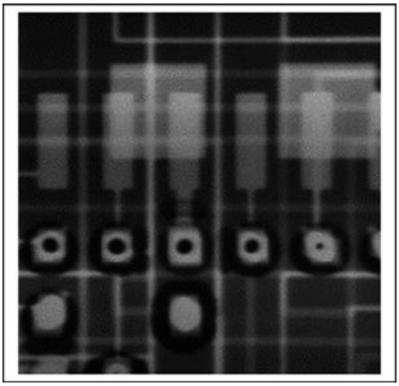
41.4 acn

Format	*acn*(*a*)
Arguments	a Increment to applied intensity values ($-255 \le a \le 255$)
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Add a constant to all intensities in the current image
Definition	$C \Leftarrow A + a$ with hard limits placed at 0 and 255
Switch images	Yes
Typical uses	Used to improve contrast. Also used within functions, such as *blo* and *enc*
Remarks	Also see *blo*, *din*, *enc*, *hin* and *heq*
Illustration	
Input image	PCB
File number	135
Command	*acn*(*−34*) (The minimum intensity in the PCB image is 34)

Left: original



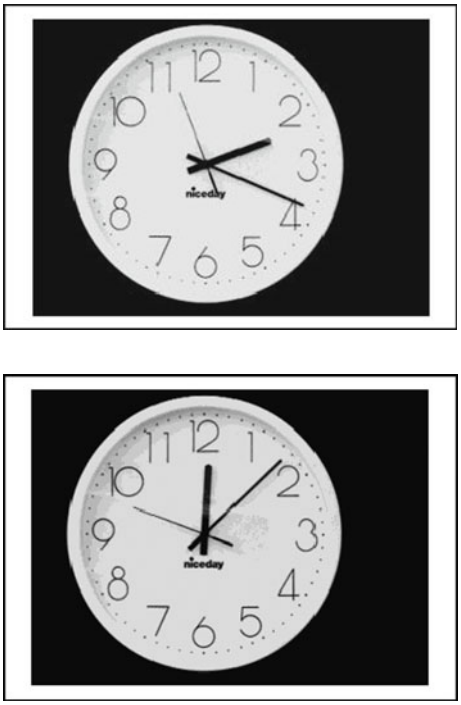
Right: after processing



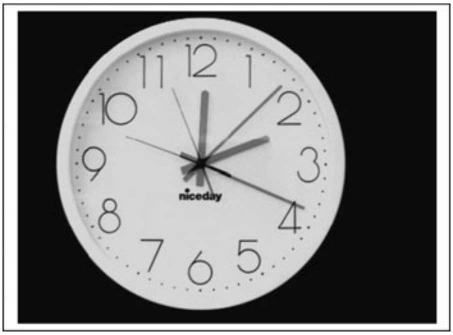
41.5 adi

Format	*adi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Add the intensities in the current and alternate images
Definition	C ⇐ (A + B)/2
Switch images	Yes
Typical uses	Image averaging Superimposing two images, for display purposes
Remarks	*adi* gives a similar effect to that seen in a photographic double exposure
Illustration	
Input image	Clock 1 and Clock 2
File number	142 and 143
Command	*adi*

Left: two originals



Right: after processing



41.6 aia

Format	*aia*(*a*)	
Arguments	*a*	Name of the folder where new images will be deposited
Default value	*a*	QT_images
Output values	None	
Image type	Binary, grey or colour	
Type	QT maintenance/extension	
Function	Add the current image to the image archive, stored in folder *a*, or by default in QT_images The new image file is in TIFF format	
Switch images	No	
Typical uses	*aia*	Saving pictures as they are captured from a camera
Remarks	*aia* is easier to use than *wri*, as the user does not have to worry about typing the file name. The image can be read back using *rni*. Also see *sia*	

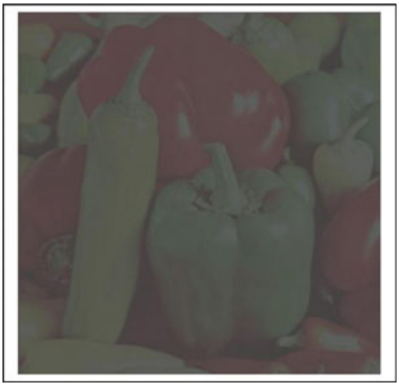
41.7 aic

Format	*aic*
Arguments	None
Output values	None
Image type	Colour
Type	Monadic
Function	Apply a linear stretching of the intensity scale of the RGB channel between the limits [*a*, *b*], where *a* is the minimum of the intensities in the RGB channels and *b* is the maximum. [*a*, *b*] is mapped to [0, 255]
Switch images	Yes
Typical uses	Increasing contrast of colour images
Remarks	The following have similar functions: *pci*('*enc*') *pci*('*heq*') *Also see air*, *pci*

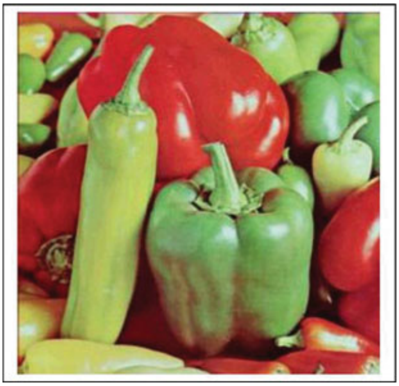
Illustration

Input image	Peppers
File number	73
Preprocessing	*rci*(*73*), *pci*('*hin*'), *pci*('*hin*'), *pci*('*hin*'), *acn*(*67*)
Command	*aic* *pci*('*enc*') *pci*('*heq*')

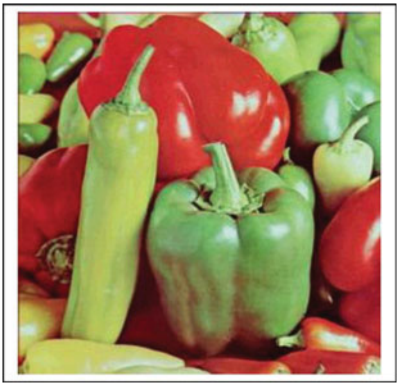
Top-left: original



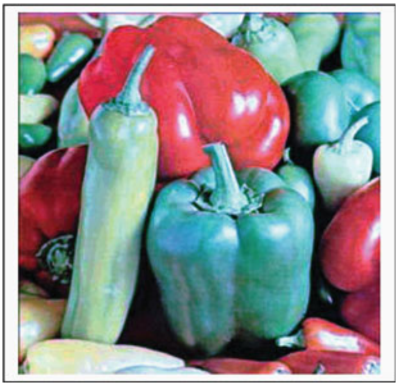
Top-right: *aic*



Bottom-left: after *pci*('*enc*')



Bottom-right: after *pci*('*heq*')



41.8 aid

Format	*aid*
Arguments	None
Output values	None
Image type	Any
Function	Assistance for the user
Switch images	No
Remarks	Also see *hlp*, *doc*, *img*, *author*

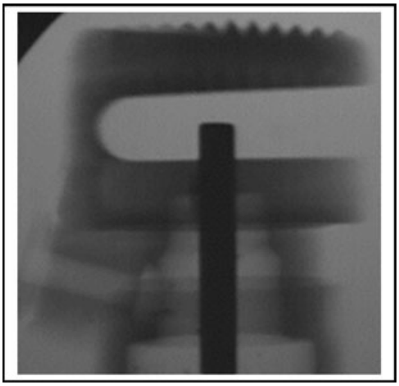
41.9 air

Format	*air*(*a*, *b*)
Arguments	a Lower intensity limit b Upper intensity limit

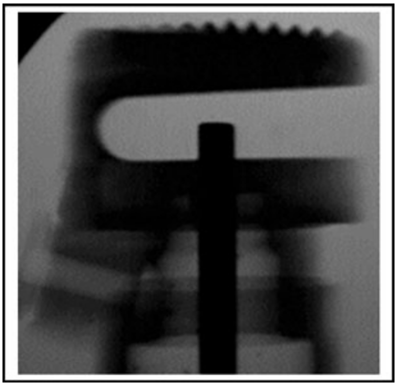
Defaults	No arguments
	a = 13; b = 242 (approximately 5% and 95% of white level)
	Single argument
	b = 255 − a

Output values	None
Image type	Grey
Type	Monadic
Function	Apply a linear stretching of the intensity scale between the limits [a, b]; pixels with intensities outside this range are set to 0 or 255
Definition	$C \Leftarrow 255*(A - a)/(b - a)$ with hard limits placed at 0 and 255
Switch images	Yes
Typical uses	Increasing contrast
Remarks	Also see *blo*, *din*, *enc*, *hin* and *heq*
Illustration	
Input image	Aerosol spray assembly
File number	111
Command	*air*(*50*, *200*)

Left: original



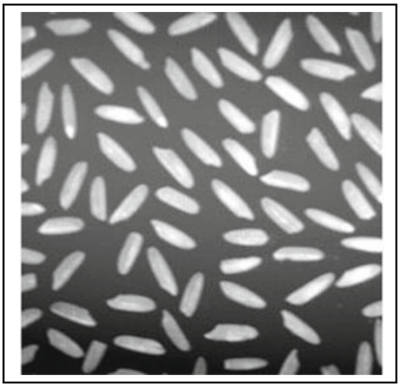
Right: after processing



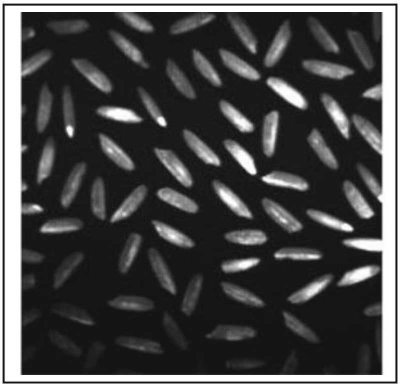
41.10 alg

Format	*alg*
Arguments	None
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Antilogarithm (exponential) of intensities in the current image
Definition	$C \Leftarrow 255 * \text{antilog}(A)/\text{antilog}(255)$
Switch images	Yes
Typical uses	Used to improve contrast within bright regions of the image
Remarks	Also see *nlg*, *sqr* and *sqt*
Illustration	
Input image	Rice grains after contrast enhancement (*enc*)
File number	3
Command	*alg*

Left: original



Right: after processing

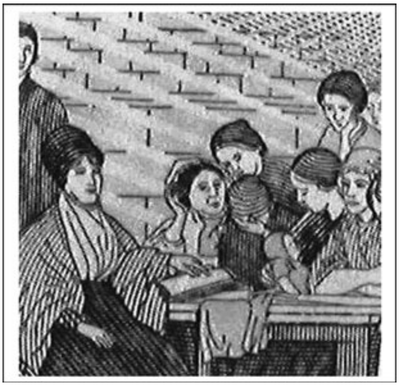


41.11 ani

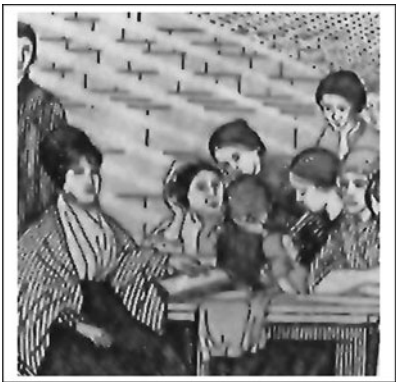
Format	*ani*(*a*, *b*, *c*)	
Arguments	*a*	*Number of iterations* (*niter in anisodiff*)
	b	Conduction coefficient (*kappa* in anisodiff)
	c	Select the Perona Malik diffusion equation to be used
Defaults	*a*	10
	b	50
	c	1 (Perona-Malik diffusion equation No. 1)
Output values	None	
Image type	Grey	
Type	Image filter	
Function	Apply the Anisotropic diffusion filter defined by P. Perona and J. Malik	
Switch images	Yes	
Reference	Perona P, Malik J (July 1990) Scale-space and edge detection using ansotropic diffusion. IEEE Transactions on Pattern Analysis and Machine Intelligence, 12(7):629–639	
Remarks	With minor modifications, the M-file *anisodiff* was written by Peter Kovesi, School of Computer Science and Software Engineering, The University of Western Australia, Email: *pk@csse.uwa.edu.au*. URL *http://www.csse.uwa.edu.au*	

Illustration	
Input image	Currency note (detail)
File number	211
Command	*ani*

Left: original



Right: after processing



41.12 asi/mxs

Format *asi*(*a*, *b*, *c*)
mxs(*a*, *b*, *c*, *d*)

Arguments *a* Number of images acquired
b Camera
c Time delay
d Maximum/minimum selector (*mxs* only)

Defaults *a* None
b 6
c 5 (seconds)
d 1 (*mxs* computes the maximum over *a* images)

Output values None

Image type Grey

Type Image acquisition

Function asi Average *a* images from camera *b*. Time interval between samples: *c* seconds
mxs ($d = 0$) Minimum of *a* images from camera *b*. Time interval: *c* seconds
mxs ($d = 1$) Maximum of *a* images from camera *b*. Time interval: *c* seconds

Switch images Yes

Typical uses Eliminating camera noise (static scenes) Obtaining a back-ground image, clear of vehicles/ people when analysing traffic

Remarks Imagine a static camera viewing a clock with a white face, black numerals and black hands. For suitable values of *a* and *c*, *mxs*(*a*, *b*, *c*, *0*) derives an image in which the hands have been eliminated; the clock appears as if there were no hands. This image can then be subtracted from a ‘snap-shot’ image of the clock, to remove back-ground details of the face, and provide a clear view of the hands

41.13 author/bgb

Format	*author*
Arguments	None
Output values	None
Image type	Not relevant
Type	Information
Function	Learn about the author of QT
Switch images	No

41.14 avg

Format	*a* = *avg*
Arguments	None
Defaults	Not applicable
Output values	*a* Average intensity
Image type	Grey-scale
Type	Grey-scale image measurement
Function	Find the average intensity over the whole image
Switch images	No
Typical uses	Choosing a threshold parameter
Remarks	Also see *dev*

41.15 bay

See *chu*.

41.16 bbx

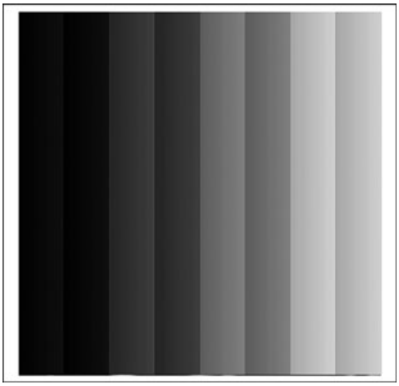
Format	$[a, b, c, d] = bbx$	
Arguments	None	
Defaults	Not applicable	
Output values	a	Minimum X-coordinate of the first blob found
	b	Minimum Y-coordinate of the first blob found
	c	Maximum X-coordinate of the first blob found
	d	Maximum Y-coordinate of the first blob found
Image type	Binary	
Type	Binary image measurement	
Function	Bounding box	
Definition	Perform a raster scan to find one object. Scan direction: top to bottom; left to right. Find the minimum and maximum X and Y coordinates	
Switch images	No	
Typical uses	Analysing/locating blob like objects	
Remarks	Also see *mar*	

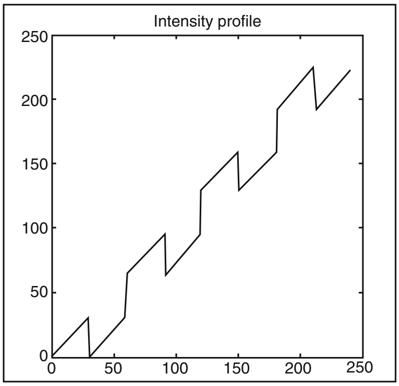
41.17 bcl/bcp/bst

Format	*bcl*(*a*)/*bcp*(*a*)/*bst*(*a*)
Arguments	a Index number of bit to be cleared/complemented/set ($1 \leq a \leq 8$)
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	*bcl*: For each pixel, set bit number *a* to 0 in the 8-bit binary representation of its intensity *bcp*: For each pixel, complement bit number *a* in the 8-bit binary representation of its intensity *bst*: For each pixel, set bit number *a* to 1 in the 8-bit binary representation of its intensity
Switch images	Yes
Remarks	Bit-set and bit-complement operations can be implemented by changing line 5 of bcl as follows: Bit set (bst): *current = bitset(current, a, 1)*; Bit complement (bcp): *current = bitcmp(current, a)*; These functions have only limited use. Also see *sca*
Illustration	
Input image	Intensity wedge (*wgx*)
Command	*bcl*(6), *plt*

Left: after processing

Right: mapping function





41.18 bcp

See *bcl.*

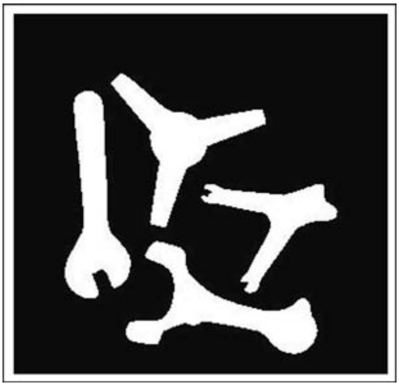
41.19 bed

Format	*bed*(*a*)
Arguments	a Connectivity (a = 4 or 8)
Defaults	a 8 (8-connectivity)
Output values	None
Image type	Binary
Type	Blob transform
Function	Binary edge detector
Definition	White pixels that have at least one black *a*-neighbour (*a* = 4 or 8) are set to white. All other pixels are set to black
Switch images	Yes
Typical uses	Inspecting object silhouettes
Remarks	The output is a binary image containing a white arc that traces the outer edge of the object. The edges of lakes (holes) are similarly defined. All blobs are processed in this way

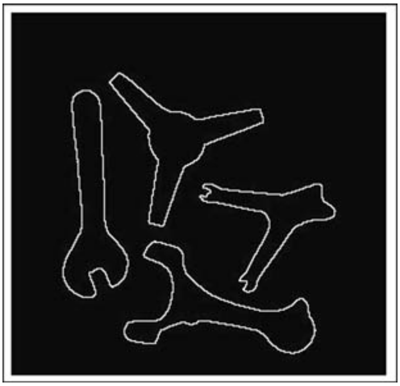
Illustration

Input image	Metal components
File number	46
Command	*bed*

Left: original image



Right: *bed*



41.20 bgb

See *author.*

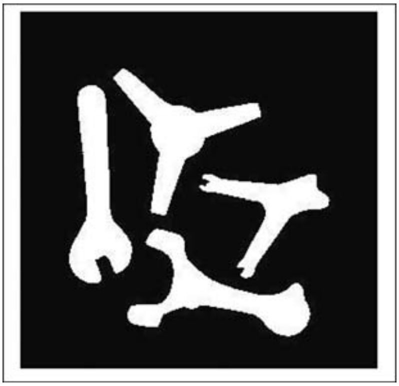
41.21 big

Format	*big*(*a*)	
Arguments	*a*	Rank size of blob to be isolated
Defaults	a	1
Output values	None	
Image type	Binary	
Type	Blob transform	
Function	Isolate the *a*th biggest blob in a binary image	
Switch images	Yes	
Typical uses	Analysing scenes with several large blobs and possibly many smaller ones	
Remarks	*big* will only work properly if there are fewer than 255 white blobs in the image. Otherwise *ndo* will saturate, combining many blobs into a single label. Also see *ndo* and *kgr*	

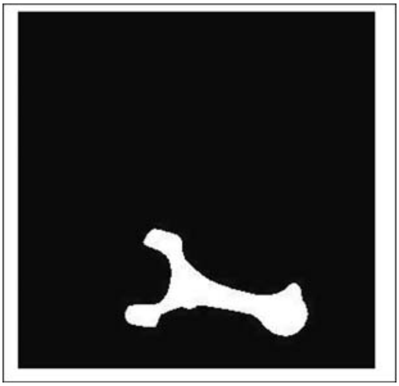
Illustration

Input image	Metal objects
File number	46
Command	*thr*, *big*(*1*)

Left: original



Right: after processing



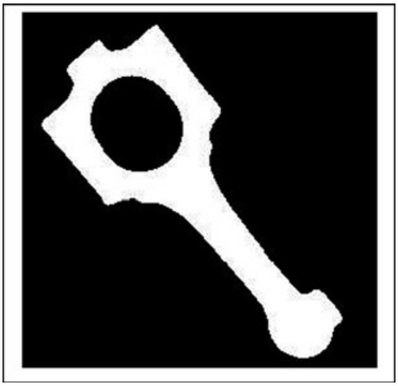
41.22 blf/lak

Format	*blf*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Fill all holes (lakes) in the current image
Switch images	Yes
Typical uses	Blob shape analysis
Remarks	A lake is an 8-connected black region that is totally enclosed within an 8-connected white region. The function *lak* isolates the lakes. Also see *chu*

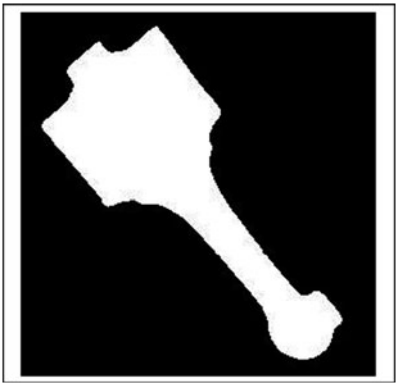
Illustration

Input image	Con-rod
File number	47

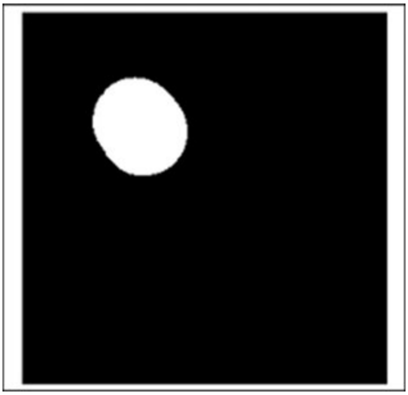
Top-left: original



Top-right: after *blf*



Bottom: after *lak*



41.23 blo

Format	*blo*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Monadic
Function	Expand the central part of the intensity range; level 64 is mapped to 0 and level 192 to 255. Hard limiting is applied at 0 and 255
Definition	C ⇐ 2∗(A − 64) with hard limits placed at 0 and 255
Switch images	Yes
Typical uses	Increasing contrast after high-pass filtering, where intensities tend to be clustered around mid-grey (level 128)
Remarks	Functionally equivalent to *air*(*64*, *192*)

41.24 blp/brp/lbp/ltp/rbp/rtp/tlp/trp

Format	[*x*, *y*] = *blp* [*x*, *y*] = *brp* Etc.
Arguments	None
Output values	*x* X-coordinate of the point found *y* X-coordinate of the point found
Image type	Binary
Type	Image analysis
Function	Find the following points: *blp* – Bottom-left point *brp* – Bottom-right point *lbp* – Left-bottom point *ltp* – Left-top point *rbp* – Right-bottom point *rtp* – Right-top point *tlp* – Top-left point *trp* – Top-right point
Switch images	No
Remarks	Also see *mar*

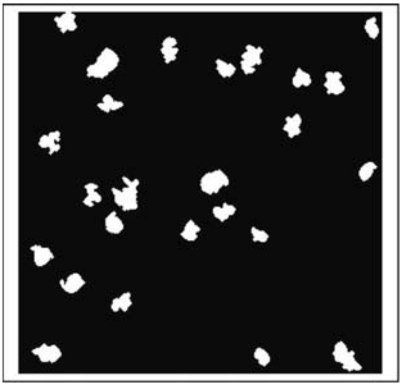
41.25 bnb

Format	*function* [*u*, *v*, *r*] = *bnb*	
Arguments	None	
Output values	u	X-coordinates of a white point in the bridge
	v	Y-coordinates of a white point in the bridge
	r	A measure of the size of the gap that has been bridged
Image type	Binary	
Function	Find the shortest bridge between nearby blobs. The position of the centre of the bridge ([u, v]) is returned, together with the approximate size of the gap between the closest blobs. The centre of the bridge is identified in the output image by a cross	
Switch images	Yes	
Typical uses	Analysing binary images	
Remarks	A C-shaped blob will be detected first, if the gap is smaller than the distance between separate blobs	

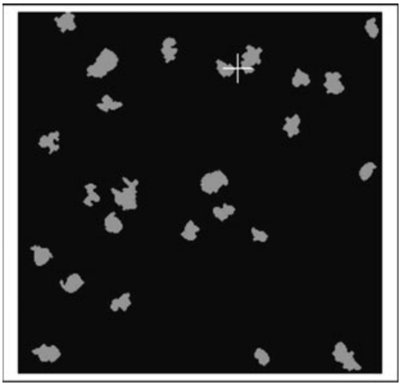
Illustration

Input image	*spn*, *caf*, *enc*, *thr*, *kgr*(*50*), *dil*, *blf* (Collection of 'random' blobs)
Commands	*bnb*, *adi*, *mxi*

Left: original image



Right: result of processing



41.26 bpa/cab/cxa/eab/ecy/eqd/ext/far/oab/mab/sly

Format	$b = bpa(a)$
Arguments	*a* Measurement required (for options, see the table below)
Defaults	Not applicable
Output values	*b* Vector of measurements
Image type	Binary
Type	Binary image measurement
Function	Calculate shape/size parameters of all blobs in a binary image
Definition	The measurement specified by the input parameter a is derived for each blob in the input image. For the measurement options available, see the table below
Switch images	No
Typical uses	Characterisation of multi-blob images, such as those derived from granular materials Analysis of the surface properties of spot-like features on a web or sheet material
Remarks	When the command $q = bpa$(‘*Area*’) is executed, a vector of length *N* is generated that measures the area of each of the (N) blobs in the image Similarly, in every other case, except when the input parameter *a* is equal to ‘*Centroid*’, the output vector *b* contains one measurement value for each blob in the image. For the special case *a* = ‘*Centroid*’, the output vector is of the form $\{X_1, Y_1, X_2, Y_2, X_3, Y_3, \ldots\}$, where $[X_i, Y_i]$ is the centroid of the *i*th blob. Notice that *bpa* is similar to the auxiliary function *blob_parameters*, which is used by the blob-analysis functions *lmi* and *cgr*. However, the latter measure only one blob. Additional functions that are easier to use can be defined in terms of *bpa*:

Name	**Function**	**Implementation**
cab	Centroids	*bpa*(‘*Centroid*’)
cxa	Convex areas	*bpa*(‘*ConvexArea*’)
eab	Euler numbers	*bpa*(‘*EulerNumber*’)
ecy	Eccentricities	*bpa*(‘*Eccentricity*’)
eqd	Equivalent diameters	*bpa*(‘*EquivDiameter*’)
ext	Extent scores	*bpa*(‘*Extent*’)
far	Areas after lakes have been filled	*bpa*(‘*FilledArea*’)
oab	Orientations	*bpa*(‘*Orientation*’)
sly	Solidities	*bpa*(‘*Solidity*’)

The function *mab* measures blob parameters for all blobs. The result is an array with 13 columns and *N* rows, where *N* is the number of blobs in the image

Table: Permitted values for the input parameter, *a*, for command *bpa*

Argument	Measurement (These are calculated for each blob separately)
Area	Number of white pixels
Centroid	Coordinates of the centroid. (Odd-numbered elements of the output indicate the horizontal coordinates; even-numbered elements indicate the vertical coordinates)
ConvexArea	Number of pixels in the convex hull
Eccentricity	Eccentricity of the ellipse that has the same second-moments as the blob. (Eccentricity is the ratio of the distance between the foci of the ellipse and the length of its major axis. It lies within the range [0, 1].)
EulerNumber	One minus the number of lakes ('holes')
Extent	Proportion of the pixels in the minimum bounding box that are also in the blob. (That is, the area of the blob divided by the area of its bounding box)
FilledArea	Number of on pixels after lakes ('holes') have been filled
MajorAxisLength	The length of the major axis of the ellipse that has the same values for the second moments as the blob
MinorAxisLength	The length of the minor axis of this ellipse
Orientation	Orientation of the principal axis (That is the angle between the horizontal axis and the major axis of this ellipse. Measured in degrees)
Solidity	Proportion of the pixels in the convex hull that are also in the blob (This is equivalent to Area/ConvexArea)

Typical output when *bpa* is applied to the image of four metal objects (File number 46. See *ndo.*)

***u* = *bpa*('*Area*')**

```
        u = 4332    4215     4476     2926
```

***v* = *bpa*('*ConvexArea*')**

```
        v = 6337    8455     9535     6006
```

***w* = *bpa*('*Centroid*')**

```
       w = 64.9162 154.9234 133.0643 101.8769 167.1032 238.0487 210.2584 165.8226
```

The measurements are listed in the following order:
Spanner (*wrench*) *3-pointed star* *Con-rod* *Y-shaped part*

Function *mab* (same image)

Area	Convex area	Ecc.	Eul no.	Equiv. diam.	Ext.	Fill. area	Maj. axis	Min axis	Solid.	X centr.	Y centr.	Orient.
4332	6286	1.0	1	74.3	0.5	4332	192.5	041.0	0.7	64.9	154.9	−87.6
4215	8348	0.2	1	73.3	0.3	4215	107.6	106.4	0.5	133.1	101.9	−59.4
4476	9471	0.9	1	75.5	0.3	4476	180.9	071.3	0.5	167.1	238.0	−14.4
2926	5931	0.5	1	61.0	0.3	2926	099.5	083.3	0.5	210.3	165.8	20.0

41.27 bst

See *bcl.*

41.28 cab

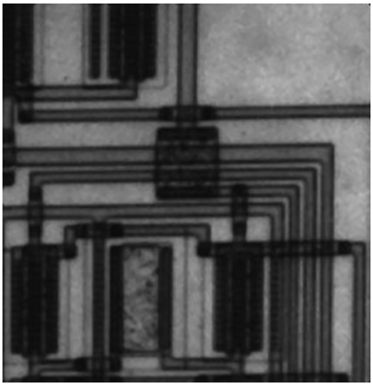
See *bpa.*

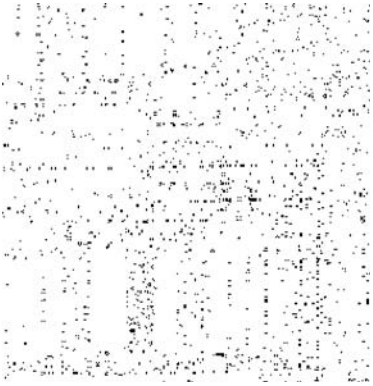
41.29 cae

Format	$b = cae(a)$
Arguments	a Allowed value for the square of intensity difference
Defaults	a 0
Output values	b Number of pixels with similar intensity values
Image type	Grey
Type	Dyadic
Function	Identify and count the points where the square of the difference of intensities in the current and alternate images is less than or equal to a given parameter, a
Definition	$C(i, j) = 255$, if (i, j)th $[c(i, j) - a(i, j)]$^2 $\leq a$ $C(i, j) = 0$, otherwise b is the number of points for which the condition $[c(i, j) - a(i, j)]$^2 $\leq a$ applies
Switch images	Yes
Typical uses	Comparing similar images, identifying their differences
Remarks	If the input parameter (a) is zero, *cae* finds where the images are identical
Illustration	
Input images	Circuit and the same image after applying *mdf* (median filter)
File number	*136*
Command	*mdf*, *cae*(5)

Top-left: original

Top-right: after processing (Black pixels indicate where *mdf* has made a significant change)





41.30 caf

Format *caf*(*a*)

Arguments *a* Filter kernel size

Defaults *a* 7

Output values None

Image type Grey

Type Linear filter

Function Averaging filter within a circular window of diameter *(2a + 1)* pixels

Description A square array of size (2*a* + 1).(2*a* + 1) is computed first. For *a* = 5, this array has the following form

0	0	0	*	*	*	*	0	0	0
0	0	*	*	*	*	*	*	0	0
0	*	*	*	*	*	*	*	*	0
*	*	*	*	*	*	*	*	*	*
*	*	*	*	*	*	*	*	*	*
*	*	*	*	*	*	*	*	*	*
*	*	*	*	*	*	*	*	*	*
0	*	*	*	*	*	*	*	*	0
0	0	*	*	*	*	*	*	0	0
0	0	0	*	*	*	*	0	0	0

where '$*$' represents 255. In general, the array generated by *caf*(*a*) contains a set of non-zero elements arranged to form an approximation to circular disc of radius *a*. This array defines the weight matrix used in a linear convolution filter. Thus, all pixels lying within a disc of radius *a* and centred on pixel (*i*, *j*) are averaged to form the new value for the intensity at (*i*, *j*). The MATLAB code refers to the operator *dcd*(*a*), which draws a solid circular disc of radius *a*, located at the centre of an image of size $a*a$

Switch images Yes

Typical uses Reducing the effects of noise

As part of a high-pass filter:

caf(*m*), *sub*

(*caf* performs low-pass filtering, so subtracting its output from the original image accentuates high spatial frequencies)

caf is also used within a band-pass filter, implemented thus:

caf(*m*), *wri*, *swi*, *caf*(*n*), *rei*, *sub*

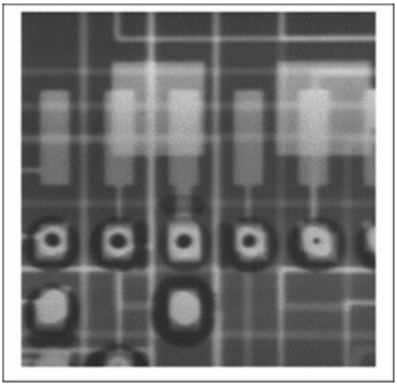
where *m* and *n* are positive integers,

Remarks *caf* performs isotropic low-pass filtering; horizontal and vertical edges are blurred by equal amounts. The effect becomes more pronounced as *a* is increased. Also see *raf*, *lpf*

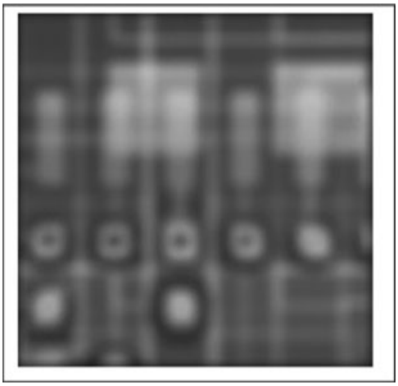
Illustration

Input image	Printed circuit board
File number	135
Command	*caf*(*11*)

Left: original



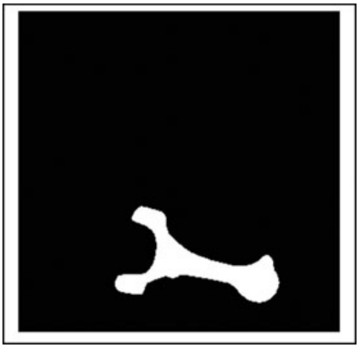
Right: after processing



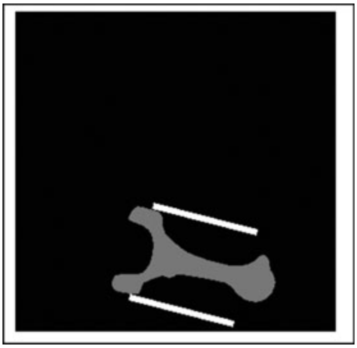
41.31 caliper

Format	p = *caliper*(*w*, *n*)	
Arguments	w	Width of the caliper jaws
	n	maximum opening of the caliper jaws
Defaults	w	50
	n	100
Output values	p	Object diameter
Image type	Binary	
Type	Binary image measurement	
Function	Virtual caliper gauge	
Switch images	Yes	
Typical uses	Measuring object diameter	
Remarks		
Illustration		
Input image	*Conrod* (*one of the objects in image 46*)	
File number	46	
Command	*rni*(*46*), *thr*, *big*, *caliper*(*25*, *100*), *adi*, *mxi*	

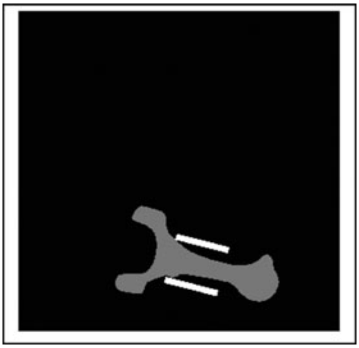
Top-left: original image



Top-right: after processing



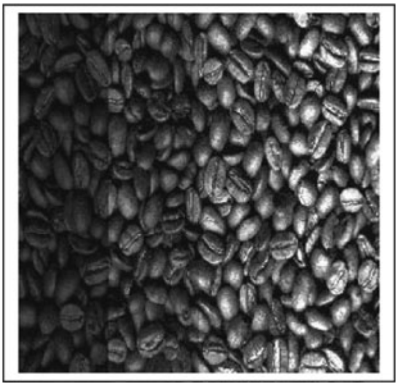
Bottom-left: shorter caliper jaws



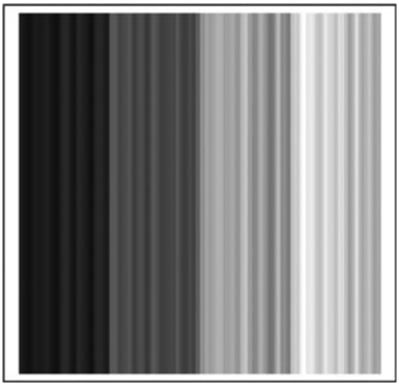
41.32 cav

Format	*cav*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Image measurement
Function	Average for each column in the image
Definition	The *i*th pixel in each row is the average (mean) of the intensities in column *i*
Switch images	Yes
Typical uses	Texture analysis
Remarks	Use *yxt*, *cav*, *yxt* to calculate the average for each row
Illustration	
Input image	Coffee beans (image 4) modified by multiplying by an intensity 'stair-case'.
Image generation	*wgx*, *sca*(*2*), *acn*(*64*), *rni*(*4*), *mul*, *enc*
Command	*cav*

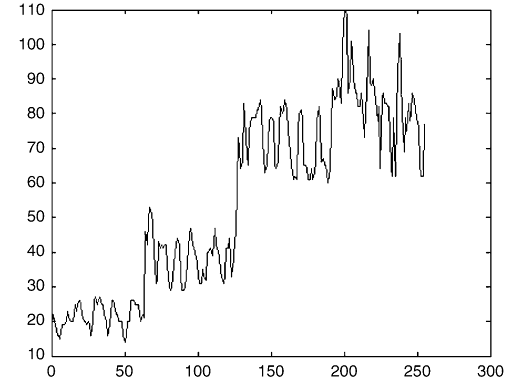
Top-left: original



Top-right: *cav*



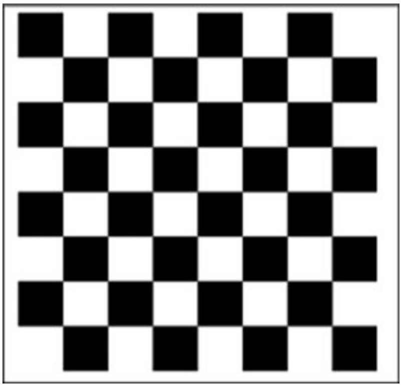
Bottom-left: *cav*, *plt*



41.33 cbd

Format	*cbd*
Arguments	None
Defaults	Not applicable
Output values	None
Type	Drawing and image generation
Switch	Yes
Function	Generate a simple (8∗8) ‘chessboard’ pattern
Switch images	Yes
Typical uses	Testing various image processing functions, such as filters
Remarks	Also see *grd*
Illustration	
Commands	*cbd*

Below: chessboard



41.34 cbl

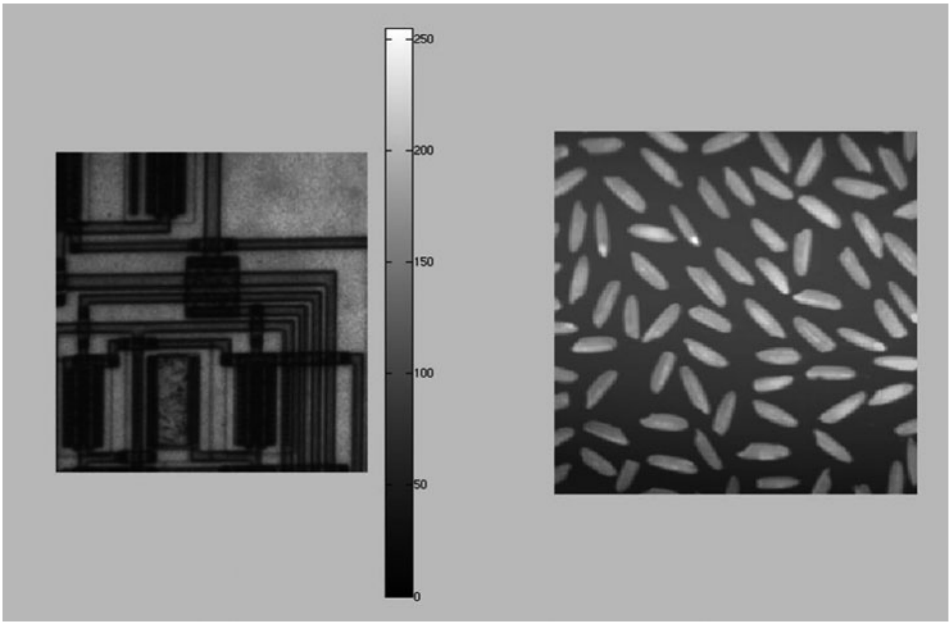
Format	$b = cbl(a)$	
Arguments	a	Connectivity (4- or 8-connected Hence, $a \in \{4, 8\}$)
Defaults	a	8
Output values	b	Number of blobs
Image type	Binary	
Type	Binary image measurement	
Function	Count the number of a-connected ($a \in \{4, 8\}$) blobs in a binary image	
Switch images	No	
Typical uses	Counting blobs. Computing average blob area (using *cwp*, as well)	
Remarks	Notice that *cbl* computes the number of blobs directly, while *eul* computes the Euler number (i.e., the number of blobs minus the number of holes)	

41.35 cbr

Format	*cbr*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Miscellaneous
Function	Draw a colour bar beside the current image
Switch images	No
Typical uses	Monitor set-up. Also, aids understanding of image structure
Remarks	Also see *pxv*

Illustration

Screen shot of *Figure No. 1*. The current image is always displayed on the left and the alternate image on the right



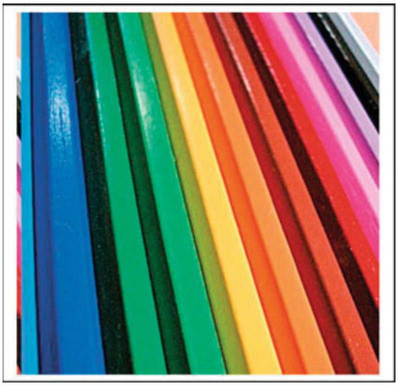
41.36 ccv

Format	[*r*, *g*, *b*] = *ccv*(*x*, *y*)	
Arguments	*x*	X-address of the pixel to be accessed
	y	Y-address of the pixel to be accessed
Defaults	None	
Output values	*r*	R-channel vale value at point [*x*, *y*]
	g	G-channel vale value at point [*x*, *y*]
	b	B-channel vale value at point [*x*, *y*]
Image type	Colour	
Type	Accessing individual pixels	
Function	Find the RGB values [*r*, *g*, *b*] at a given point [*x*, *y*] in the current image	
Switch images	No	
Typical uses	Analysing colour images. Designing colour filters	
Remarks	Use *ccv*, rather than accessing individual pixels of the current image directly, since it follows the QT convention that the x-address precedes the y-address. Also see *civ* and *scv*	

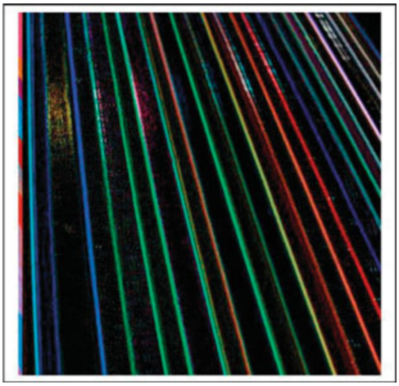
41.37 cdf

Format	*cdf*
Arguments	None
Output values	None
Image type	Colour
Type	Colour image processing
Function	Colour difference between two images. The RGB channels are processed separately. First, the two images are subtracted. Then, the ‘absolute value’ of the difference is calculated
Switch images	Yes
Typical uses	Filtering and edge detection in colour images
Remarks	See *abv* for an explanation of the term ‘absolute value’.
Illustration	
Input image	Pencils and the same image shifted horizontally by 5 pixels
File number	270
Command	*rci(270), pci(‘psw(5, 0)’), cdf, pci(‘enc’)*

Left: original



Right: after processing



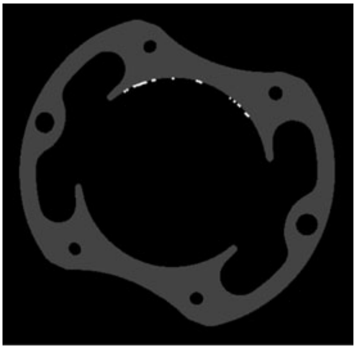
41.38 ceb

Format	*ceb*(*a*)
Arguments	*a* Size limit (number of pixels)
Default	*a* 5000
Output values	None
Image type	Binary edge image
Type	Binary image analysis
Function	Fit a circle to the set of edge points enclosing a blob, using the least-squares algorithm
Switch images	Yes
Typical uses	Analysing a binary image with a single continuous edge contour
Remarks	*fcl* cannot accommodate a closed edge contour, whereas *ceb* can. Also see *dec*

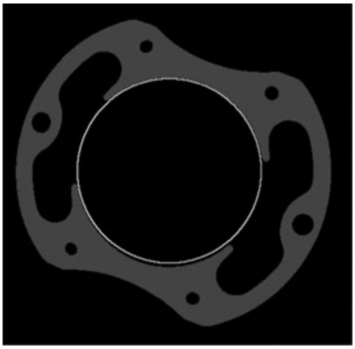
Illustration

Input Image	*Binary image derived from image 174* (*stator for electric motor*), *followed by manual selection of part of the edge*
Commands	*ceb*

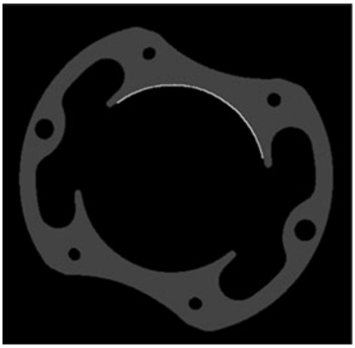
Top-left: white points, starting data for ceb



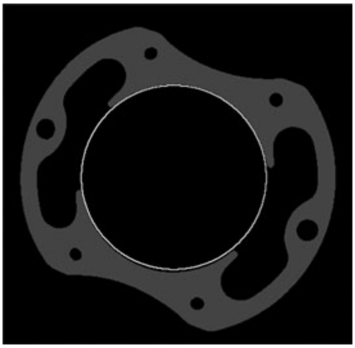
Top-right: output from *ceb* compared to original



Bottom-left: as above, but more white points



Bottom-*right*: circle is slightly better fit



41.39 ced/led/ped/zed

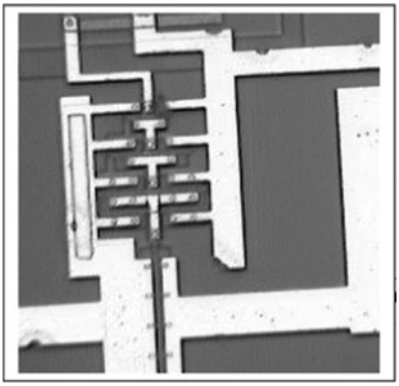
Format	b = *ced*(*a*)
	b = *led*(*a*)
	b = *ped*(*a*)
	b = *zed*(*a*)	

Arguments	*a*	Intensity threshold
Defaults	*a*	Calculated automatically
Output values	Calculated intensity threshold	
Image type	Grey	
Type	Edge detector	
Function	Canny/Laplacian of Gaussian/Prewitt/and Zero-cross edge detector functions, with optional automatic thresholding	
Switch images	Yes	
Typical uses	Highlighting edges (i.e., regions of large intensity gradient)	
Remarks	The following code is representative for all four functions, simply substitute ‘*led*’, ‘*ped*’ or ‘*zed*’ in lines 6 and ‘9’. These are more sophisticated functions than those listed under *edd* and *sed*, since they automatically perform thresholding, thereby generating a binary image. This can be a disadvantage, since the user effectively loses control of the processing and the speed of operation is reduced. All four functions produce similar results. For the ‘log’ and ‘zerocross’ methods, if the input parameter, *a*, is zero, the output image contains closed contours	

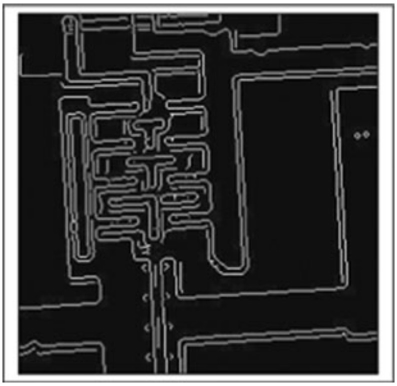
Illustration

Input image	Thick film circuit
File number	137
Command	*ced*

Left: original



Right: after processing



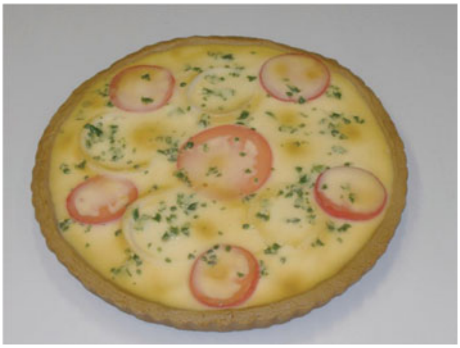
41.40 cen/chq/cgm

Format	*cen*	
	chq	
	cgm(*a*, *b*, *c*)	
Arguments	*a*	R-channel gamma adjustment (*cgm* only)
	b	G-channel gamma adjustment (*cgm* only)
	c	B-channel gamma adjustment (*cgm* only)
Defaults	None	
Output values	None	
Image type	Colour	
Type	Colour image processing	
Function	*Equivalent to cen, chq, cgm*	
Switch images	Yes	
Typical uses	Contrast adjustment for easier viewing/processing	
	Compensating for lighting variations	
Remarks	Also see *pci*	

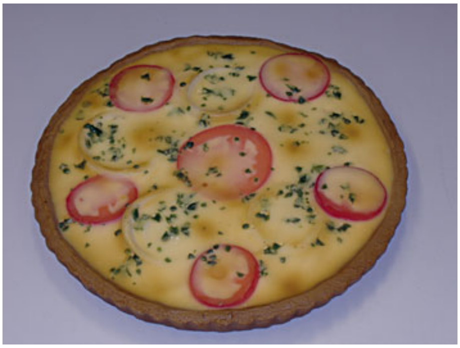
Illustration

Input image	Plastic replica of a pizza
File number	219
Commands	*cen, chq, cgm(0.7,1.2,1.2)*

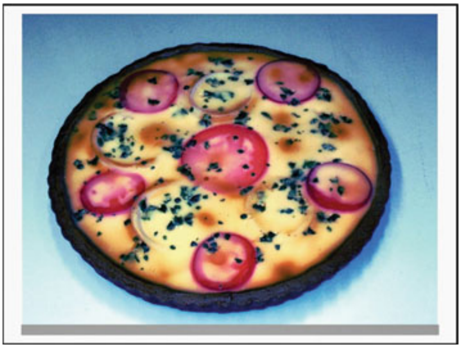
Top-left: original



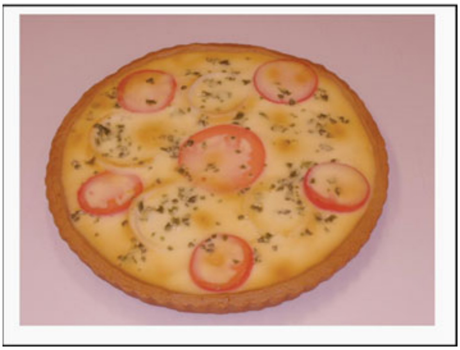
Top-right: after processing, *cen*



Bottom-left: after processing, *chq*



Bottom-right: after processing, *cgm*(*0.7*, *1.2*, *1.2*)



41.41 ceo

Format	*ceo*(*a*)
Arguments	*a* Select the edge detection operator to be applied
Defaults	*a* 0
Output values	None
Image type	Colour
Type	Colour image processing
Function	Apply the edge detector selected by the user to each of the RGB channels separately
Switch images	Yes
Remarks	The input parameter, *a*, selects the function applied:

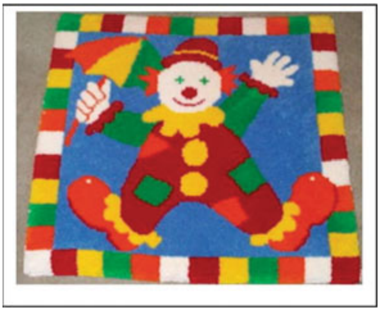
Input parameter, *a*	Edge detector
0 (default)	Dilate, subtract & enhance contrast
1	Sobel
2	Roberts
3	Prewit
4	Canny
Other	Dilate & subtract. Do not enhance contract

Also see *pci*

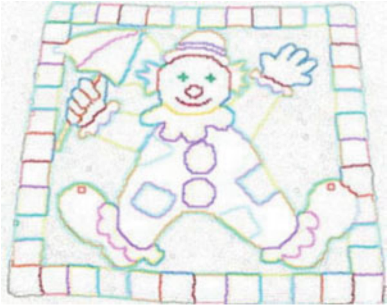
Illustration

Input image	rug
File number	354
Command	*ceo*(*0*)

Left: original



Right: after processing

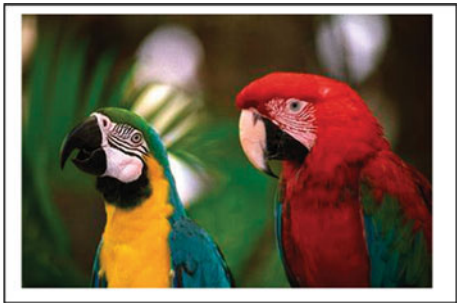


41.42 cga

Format	*cga*(*a*, *b*, *c*)	
Arguments	*a*	Gamma adjustment made to the *R* channel
	b	Gamma adjustment made to the *G* channel
	c	Gamma adjustment made to the *B* channel
Defaults	*b*	*a*
	c	*a*
Output values	None	
Image type	RGB colour image	
Type	Image enhancement	
Function	*3 arguments supplied*: Apply a (different) gamma adjustment to each of the RGB channels separately *1 argument supplied*: Apply the same gamma adjustment to each of the RGB channels	
Typical uses	Image enhancement for visual examination of a scene with low visibility features	
Remarks	Also see *gma*	
Illustration		
Input image	Birds	
File number	144	
Command	*cga*(*1.5*, *1.6*, *1.7*)	

Left: original

Right: after processing



41.43 cgp

Format	$b = cgp(a)$
Arguments	a Grey level, $a \in [0, 255]$.
Defaults	None
Output values	b Number of pixels with intensity a
Image type	Grey-scale
Type	Grey-scale image measurement
Function	Count the number of pixels with intensity a
Switch images	No
Typical uses	Used in conjunction with *ndo*, *cgp* is able to identify the biggest blob, second biggest blob, etc. in a binary image
Remarks	Notice that *cwp* is equivalent to *cgp*(*255*). Also see *hpi*

41.44 cgr

Format	$[a, b] = cgr$
Arguments	None
Defaults	Not applicable
Output values	a X-coordinate of the centroid
	b Y-coordinate of the centroid
Image type	Binary
Type	Binary image measurement
Function	Calculate the coordinates of the geometric centroid of a blob-like figure
Switch images	No
Typical uses	Finding the position of a blob
Remarks	If there is more than one blob, *cgr* computes the centroid of just one: the first blob that is encountered during a top-to-bottom, left-to-right raster scan

41.45 cgr_all/lmi_all/npo_all

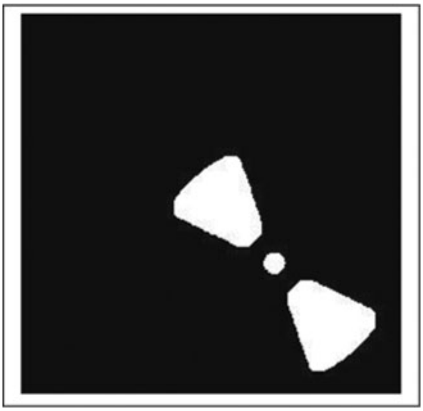
Format	[*x*, *y*] = *cgr_all* [*x*, *y*, *z*] = *lmi_all* *npo_all*	
Arguments	None	
Output values	*x*	X-coordinate, all blobs considered together
	y	Y-coordinate, all blobs considered together
	z	Axis of minimum second moment, all blobs considered together
Image type	Binary	
Type	Binary image analysis/manipulation	
Function	The following calculations/operations are performed taking all non-black pixels into account:	
	cgr_all	Centroid
	lmi_all	Centroid and orientation of axis of minimum second moment
	nxy_all	Normalise, so centroid is at the centre of the image
	npo_all	As *nxy_all* and normalise axis of minimum second moment
Switch images	*cgr_all*	No
	lmi_all	No
	nxy_all	Yes
	npo_all	Yes
Remarks	In the illustration below (at bottom-right), three aligned image features (i.e., small circular hole and two wedge-shaped holes) are used to calculate the parameters needed to normalise the position and orientation of a gear These functions all rely on the calculation of moments, which is performed by *moment*	

Illustration

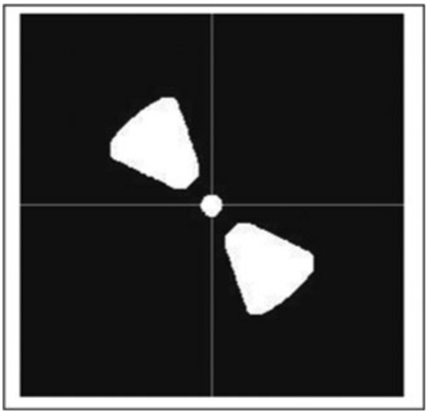
Input image Gear (image 210) after thresholding

Command *thr*(*115*)

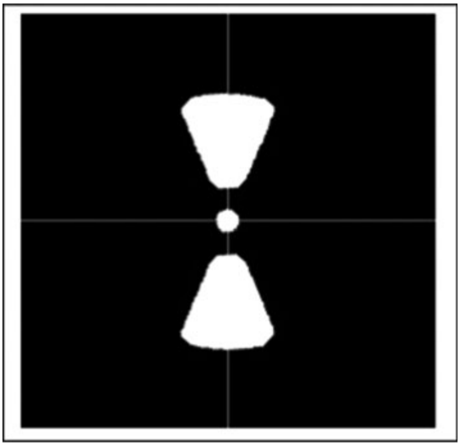
Top-left: 3 features, aligned along a straight line, were selected (Program details are an unnecessary distraction for this illustration)



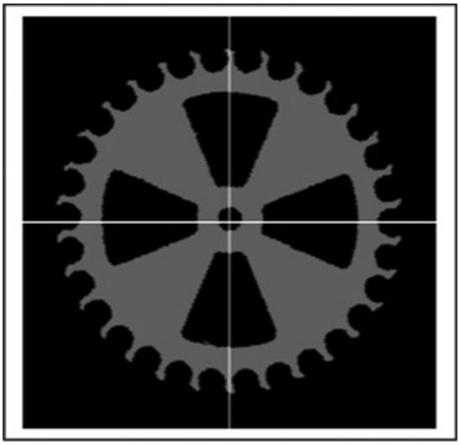
Top-right: *nxy_all* fixes the position of the centroid of the three blobs, but not the orientation



Bottom-left: *npo_all* fixes the position and orientation of the three blobs taken together



Bottom-right: normalised position and orientation of the gear, based on values calculated by *lmi_all* operating on the image at *top-left*



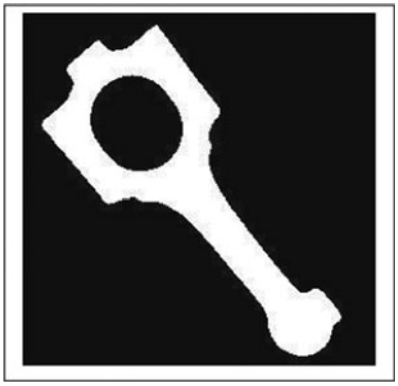
41.46 chu/cvd/bay

Format	*chu*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Convex hull of a single blob
Switch images	Yes
Typical uses	The ratio of the area of a blob to that of its convex hull is a useful shape measure and also forms the basis for a simple test of convexity Convex hull forms the basis of an hierarchical shape description known as the Concavity Tree representation
Remarks	The convex hull of a blob is the area that would be enclosed within a rubber band stretched around it. The convex hull encloses two types of concavity: indentations ('bays') and holes ('lakes') Notice that the function implemented by *chu* calculates the convex hull of only one connected binary object at a time (i.e., the one that is found first by a raster scan running from top to bottom and left to right.) The function *cvd* calculates the convex deficiency. This is the difference between the convex hull and the original blob. The function *bay* isolates the bays (indentations)

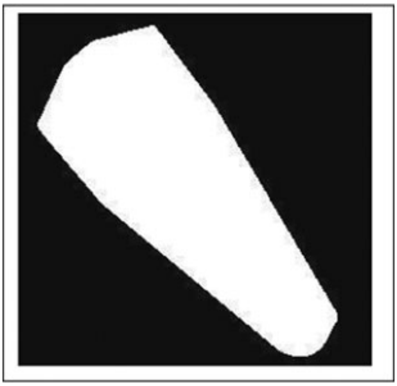
Illustration

Input image	Con-rod
File number	47
Command	*thr*, *chu* (N.B. *thr* avoids the artifacts created by storing a binary image in JPEG format. Although image file 47 is a TIF file now, it was originally generated and stored in JPEG format)

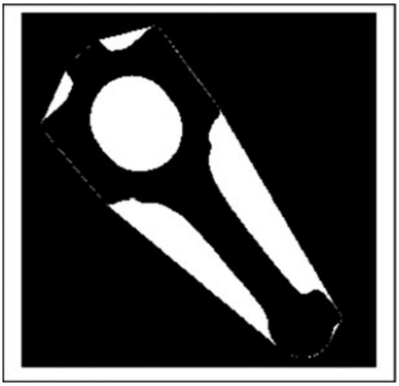
Top-left: original



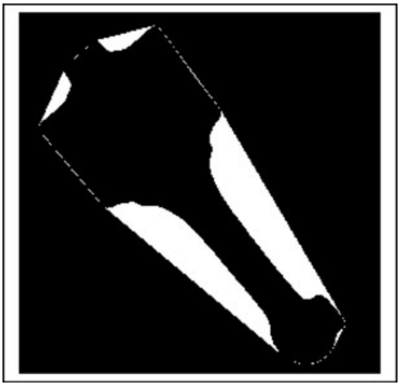
Top-right: after chu



Bottom-left: after *cvd*



Bottom-right: after *bay*



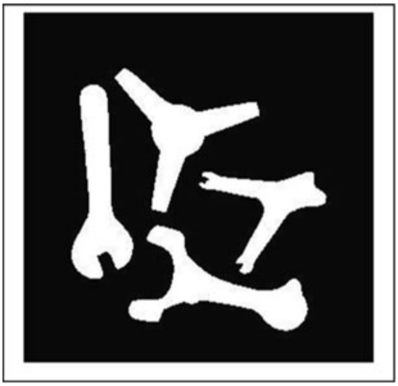
41.47 chu_all

Format	*chu*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Convex hull of a set of separate blobs
Switch images	Yes
Typical uses	Analysing complex objects incorporating several blob-like features
Remarks	*chu* funds the convex hull of a single blob, whereas *chu_all* finds the smallest convex polygon that encloses a set of disconnected blobs

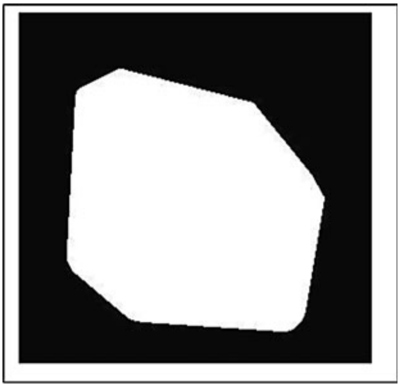
Illustration

Input image	Metal parts
File number	46
Command	*chu_all*

Left: original



Right: after processing



41.48 cig

Format	$b = cig(a)$	
Arguments	*a*	Intensity level
Defaults	*a*	128
Output values	*b*	Number of pixels
Image type	Grey	
Type	Image measurement	
Description	Count points with intensity greater than or equal to a given value	
Switch images	No	
Typical uses	Image analysis	
Remarks	Also see *cgp*	

41.49 cim

Format	$[b,c] = cim(a)$	
Arguments	*a*	Control (switch drawing on/off)
Defaults	*a*	0 (drawing off)
Output values	*b*	X-coordinate of the centre of the image
	c	Y-coordinate of the centre of the image
Image type	Grey	
Type	Image measurement	
Function	Find the coordinates of the centre of the image (if $a = 0$); draw the centre of the image ($a > 0$)	
Switch images	Yes	
Typical uses	Image analysis	
Remarks	Also see *dgw*	

41.50 cir

Format *cir*(*a*, *b*, *c*, *d*)

Arguments *a* X-coordinate of circle centre

b X-coordinate of circle centre

c Radius of circle

d Intensity of circle

Defaults *d* 255

Output values None

Image type Grey or binary

Type Drawing

Function Draw an 'open' circle

Definition A circle centred on [*a*, *b*] and of radius *c* and intensity *d* is superimposed on the current image

Switch images Yes

Typical uses Annotating images for publication

Remarks The program listed below generates a 'circle' consisting of 20000 points. This number can be increased (line 15) to make sure that any gaps are filled, but execution will take longer

41.51 civ

Format *a* = *civ*(*b*, *c*)

Arguments *b* X-address of the pixel to be accessed

c Y-address of the pixel to be accessed

Defaults None

Output values *a* Intensity value at *[b, c]*

Image type Any

Type Accessing individual pixels

Function Find the intensity (*a*) at point [*b*, *c*] in the current image

Switch images No

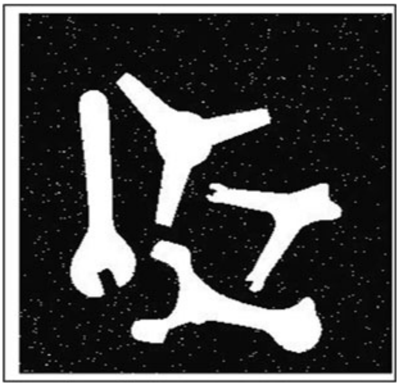
Typical uses Analysing the output of *ftm*, *rdn*, *npo* and other operators that produce an image that is normalised spatially

Remarks Use *civ*, rather than accessing individual pixels of the current image directly, since it follows the QT convention that the x-address precedes the y-address. It also avoids the need to define the current image as *global* via the Command Window

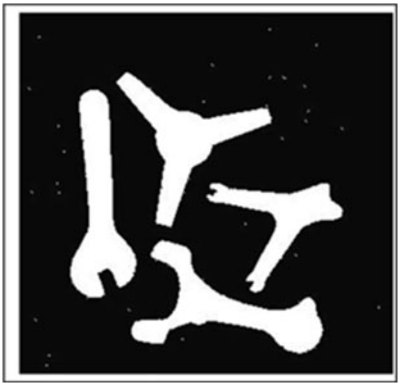
41.52 cln

Format	*cln*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Remove isolated white pixels
Definition	White pixels that have no white 8-neighbours are set to white. All other pixels remain unchanged
Switch images	Yes
Typical uses	Noise reduction
Remarks	Also see *kgr*
Illustration	
Input image	Metal components with superimposed salt-and-pepper noise
Image generation	rni(46), thr, spn, blf
Command	*cln*

Left: original image



Right: *cln*



41.53 cls

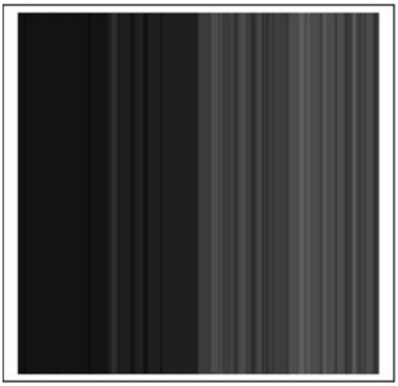
See *dil.*

41.54 cmd

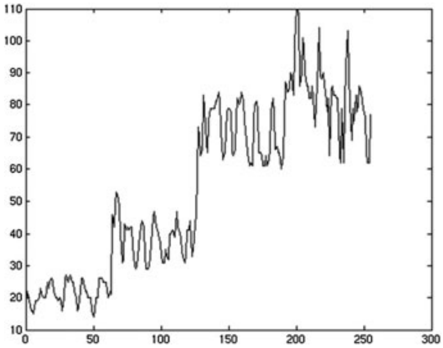
Format	*cmd*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Image measurement
Function	Median intensity for each column in the image
Definition	The *i*th pixel in each row is the median of the intensities in column *i*
Switch images	Yes
Typical uses	Texture analysis
Remarks	Use *yxt*, *cmd*, *yxt* to calculate the median for each row
Illustration	
Input image	Coffee beans (image 4) modified by multiplying by an intensity 'stair-case'.
Image generation	*wgx*, *sca*(*2*), *acn*(*64*), *rni*(*4*), *mul*, *enc*
Command	*cmd*

Top-left: original

Top-right: *cmd*



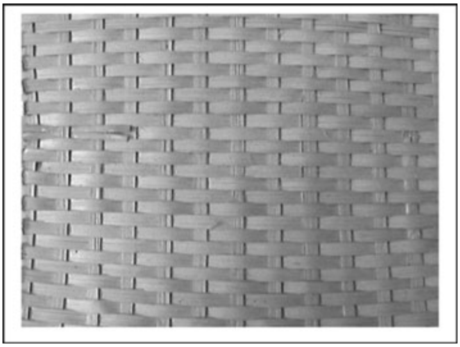
Bottom: *cmd*, *plt*



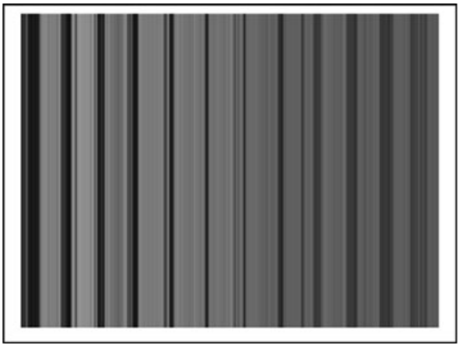
41.55 cmn

Format	*cmn*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Image measurement
Function	Minimum intensity for each column in the image
Definition	The *i*th pixel in each row is the minimum of the intensities in column *i*
Switch images	Yes
Typical uses	Texture analysis
Remarks	Use *yxt*, *cmn*, *yxt* to calculate the minimum intensity for each row
Illustration	
Input image	Wicker-work web
File number	*163*
Command	*cmn*

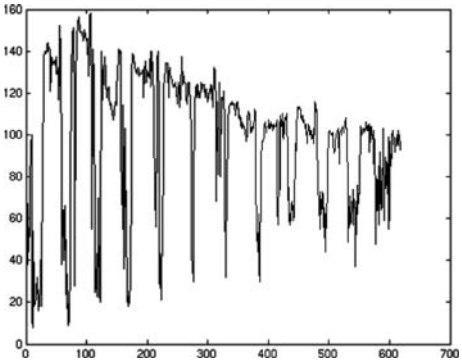
Top-left: original



Top-right: *cmn*



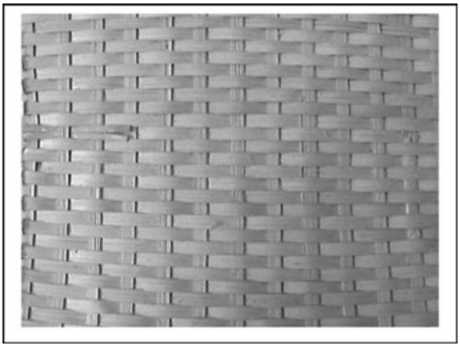
Bottom: *cmn*, *plt*



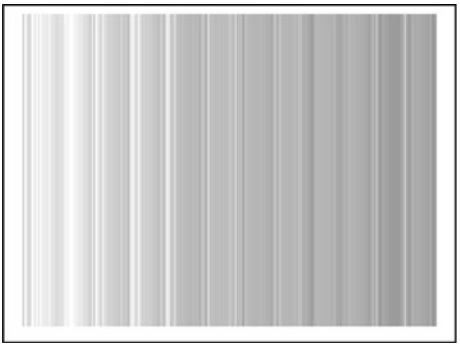
41.56 cmx

Format	*cmx*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Image measurement
Function	Maximum intensity for each column in the image
Definition	The *i*th pixel in each row is the maximum of the intensities in column *i*
Switch images	Yes
Typical uses	Texture analysis
Remarks	Use *yxt*, *cmn*, *yxt* to calculate the maximum intensity for each row
Illustration	
Input image	Wicker-work web
File number	*163*
Command	*cmx*

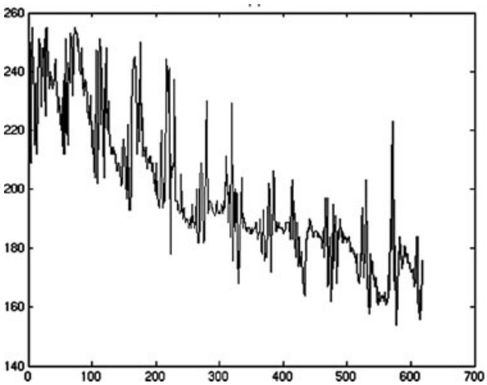
Top-left: original



Top-right: *cmx*



Bottom-left: *cmx*, *plt*



41.57 cnr

Format	*cnr*(*u*, *v*)	
Arguments	*u*	Separation parameter for edge-follower (bugs)
	v	Rescaling parameter, for improving clarity of resulting image
Defaults	*u*	10
	v	20
Output values	None	
Image type	Binary image, single blob, no lakes	
Type	Binary image analysis	
Switch	Yes	
Function	Shade the edge of the blob to highlight corners	
Switch images	Yes	
Typical uses	Feature detection, prior to analysing blob geometry	
Remarks	This operator uses an edge-follower incorporating three “bugs”. The separation of these bugs is controlled by the input parameter *a*. If *a* is large, only major changes in edge direction are detected. Also see *hcd*	

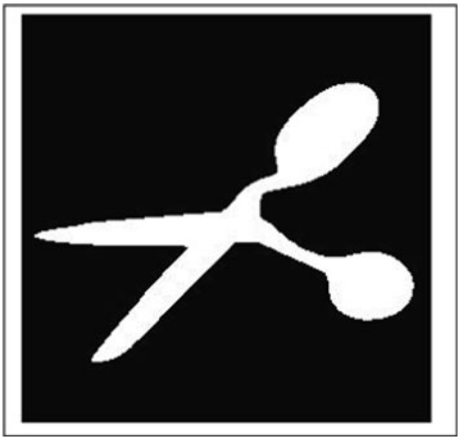
Illustration

Input image *rni*(*49*), *thr*, *blf*

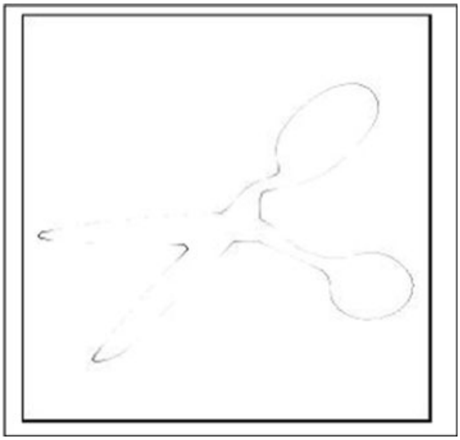
Commands (i) *cnr*, *neg* (*neg* included for sake of illustration)

(ii) *cnr*, *thr*(*100*), *dil*, *rei*('*original*'), *swi*, *adi*, *mxi*

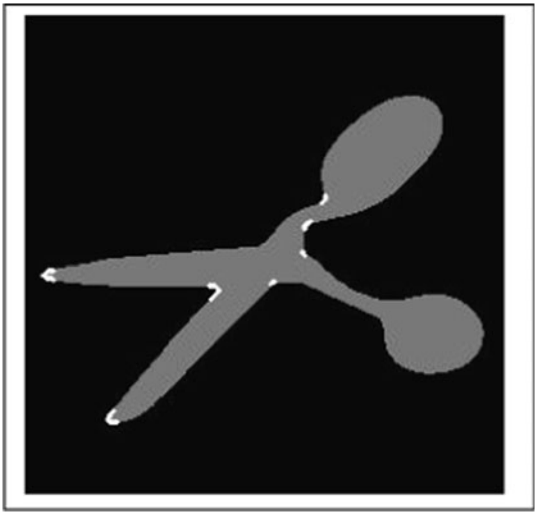
Left: original image



Top-right: *cnr*, *neg*



Bottom: *cnr*, *thr*(*100*), *dil*, *rei*('*original*'), *swi*, *adi*, *mxi*



41.58 cob

Format	*cob*(*a*)
Arguments	*a* Connectivity (4 or 8)
Defaults	*a* 8
Output values	None
Image type	Binary
Type	Miscellaneous
Function	Choose one or more *a*-connected binary objects ($a = 4$ or 8) with the cursor
Switch images	Yes
Typical uses	Interactive selection of blobs in a complex image, prior to more detailed analysis
Remarks	Click on the blob that is to be isolated. Then, press *RETURN*. If more than one blob is to be retained, click on each one in turn, then press *RETURN*. Since it is interactive, the function *cob* is provides a convenient way to avoid a lot of processing, when concentrating on other parts of a complex blob-analysis algorithm

41.59 con/dgr/glc/hgr/lpc/shp/vgr

Format	$[b, c] = con(a)$	
Arguments	*a*	Filter kernel. 1-d or 2-d array
Defaults	None	
Output values	*b*	Multiplicative normalising constant (*k1* in MATLAB listing)
	c	Additive normalising constant (*k2* in MATLAB listing)
Image type	Grey	
Type	Linear filter	

Function: Normalised convolution of a given weight matrix (input array *a*) with the current image. The periphery of the output image is masked to eliminate edge effects

Description: The input array, *a*, defines the weight matrix; the weights can have any real values (positive, zero or negative). First, the normalising coefficients (*k1* and *k2* in the MATLAB function), are computed from the weight matrix. The rescaled weight matrix (*a.k1*) is then convolved with the input image and the constant *k2* is added to the result. Finally, the periphery of the edge is masked (using *edg*), to eliminate edge effects

Switch images: Yes

Typical uses: Low-pass filtering, reducing the effects of noise. High-pass filtering, eliminating slow variations in back-ground intensity

Remarks: Many useful functions can be expressed in terms of *con*:

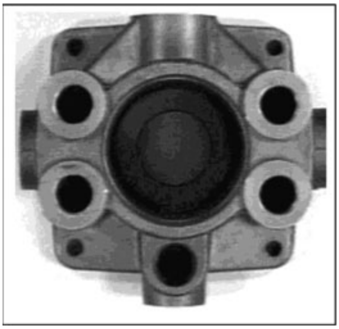
Weight matrix	Operation
[*0, 0, 0; 0, −1, 0; 0, 0, 0*]	Same result as negate (*neg*)
[*0, 0, 0; 1, 0, −1; 0, 0, 0*]	Horizontal gradient (*hgr*)
[*0, 1, 0; 0, 0, 0;0,−l, 0*]	Vertical gradient (*vgr*)
[*−1, −, 1, −1; −1, 8,−1; −1,−1, −1*]	Highlight 1-pixel spots (*lpc*)
[*− l, −, l, −l; −1, 9, −1; −1, −1, −1*]	Sharpen (*shp*)
[*1, 2, 1; 0, 0, 0; −1, −2,−1*]	Horizontal smoothing, vertical difference. (*sed* uses two operators like this)
[*0, 0, 1; 0, 0, 0; 0, 0, 0*]	Shift up one row and right-wards one column
[*1, 0, 0; 0, 0, 0; 0, 0, −1*]	Diagonal gradient (*dgr*)
[*1, 1, 1; 1, 1, 1; 1, 1, 1*]	Count white neighbours. (Binary image operator) Functionally equivalent to *cnw*, *enc*
[*1, 1, 1; 1, −1, −1; 1, −1, 1*]	Detects *top-left* corners. Use *thr*(*255*) after *con*

Note: In some versions of QT for MS-WINDOWS, the mnemonic *con* causes problems and is renamed *glc*.

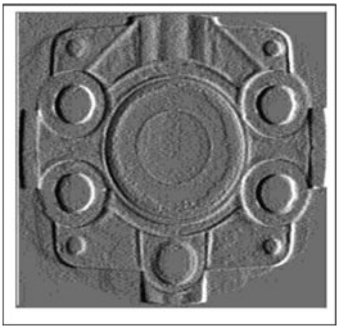
Illustration

Input image	Hydraulics component
File number	37

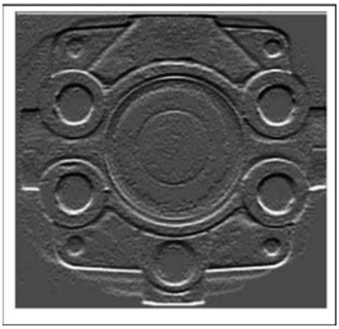
Top-left: original image



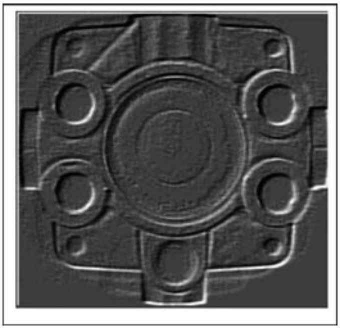
Top-right: *hgr*



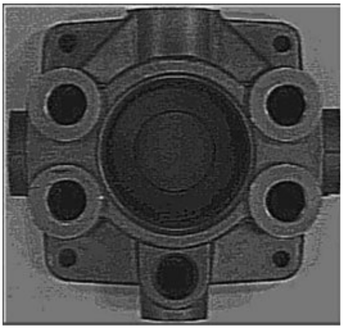
Centre-left: *vgr*



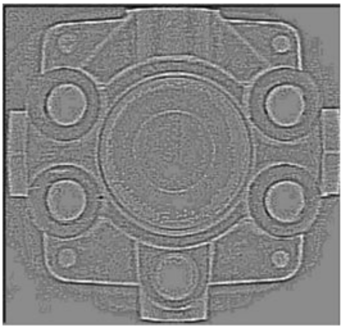
Centre-right: *dgr*



Bottom-left: *con*([−1,−1,−1; −1, 9,−1; −1,−1,−1])



Bottom-right: *con*([−1,−1,−1; −1, 8,−1; −1,−1,−1])



41.60 cpy

Format	*cpy*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Miscellaneous
Function	Copy the current image to the alternate image

41.61 crk

See *dil.*

41.62 crp

Format [*a*, *b*, *c*, *d*] = *crp*(*a*, *b*, *c*, *d*)

Arguments *a* X-coordinate of the left-hand side of the cropping rectangle

b Y-coordinate of the top of the cropping rectangle

c Width of the cropping rectangle

d Height of the cropping rectangle

Defaults *No arguments supplied*: Use the cursor to define the cropping rectangle

Output values *a* X-coordinate of the left-hand side of the cropping rectangle

b Y-coordinate of the top of the cropping rectangle

c Width of the cropping rectangle

d Height of the cropping rectangle

Image type Grey-scale or binary

Type Miscellaneous

Function Crop the image; keep only those pixels that lie within the cropping rectangle

Definition *No arguments specified*: Cursor defines diagonal corners of the cropping rectangle

Four arguments specified: Crop the image to the specified rectangle

Switch images Yes

Typical uses Defining a region of interest (ROI), so that subsequent processing is faster

Remarks The cropping rectangle can be defined interactively by the user, static (fixed by specifying constant values within the program), or dynamic (the input parameters [*a*, *b*, *c*, *d*] are calculated within the program)

Illustration

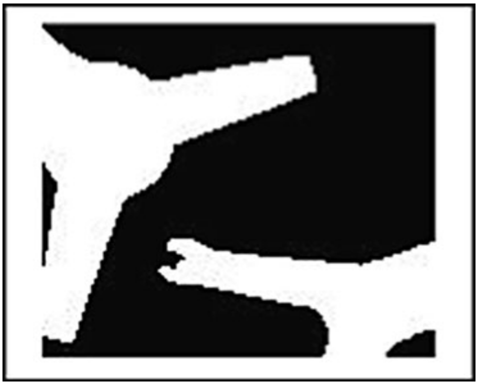
Input image Metal components

File number 46

Command *crp* (User selects the region of interest with the cursor)

Left: original image

Right: *crp*



41.63 crs/dcr/dsq

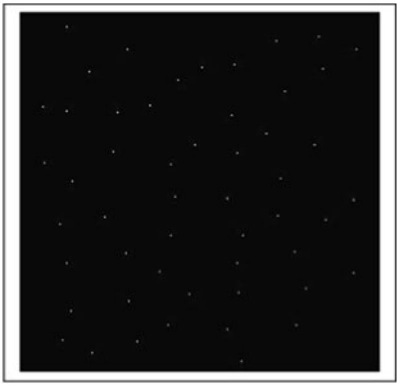
Format	*crs*(*a*) *dsq*(*a*) *dcr*(*a*)
Arguments	*a* Size of symbol to be drawn
Defaults	*a* 3
Output values	None
Image type	Binary image containing one or more isolated white pixels
Type	Drawing
Function	Replace isolated white pixels by symbols that are easier to see: up-right cross (*crs*), diagonal cross (*dcr*), or square (*dsq*)
Switch images	Yes
Typical uses	Displaying results, preparing documents
Remarks	Some operations (e.g., *shk*) generate single, isolated pixels that are difficult to see, particularly. These three functions are used to display them as small symbols that are easier to see

Illustration

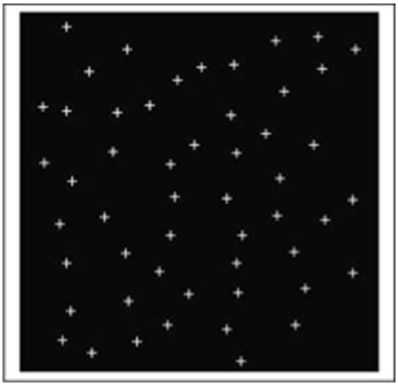
Image generation *rni*(*3*), *enc*, *thr*(*97*), *kgr*(*50*), *rbe*, *shk*

Commands (*i*) *crs*(*3*)
(*ii*) *dcr*(*3*)
(*iii*) *dsq*(*3*)

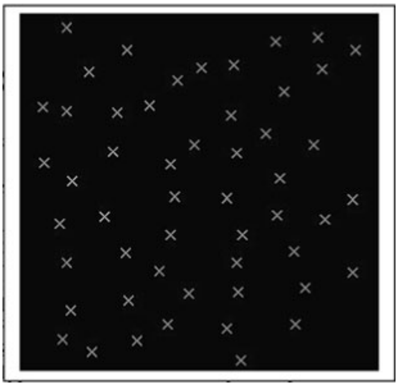
Top-left: original image



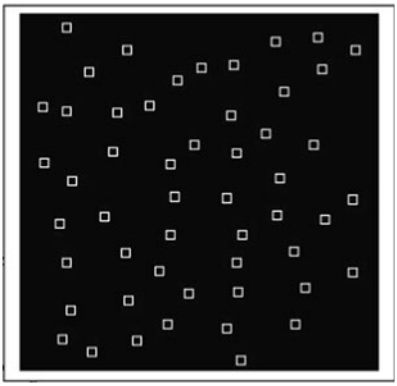
Top-right: up-right crosses, *crs*



Bottom-left: diagonal crosses, *dsq*



Bottom-right: squares, *dsq*



41.64 cse

Format	*b* = *cse*(*a*, *b*)
Arguments	*a* Structuring element type *b* Structuring element size
Defaults	None
Output values	Structuring element: a square logical array, consisting of 0s and 1s
Image type	None
Type	Morphology
Function	Generate a structuring element for either dilation (*gbd*) or erosion (*gbe*)
Switch images	No
Typical uses	Used only in conjunction with *gbd* or *gbe*
Remarks	The function *cse* can be used to generate several frequently used structuring elements:

Input, a	*Structuring element*
1	Horizontal line
2	Vertical line
3	Diagonal line (top-left to bottom-right)
4	Diagonal line (top-right to bottom-left)
5	Up-right cross
6	Diagonal cross
7	Open square
8	L-shape (L is upside-down):
9	V-shape (angle 45°)
10	V-shape (angle 90°)
11	V-shape (angle 135°)
12	Open diamond
13	Open circle

cse has little use apart from generating structuring elements for *gbd*/*gbe*. It is possible to generate structuring elements simply by entering the array via the keyboard, or combine two templates of the same size using a script:

```
a = cse(6, 15)      % Diagonal cross SE, 15*15 pixels
b = cse(7, 15);     % Open squares SE, 15*15 pixels
c = a | b;          % Logical OR of SEs a and b
gbd(c)              % Dilation. Alternatively, use gbe (erosion) here
```

The MATLAB function *strel* is also able to creating structuring elements, including multiple lines, diamond, rectangle, disc and octagon

Also see *gbd* and *gbe*

41.65 csg

Format *csg*(*a*)

Arguments *a* Enable/disable superimposition of plots and control colour of plots

Defaults *a* 0 (plot in red and clear previous plots)

Image type Colour

Type Colour image analysis

Function The user first draws a closed polygonal mask over the image. The colours of pixels within this region are represented by a cloud of points in RGB space. The user is then able to explore the 3D scattergram interactively, using the mouse to choose the viewing point (This is a standard MATLAB feature)

Switch images Yes

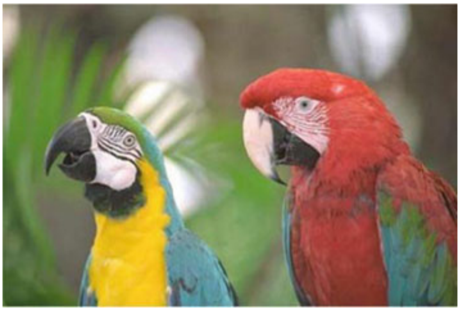
Remarks This function is useful for investigating the clustering of points in RGB space. *csg* is an aid to understanding, particularly when designing colour recognition systems (Also see *pgn* and *mci*)

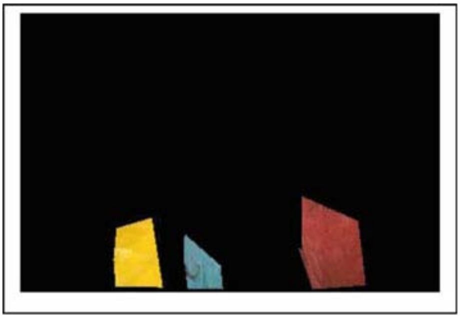
Illustration

Input image	Birds
File number	74
Commands	*rni*(*74*), *csg*(*0*), *wri*(*1*), *rni*(*74*), *csg*(*2*), *rei*(*1*), *mxi*, *wri*(*1*), *rni*(*74*), *csg*(*4*), *rei*(*1*), *mxi*

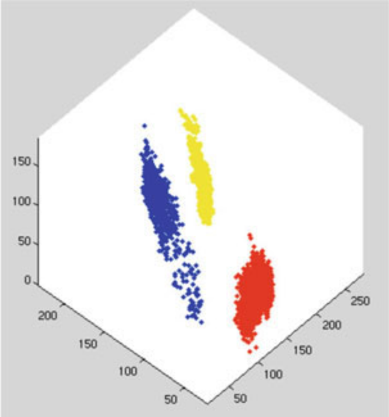
Top-left: original colour image

Top-right: mask regions selected with the mouse





Bottom: RGB scattergram. Notice that there are three clusters; one cluster is generated by each of the three masked regions. Since these clusters are well separated, it is a trivial exercise to design a system/program to recognize these particular samples of red, yellow and blue



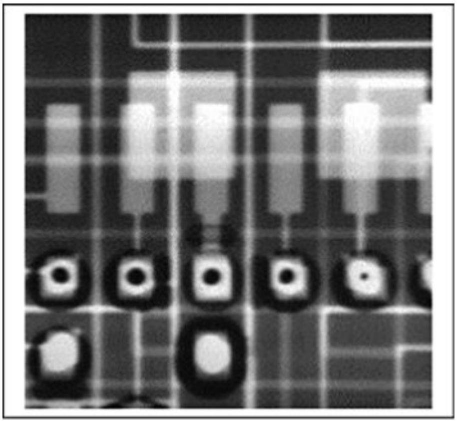
41.66 csh/rsb

Format	*csh*(*a*) *rsb*	
Arguments	*a*	Index number of column to be copied (*csh* only)
Defaults	*a*	Index of right-most column (*csh* only)
Output values	None	
Image type	Grey-scale or binary	
Type	Global transform	
Function	*csh*:	Copy given column to all other columns; spread this column horizontally
	rsb:	Copy the bottom row into every other row
Switch images	Yes	
Typical use	Drawing an intensity profile as an image	
Remarks	Also see *kgr*	

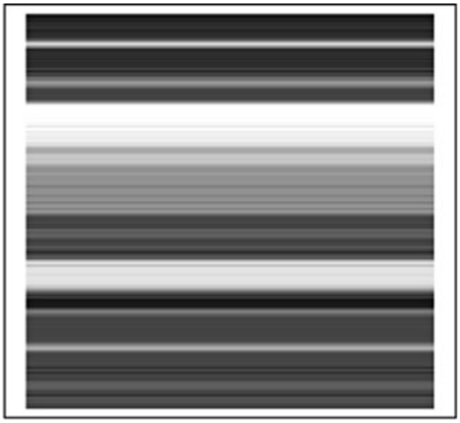
Illustration

Input image	Printed circuit board, x-ray image
File number	135
Commands	*enc, csh*

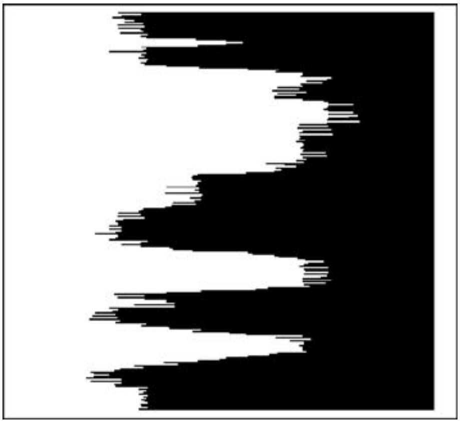
Top-left: original image



Top-right: *enc, csh*



Bottom-left: *[a, b] = cim, csh(a), wgx, sub, thr*



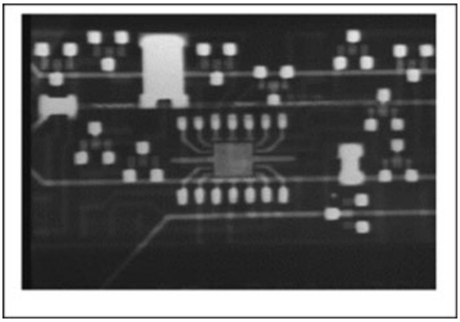
41.67 csi

Format	*[w, k1, k2] = csi(a, b, c, d)*	
Arguments	*a*	Processing window, X-coordinate of top-left-most point
	b	Processing window, Y-coordinate of top-left-most point
	c	Processing window, width
	d	Processing window, height
Defaults	None	
Output values	*w*	Convolution weight matrix
	k1	Normalisation coefficient (See *con*)
	k2	Normalisation coefficient (See *con*)
Image type	Grey scale or binary	
Type	Linear filter	
Switch	Yes	
Function	Convolve a sub-image with the whole image	
Definition	Crop the input image by selecting the rectangle defined by *[a, b, c, d]*. Use this sub-image to generate a weight matrix (*w* in the MATLAB listing). Convolve this with the (whole) input image	
Switch images	Yes	
Typical uses	Identifying repeated small features	
Remarks	Use *crp* to select the cropping rectangle	

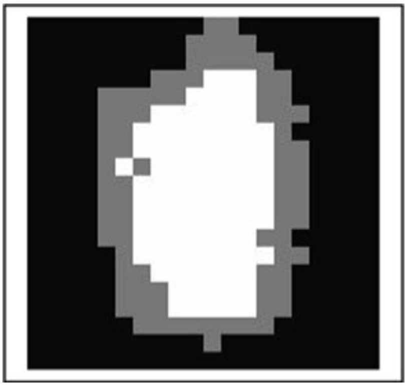
Illustration

Input images PCB x-ray
File numbers 96
Command: *csi*(*140*, *160*, *20*, *20*)

Top-left: original

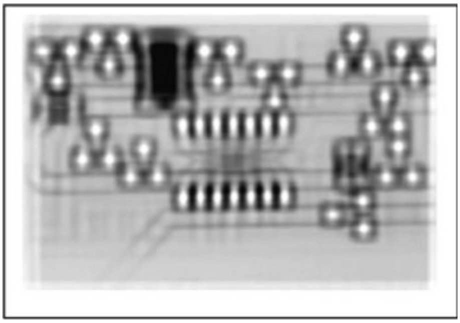


Top-right: weight matrix generated by *csi*(*140*, *160*, *20*, *20*)

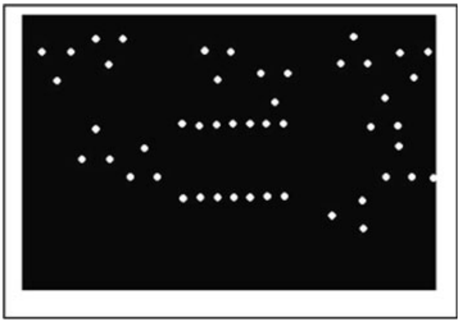


Key	
Intensity	**Weight**
Black	−1
Grey	0
White	+1

Bottom-left: after *csi*



Bottom-right: peak intensities, found by thresholding



41.68 csk

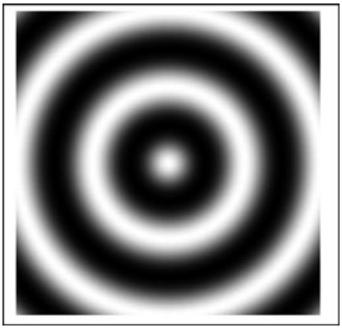
Format	*csk*
Arguments	None
Output values	None
Image type	Any
Type	Stack operator
Function	Clear the image stack. The image files are not destroyed; each image in the stack (i.e., *stack_image*(*i*), where *i* = *0*, *2*, .., (*stack_size-1*)) is filled with Gaussian noise. These images are all different
Switch images	No
Remarks	Also see *rsk*

41.69 csp

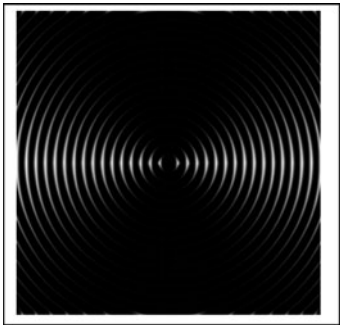
Format	*csp*(*a*, *b*)	
Arguments	*a*	Wavelength
	b	Image size
Default	*a*	Image size/2
	b	Size of current image (larger of height and width)
Image type	Grey scale	
Type	Image generation	
Switch	Yes	
Function	Generate a radially symmetric pattern in which the intensity varies as a cosine function of the distance from the centre of the image	
Switch images	Yes	
Typical uses	Testing/demonstrating image convolution filters and morphology operators	

Illustration

Left: *csp*



Right: *csp*(*16*, *512*), *neg*, *dil_r*(*15*, *3*), *neg*



41.70 ctp

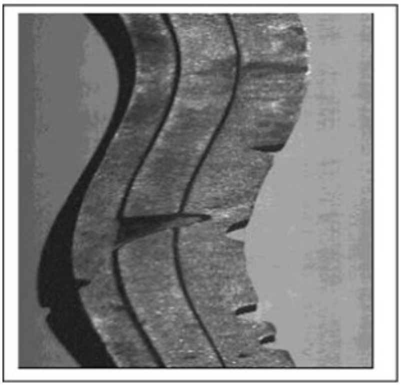
Format	*ctp*(*a*, *b*)	
Arguments	*a*	X-coordinate for the pivotal point for the axis transformation
	b	Y-coordinate for the pivotal point for the axis transformation
Defaults	*a*	X-coordinate of the centre of the image
	b	Y-coordinate of the centre of the image
Output values	None	
Type	Image warping	
Switch	Yes	
Function	Cartesian-to-polar coordinate axis transformation	
Switch images	Yes	
Typical uses	Transforming an image created using a line-scan camera, with the widget mounted on a turntable, so that it appears more natural. For example, a circular object looks circular.	
Remarks	In the illustration below, the black triangular regions at the corners are artifacts of the mapping process and should be ignored. (No information is available for these areas, so they are arbitrarily assigned the value zero.) The centre of the turntable is at the centre of this image, Hence, the displacement of the widget centre relative to that of the turntable can be estimated. *ctp* and *ptc* implement inverse functions	

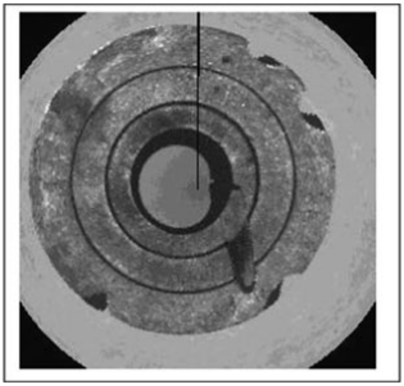
Illustration

Input image	Line-scan camera viewing a circular component mounted on a turntable
File number	99
Commands	*yxt*, *ctp*

Below: original image

Right: processed image

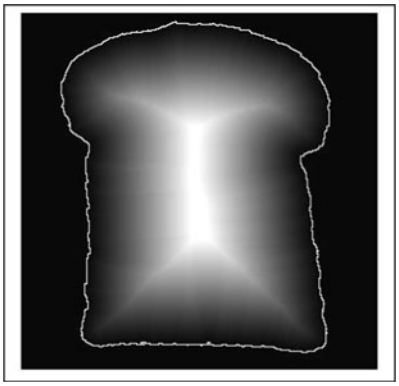




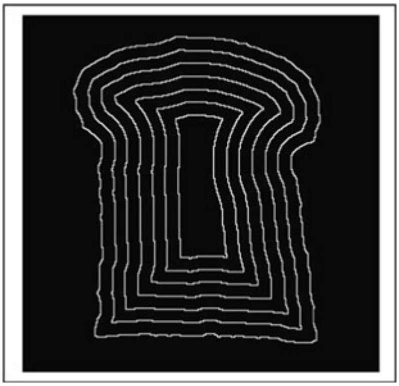
41.71 ctr

Format	*ctr*
Arguments	*None*
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Image analysis
Switch	Yes
Function	Draw intensity contours (isophotes) in the current image
Typical uses	Visualising slow intensity variations that are difficult to see otherwise
Remarks	Also see *iso*
Illustration	
Input image	Slice of bread (file number 45), after grass-fire transform (*gft*)
Image generation	*rni*(*45*), *gft*, *enc*
Commands	*ctr*

Left: original (slice outline added for clarity)



Right: after processing



41.72 cur

Format	*[a, b, c] = cur*
Arguments	None
Defaults	Not applicable
Output values	*a* X-coordinate
	b Y-coordinate
	c Intensity value
Image type	Grey or binary
Type	Measurement and analysis
Function	Find the position coordinates and intensity at a point selected interactively, with the cursor
Switch images	No
Typical uses	*cur* is used principally as an aid to understanding the structure of an image and in guiding algorithm design
Remark	The values of *a*, *b* and *c* are defined by the latest clicked position of the cursor before the user presses RETURN

41.73 cwp

Format	*a = cwp*
Arguments	None
Defaults	Not applicable
Output values	*a* Number of white pixels
Image type	Binary
Type	Binary image measurement
Function	Count the number of white pixels in a binary image
Switch images	No
Typical uses	Measuring the area of a single blob, or the average area of a number of blobs (Use *cbl* to count them)
Remarks	Also see *cgp*

41.74 cxa

See *bpa.*

41.75 dab

Format *dab*(*a*)

Arguments *a* *QT command that is to be performed on all blobs in the current image*

Defaults None

Output values None

Image type Binary

Type Controls image processing

Function Perform the image processing operation defined by input parameter *a*, on all blobs

Switch images Yes

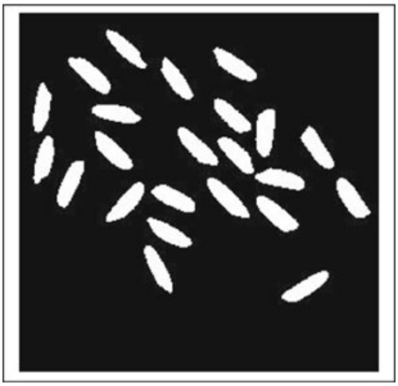
Typical uses Analysing images containing multiple blobs

Remarks Notice that *dab*('*chu*') draws the convex hull of each blob separately; it does not form the convex hull of the complete collection. On the other hand, *chu* draws the convex hull of just one blob. Also see *cgr_all*, *nxy_all*, *npo_all*,

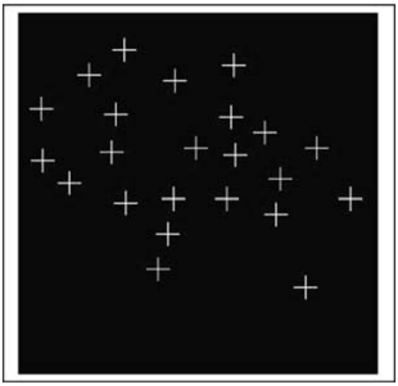
Illustration

Input images	(i) *rni*(*3*), *enc*, *thr*, *rbe*, *kgr*(*300*)
	(ii) *rni*(*46*), *thr*
Commands	(i) *[a, b]* = *cim*; *dab*('*dcg*')
	(*ii*) *dab*('*chu*')

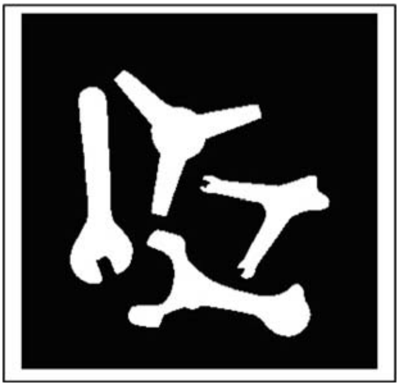
Top-left: rice grains after preprocessing



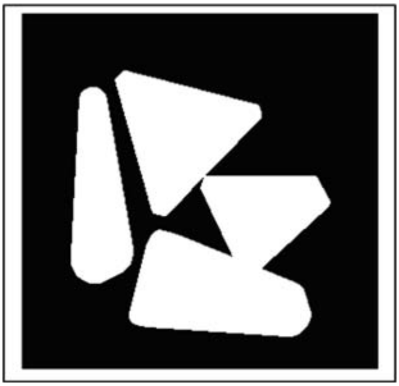
Right: after *dab*('*dcg*')



Bottom-left: Four objects (image 46)



Right: *dab*('*chu*')



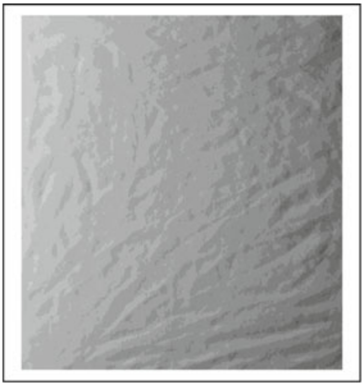
41.76 dbn

Format	*dbn*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Image filter
Switch	Yes
Function	Direction of brightest neighbour
Definition	Each pixel is assigned a value indicating the direction of the maximum intensity among its 8-neighbours
Typical uses	Enhancing low-contrast intensity variations that are difficult to see otherwise
Remarks	It may be beneficial to apply a low-pass filter (e.g., *raf*, *caf*), or median filter (*mdf*) to attenuate camera noise before using *dbn*

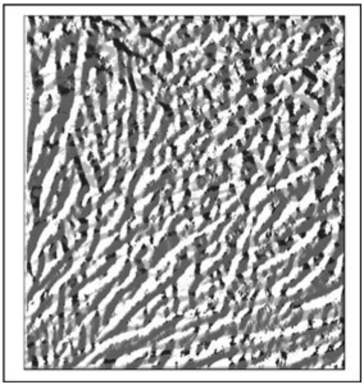
Illustration

Input image	Creased fabric (file number 28), followed by *enc*, *caf*
Image generation	*rni*(*28*), *enc*, *caf*
Commands	*dbn*, *enc*

Left: original



Right: after processing



41.77 dcg

Format	*dcg*
Arguments	None
Defaults	None
Output values	None
Image type	Binary
Type	Drawing
Function	Draw a small cross at the centroid of a blob. If there is more than one blob, the first one found during a raster scan is analysed
Switch images	Yes
Typical uses	Displaying processing results to the user
Remarks	Use *dab*('*dcg*') to show the centroids of all blobs in the input image. (See *dab*)

41.78 dci

Format	*dci*(*a*)	
Arguments	*a*	Control cross size
Defaults	*a*	0 (Draw a large cross)
Output values	None	
Image type	Grey scale or binary	
Type	Image annotation	
Function	Draw a cross (small if $a = 1$; large if $a = 0$) at the centre of the image	
Switch images	Yes	
Typical uses	Emphasising results for the user	
Remarks	Also see *dcl*	

41.79 dcl

Format	*dcl*(*x*, *y*, *a*)	
Arguments	*x*	X-coordinate of the centre of the cross
	y	Y-coordinate of the centre of the cross
	a	Size of the cross
Defaults	*a*	8
Output values	None	
Type	Drawing and image generation	
Switch	Yes	

Function: Draw an 'up-right' cross at a given point, *[a, b]*. The size of the cross is determined by the control parameter *a*

Switch images: Yes

Typical uses: Indicating the position of features detected during processing, e.g., centroid

Remarks: The length of the arms of the cross is given by *a* and may exceed the width and/or height of the image. The arms are one pixel wide. The command sequence *[p, q]* = *cgr*, *hin*, *dcl*(*p*, *q*) plots the position of the centroid of a blob. To draw a diagonal cross, lines 8 and 9 in the MATLAB program should be changed to:

$$vpl((x - a), (y - a), (x + a), (y + a), 255);$$
$$vpl((x + a), (y - a), (x - a), (y + a), 255);$$

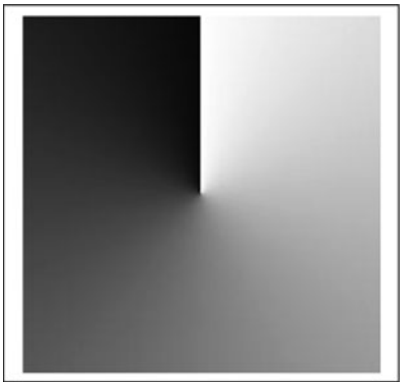
41.80 dcw

Format	*dcw*(*u*, *v*)	
Arguments	*u*	X-coordinate of the centre or 'pivotal point' of the circular wedge
	v	Y-coordinate of the centre or 'pivotal point' of the circular wedge
Defaults	*u*	Centre of the image
	v	Centre of the image
Output values	None	
Type	Drawing and image generation	
Switch	Yes	
Function	Draw a circular wedge centred at *[u, v]*.	
Switch images	Yes	
Typical uses	Measuring angles of point features in an image, relative to some reference point	
Remarks	A circular wedge is an image in which the intensity of a pixel *[p, q]* is proportional to the angle of that line through *[p, q]* and the given point *[u, v]* (the centre or 'pivotal point'), relative to the vertical axis. A set of binary 'wheel spokes' can be drawn using *dcw*, *sca*(4), *sub*, *enc*, *thr*	

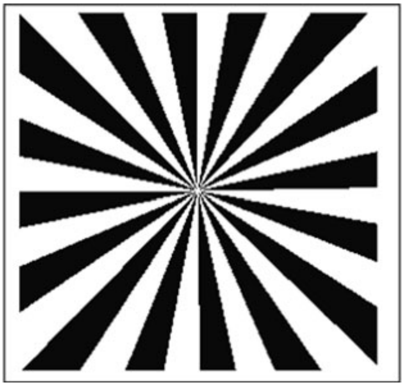
Illustration

Commands Left: *dcw*. *Right*: *dcw*, *sca*(4), *sub*, *enc*, *thr*

Left: circular intensity wedge



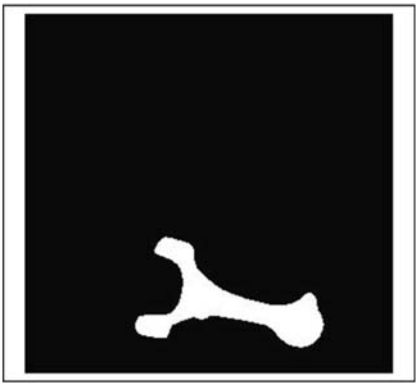
Right: 'Wheel spokes'



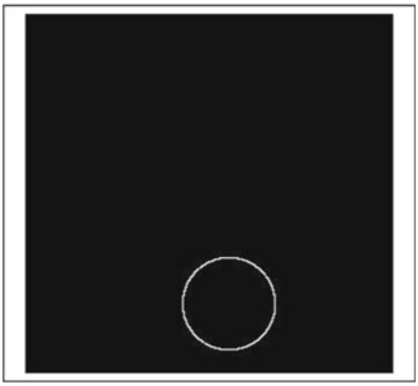
41.81 dec

Format	*dec*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Drawing
Function	Draw an ‘open’ circle of the same area as the blob in a binary image
Definition	Locate the centroid, [*a*, *b*], and calculate the radius (*c*) of the circle that has the same area as the given blob. Draw the ‘open’ circle centred on [*a*, *b*] and of radius *c*, against a white background
Switch images	Yes
Typical use	Simplifying images, when size (area), rather than shape is important. This may be useful for display purposes
Remarks	The circle can be filled using *blf*. Also see *eqd*
Illustration	
Input image	Con-rod: image with four metal components (file number 46) with *big* applied
Image generation	*rni*(*46*), *thr*, *big*
Commands	*dec*

Left: original image



Right: *dec*



41.82 delay

Format	*delay*(*a*)
Arguments	*a* Delay duration, in seconds
Defaults	None
Output values	None
Image type	Not relevant
Type	Program control
Function	Delay the program execution by a defined period (*a* seconds)
Switch images	No
Typical uses	Controlling external devices
Remarks	At any moment of his/her choosing, the user can terminate the timer and recover control, by pressing CTRL/C

41.83 dev

Format	$a = dev$
Arguments	None
Defaults	Not applicable
Output values	*a* Standard deviation of the intensity
Image type	Grey-scale
Type	Grey-scale image measurement
Function	Find the standard deviation of the intensity over the whole image
Switch images	No
Typical uses	Image enhancement. Choosing a threshold parameter
Remarks	Also see *avg* and *gli*

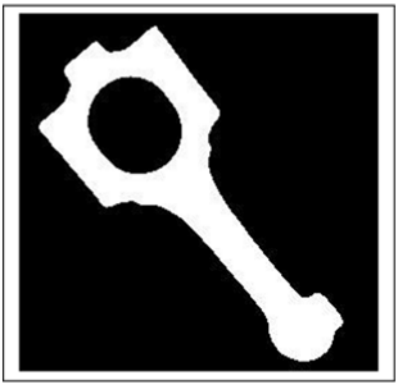
41.84 dfc

Format	*dfc*
Arguments	None
Output values	None
Image type	Binary
Type	Binary image transformation/analysis
Function	Set the intensity each white point to a value equal to the Euclidean distance from the centroid of all white pixels
Switch images	Yes
Typical uses	Object recognition
Remarks	The histogram of grey-level values generated by *dfc* provides a useful way to represent a blob independently of its orientation. Also, consider two sets of spots lying on concentric circles of different radii. Using *dfc*, it is possible to shade the spots, so that one ring can be distinguished from the other, by simple thresholding. Also see *rlc*, *gft*, *dfp* and *pon*

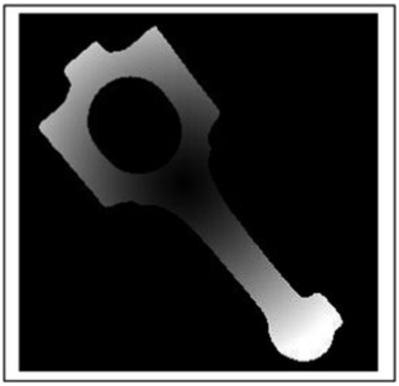
Illustration

Input image	Con-rod, after applying thr to eliminate JPEG artifacts
File number	47
Command	*dfc*, *enc*

Left: original image



Right: *after processing*



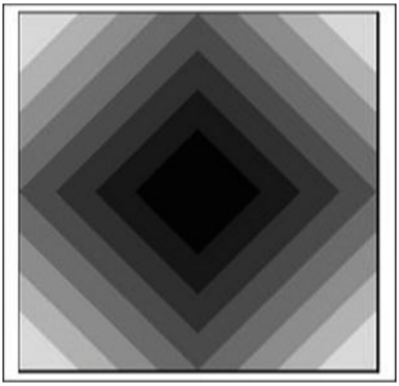
41.85 dfp

Format	*dfp*(*x*, *y*, *r*)	
Arguments	*x*	X-coordinate of the reference point
	y	Y-coordinate of the reference point
	r	Distance metric
Defaults	*r*	2 (Euclidean distance)
Output values	None	
Image type	Any	
Type	Image generation	
Function	Set the intensity each point *[x, y]* to a value proportional to the Minkowski *r*-distance from *[x, y]*. If $r = 1$, the City Block (Manhatten) distance is computed. If $r = 2$, the Euclidean distance is calculated. As *r* tends to infinity (> 20), the Minkowski r-distance approaches the Square distance	
Switch images	Yes	
Typical uses		
Remarks	Contours of constant Euclidean distance form circles. The equivalent figure for $r = 1$, is a 'diamond' (i.e., a square with sides inclined at 45° to the coordinate axes). When *r* is greater than 2, the equivalent figure is a rounded square. When *r* is infinite, the figure becomes a square with sides at 0°/90° to the axes	

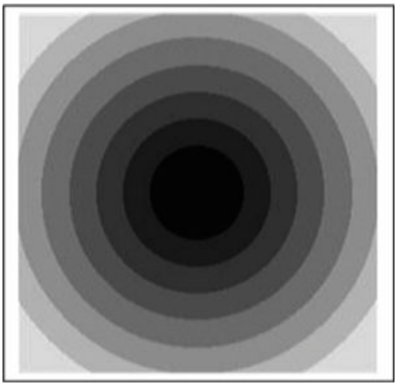
Illustration

Commands See below. *dfp* generates a smooth intensity function. The stepped effect, achieved using *sca*, was introduced here to emphasise the relationship between the metric (set by the value of *r*) and the circle-equivalent figure

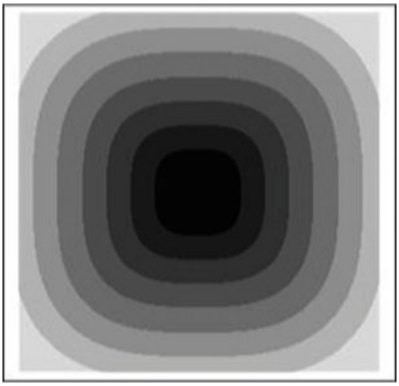
Top-left: *[a, b] = cim*; *dfp*(*a*, *b*, *1*), *enc*, *sca*(*3*)



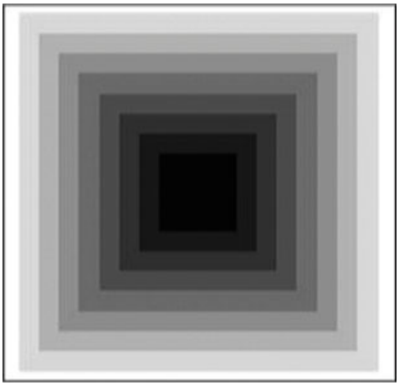
Top-right: *[a, b] = cim*; *dfp*(*a*, *b*, *2*), *enc*, *sca*(*3*)



Bottom-left: *[a, b] = cim*; *dfp*(*a*, *b*, *3*), *enc*, *sca*(*3*)



Bottom-right: *[a, b] = cim*; *dfp*(*a*, *b*, *30*), *enc*, *sca*(*3*)



41.86 dgr

See *con.*

41.87 dgw

Format	*[a, b] = dgw*	
Arguments	None	
Defaults	Not applicable	
Output values	*a*	Image width (number of columns)
	b	Image height (number of rows)
Image type	Any	
Type	Miscellaneous	
Function	Find the size of the image	
Switch images	No	

41.88 dic

Format *dic*(*u*, *v*)

Arguments *u* X-coordinate of the ‘apex’ of the cone

v Y-coordinate of the ‘apex’ of the cone

Defaults *u* Centre of the image

v Centre of the image

Output values None

Type Drawing and image generation

Switch Yes

Function Draw an intensity cone centred at *[u, v]*.

Switch images Yes

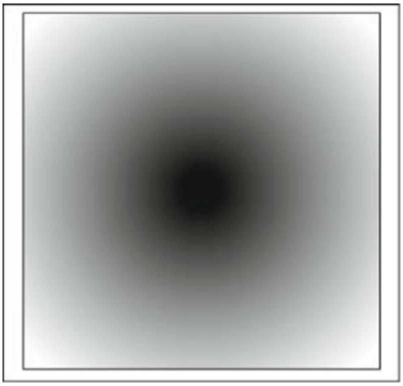
Typical uses Measuring Euclidean distance from a given point in an image

Remarks An intensity cone is a pattern in which the intensity is equal to the distance from the centre point, *[u, v]*. A set of concentric circles can be drawn using *dic*(*u*, *v*), *sca*(*3*), *sed*, *thr*(*8*)

Illustration

Command *dic*, *enc* (Note: *enc* was included to improve the contrast, for display purposes)

Below: intensity cone

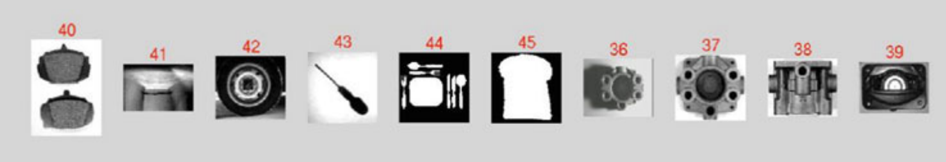


41.89 did

Format	*did*(*a*)
Arguments	*a*
Default	QT_images
Output values	None
Image type	Not applicable
Type	Display of available images
Switch images	No
Function	Dynamic image display. The images held in folder *a* (default *a* = *QT_images*) are read and displayed in ascending numerical order, in Figure 4 (full screen). When all images have been displayed, Figure 4 closes automatically. The user can terminate execution prematurely at any time, by clicking anywhere in Figure 4
Typical uses	Helping the user to identify images

Illustration

Thumbnail images are displayed in numerical sequence as *did* is running. Image 46 will be the next image to be displayed, thereby replacing the thumbnail of Image 36. Following that Image 47 replaces Images 37 and so on.



41.90 dil/cls/crk/ero/nlp/opn

Format *dil*(*a*, *b*)
crk(*a*, *b*)
cls(*a*, *b*)
ero(*a*, *b*)
opn(*a*, *b*)
nlp(*a*, *b*)

Arguments *a* Fixes size of structuring element
b Selector for structuring element

Defaults *a* 1 {See program listing for *dil*}
b 0 (disk structuring element)

Output values None

Image type Grey scale or binary

Type Non-linear filter

Switch Yes

Functions Closing (*cls*),
Crack detection (high pass filtering, *crk*),
Dilation (*dil*),
Erosion (*ero*),
Low pass filtering (*nlp*),
Opening (*opn*)

Definitions Dilation (*dil*)

$$C(i, j) \Leftarrow MAX(A(i + p, j + q) \mid [p, q]\ S),$$

(*S* is the structuring element.) That is, *C*(*i*, *j*) is set to the brightest pixel covered by the structuring element when it is resting on pixel (*i*, *j*). This rule is equivalent to the following:

When the SE rests on pixel (*i*, *j*) *and if any pixel is white within the SE, then C(i, j) is set to white*

Erosion (*ero*)

$$C(i, j) \Leftarrow MIN(A(i + p, j + q) \mid [p, q]\ S),$$

where *S* is the structuring element Closing, opening, crack detection, low-pass filtering, can be expressed as combinations of dilation and erosion, although they are implemented directly in MATLAB to improve speed

Function	Equivalent to
cls(*a*, *b*)	*dil*(*a*, *b*), *ero*(*a*, *b*)
crk(*a*, *b*)	*wri*, *dil*(*a*, *b*), *ero*(*a*, *b*), *ero*(*a*, *b*), *dil*(*a*, *b*), *rei*, *sub*
nlp(*a*, *b*)	*dil*(*a*, *b*), *ero*(*a*, *b*), *ero*(*a*, *b*), *dil*(*a*, *b*)
opn(*a*, *b*)	*ero*(*a*, *b*), *dil*(*a*, *b*)

Typical uses *dil*, *ero*, *cls* and *opn* are useful for identifying blobs/arcs that are above/below a certain size/width. *nlp* are useful for reducing the effects of noise. *crk* is particularly useful for finding crack, splits and thin arc-like defects

Remarks There are several possible shapes of structuring element for each of these functions:

Input parameter b	Structuring element
0	Disk
1	Square
2	Diamond
3	Octagon

All six functions are defined in a similar manner with small changes/ additions at line 33 in the program

Function	*Line 34 in* dil *is replaced by*
ero	`current = imerode(current, c);`

cls	`current = imdilate(current, c);`
	`current = imerode(current, c);`

opn	`current = imerode(current, c);`
	`current = imdilate(current, c);`

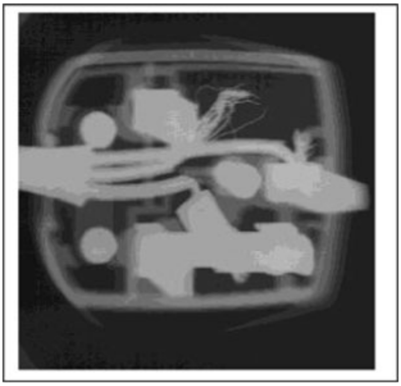
nlp	`current = imdilate(current, c);`
	`current = imerode(current, c);`
	`current = imerode(current, c);`
	`current = imdilate(current, c);`

crk	`wri`
	`current = imdilate(current, c);`
	`current = imerode(current, c);`
	`current = imerode(current, c);`
	`current = imdilate(current, c);`
	`rei`
	`sub`

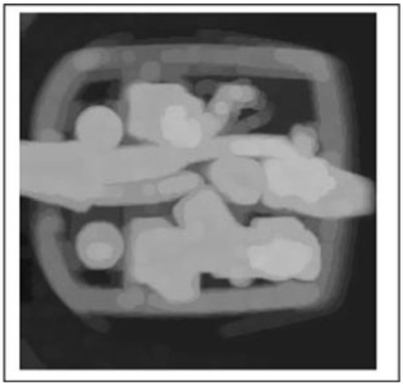
Illustration

Input image	X-ray of standard UK power plug
File number	112
Commands	See below

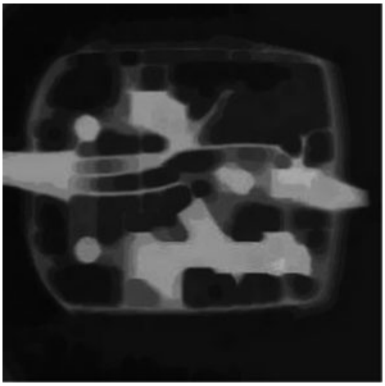
Original image



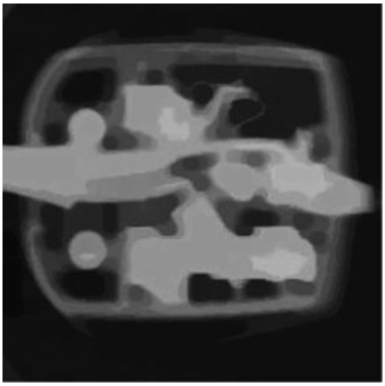
dil(5)



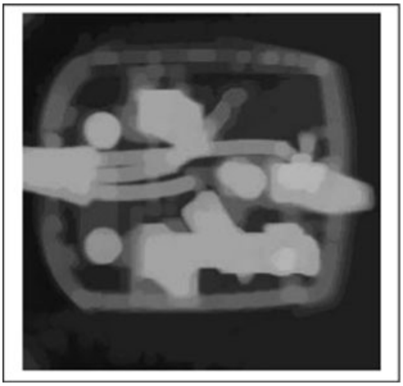
ero(5)



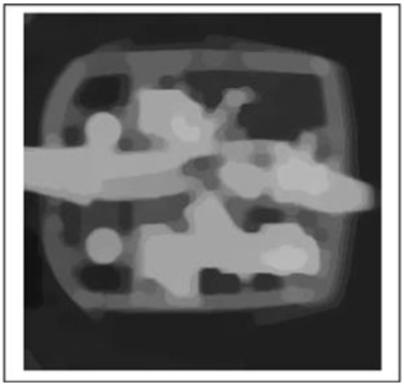
cls(5)



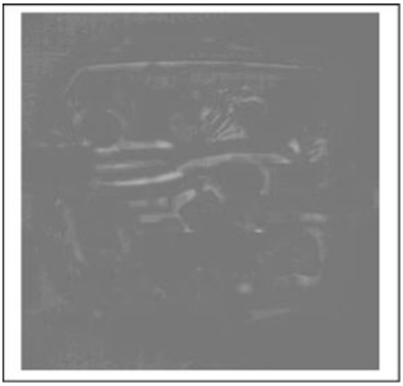
opn(5)



nlp(5)



crk(5)



crk(5), enc

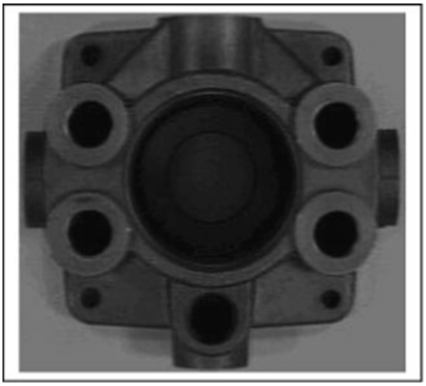
41.91 dim

Format	*[a, b] = dim*
Arguments	None
Defaults	Not applicable
Output values	*a* Image width (number of columns) *b* Image height (number of rows)
Image type	Any
Type	Miscellaneous
Function	Find the size of the image
Switch images	No

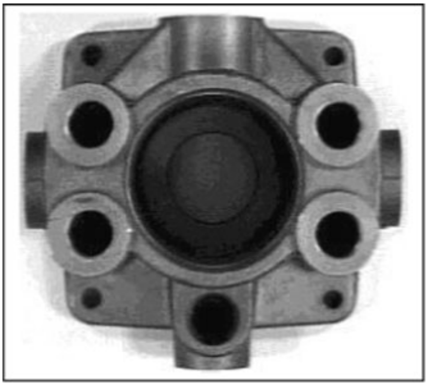
41.92 din

Format	*hin*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Monadic
Function	Double all intensities
Definition	C ⇐ 2∗A
Switch images	Yes
Typical uses	Increasing intensity/contrast, so that faint features can be seen more easily
Remarks	Also see *air*, *blo*, *hin*, *enc* and *heq*
Illustration	
Input image	Hydraulics component with *hin* applied, to generate a low-contrast image
Image generation	*rni(37), hin*
Command	*din*

Left: original



Right: after processing



41.93 dla

Format	*dla*(*a*, *b*, *c*)	
Arguments	*a*	X-coordinate of a point
	b	Y-coordinate of a point
	c	Angle (degrees, measured clock-wise relative to the horizontal)
Defaults	Not applicable	
Output values	None	
Image type	Any	
Type	Drawing	
Function	Draw a line at angle *c* through the point *[a, b]*.	
Switch images	Yes	

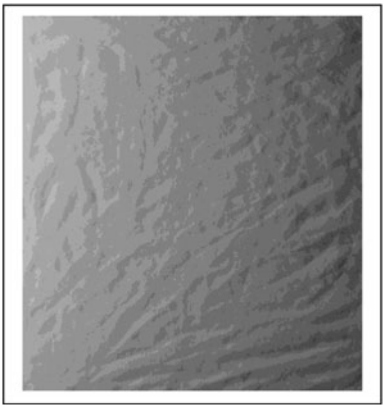
41.94 dmg

Format	*dmg*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Image filter
Switch	Yes
Function	Direction of maximum gradient
Definition	Each pixel is assigned a value indicating the direction of the maximum of the absolute values of intensity difference between opposing pairs of 8-neighbours
Typical uses	Enhancing low-contrast intensity variations that are difficult to see otherwise
Remarks	It may be beneficial to apply a low-pass filter (e.g., *raf*, *caf*), or median filter (*mdf*) to attenuate camera noise before using *dmg*

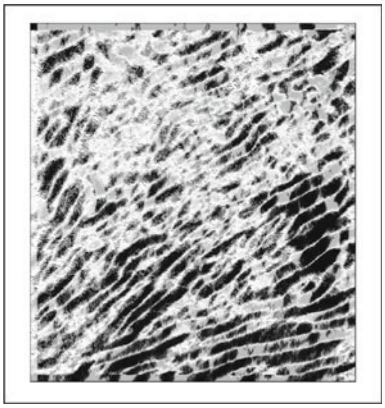
Illustration

Input image	Creased fabric (file number 28), followed by *enc*, *caf*
Image generation	*rni*(*28*), *enc*, *caf*
Commands	*dmg*, *enc*

Left: original



Right: after processing



41.95 doc

Format *doc*(*a*, *b*)

Arguments *a* Name of a QT M-function
b Selects the

Defaults No arguments Print the list of QT commands currently available
b 0, Select local PDF documentation file (PDF)
1, Visit author's web site for PDF documentation file

Output values None

Image type Not relevant

Type Not relevant

Function 1. $b = 0$, Read and display the documentation file (PDF format), held locally
2. $b \neq 0$, Read and display the contents of the PDF documentation file, held on the author's web server, for operator *a*
3. If no argument is specified, all QT command names are listed

Switch images No

Remarks The documentation files explain the function of, how to use and when to apply the given QT M-function. The significance of both input and output parameters is described. Where appropriate, default values for inputs are also defined. In many cases, images are included, to illustrate the operation of the function. The web browser, not MATLAB, will indicate when no appropriate documentation file can be found. In this case, return to MATLAB and try typing *hlp*(*a*) instead. This will indicate whether or not the specified M-function exists and will list it, if it does. Notice that the documentation file will be down-loaded onto your computer. For convenience, set the browser so that it automatically displays PDF files after down-loading

41.96 dpa

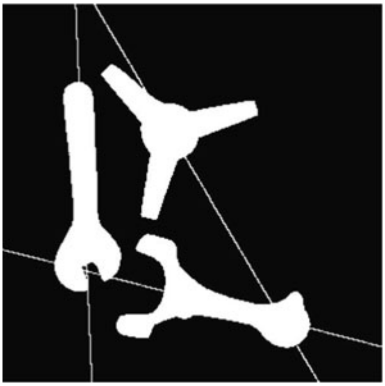
Format	$[x, y, z] = dpa$
Arguments	None
Output values	*x* X-coordinate of the centroid
	y Y-coordinate of the centroid
	z Orientation
Image type	Binary
Type	Feature extraction
Function	Draw the principal axis (axis of greatest second moment) of a single object in a binary image
Switch images	Yes
Typical uses	Visualising actions of a visually guided robot, picking up objects from a table
Remarks	Notice that *dpa* gives good results for objects that have an obvious elongation along one axis. However, an object such as a regular ‘star’ may give spurious results. (see below) Also see *lmi*, *cge*

Illustration

Input image	Four parts
File number	46
Command	*rni*(*46*), *big*(*4*), *exr*, *dab*(‘*dpa*’)

Left: original

Right: after processing



41.97 dps

Format *[a, b] = dps*

Arguments None

Output values *a* X-coordinate of the point selected by the user

b Y-coordinate of the point selected by the user

Image type Any

Function The user selects a point, *[a, b]*, with the cursor. This is then used to define the parameters for a shift with wraparound; the point *[a, b]* is shifted to the top-right corner of the output image

Switch images Yes

Typical uses Analysing binary images

Remarks Also see *cur*, *psw*

Illustration

Input image Stator

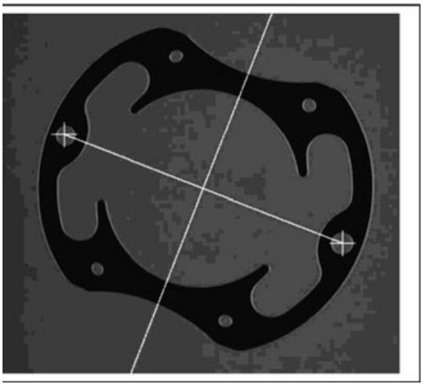
File number 174

Command *[a, b] = cur; [c, d] = cur; test(a, b, c, d)*

where test is defined as follows

```
function test(a, b, c, d)
global current
global alternate
original = current;
pbi(a, b, c, d);
dcl(a, b, 15)
dcl(c, d, 15)
vpl(a, b, c, d, 255)
alternate = original;
subplot(1, 2, 1), imshow(current)
subplot(1, 2, 2), imshow(alternate)
```

Image The user defined the two points indicated by crosses with the cursor

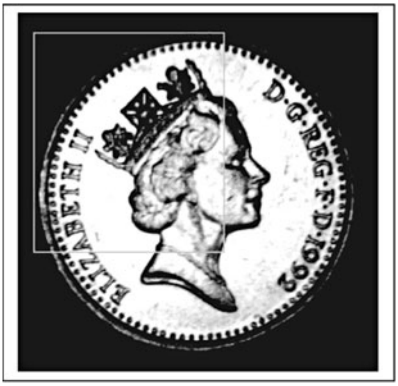


41.98 drd

Format	*drd(x, y, w, h, z)*	
Arguments	*x*	X-coordinate of the top-left corner of the rectangle
	y	Y-coordinate of the top-left corner of the rectangle
	w	Width of the rectangle
	h	Height of the rectangle
	z	Intensity of the rectangle
Defaults	*z*	255 (white)
Output values	None	
Image type	Grey	
Type	Graphics	
Function	Draw an open rectangle of intensity *z*, size *[w, h]* and whose top-left corner is at *[x, y]*.	
Switch images	Yes	
Typical uses	Annotating images	
Remarks	Also see *mar*, *dcd and dsc*	
Illustration		
Input image	Coin	
File number	23	
Command	*drd*(*12*, *15*, *135*, *156*, *128*)	

Left: original

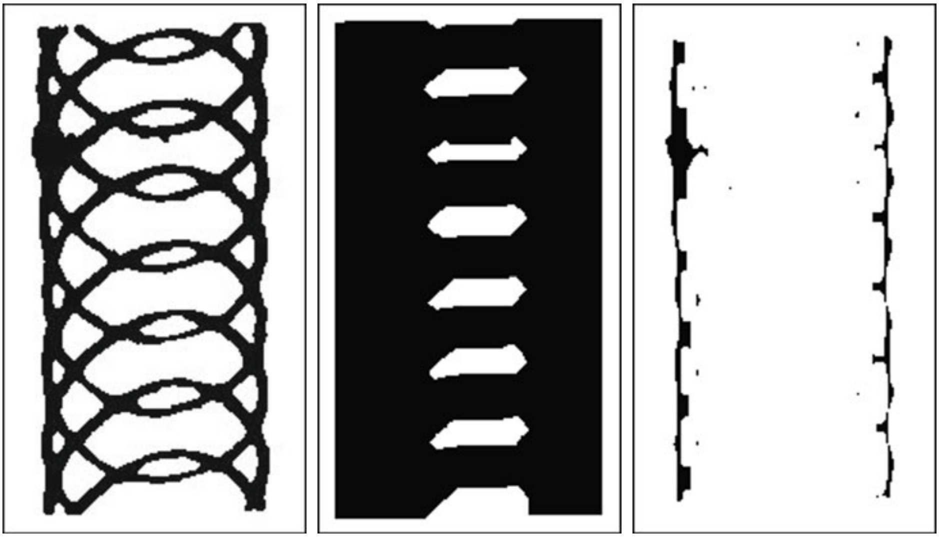
Right: after processing



41.99 dri/eri

Format	*dri*(*a*, *b*)/*eri*(*a*, *b*)	
Arguments	*a*	Structuring element width
	b	Structuring element height
Defaults	*a*	7
	b	1
Output values	None	
Image type	Binary	
Type	Morphology	
Function	Dilate/erode the image using a rectangular structuring element	
Switch images	Yes	
Typical uses	Feature detection	
Remarks	Also see *dil, erl, ero gbd, gbe, lnb, snb*	
Illustration		
Input image	Cake decoration pattern	
File number	55	
Commands	See below	

Left: original *Centre*: after *eri*(*31*, *5*) *Right*: after *dri*(*3*, *15*)



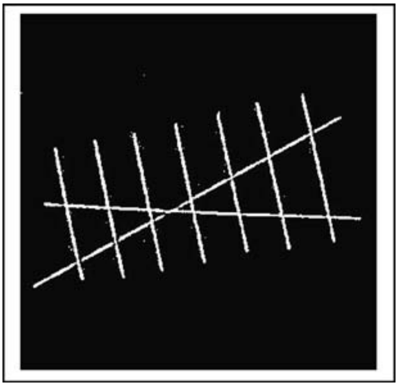
41.100 drp

Format	*drp*
Arguments	None
Defaults	None
Output values	None
Image type	Binary
Type	Image analysis
Switch	Yes
Function	Dominant Radon projection
Definition	First, the Radon transform is calculated. Then, the RT image is integrated in the vertical direction. The column which yields the peak integrated intensity is then identified. This indicates the angle by which the image must be rotated, so that the dominant feature is vertical
Typical use	Detecting linear streaks in noisy images
Remarks	Several short parallel lines, or one long single line, may contribute to the dominant peak in the integrated Radon transform

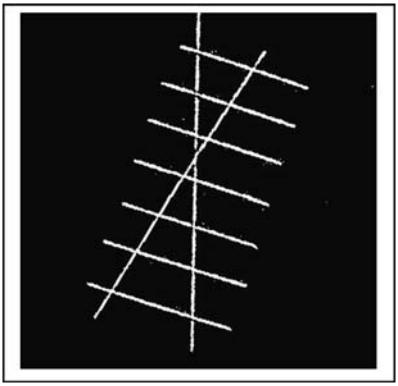
Illustration

Input image	Lines, with pre-processing to convert to binary image
Image generation	*rni*(*160*), *crk*, *thr*(*150*)
Command	*drp*

Left: original



Right: after processing



41.101 dsc

Format	*dsc*(*x*, *y*, *r*)
Arguments	*x* X-coordinate of the centre of the disc *y* Y-coordinate of the centre of the disc *r* Radius of the centre of the disc
Defaults	None
Output values	None
Image type	Any
Type	Image generation
Function	Draw a disc of radius *r* centred at *[x, y]*.
Switch images	Yes
Remarks	To draw an open circle, apply *bed* after *dsc*

41.102 dsz

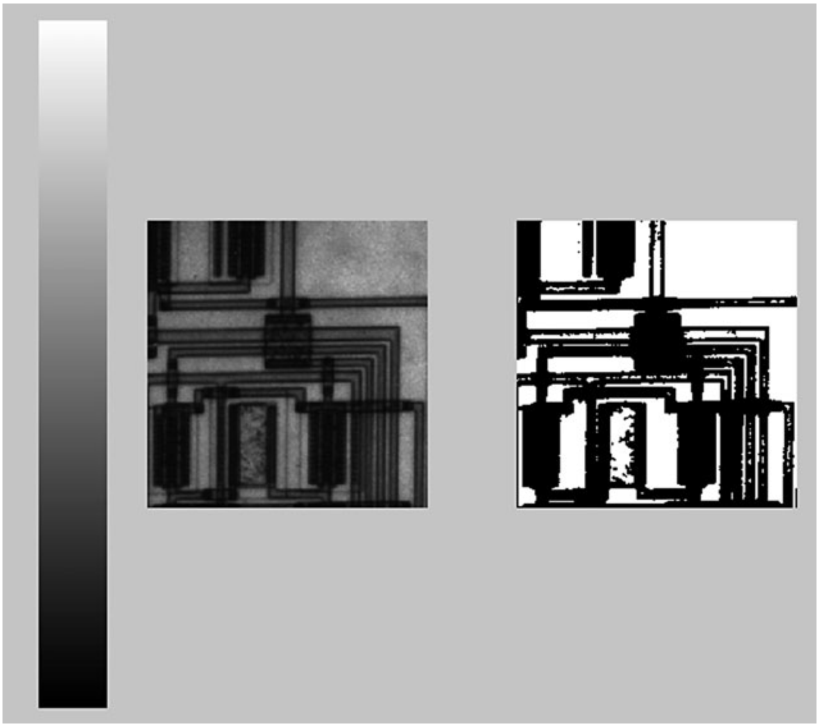
Format	*r*=*dsz*
Arguments	None
Output values	*r* Size of smallest blob to be retained
Image type	Binary
Function	The user selects a size limit (*r*) using the cursor. (The cursor is placed over a grey-scale wedge. so that the user can estimate the size of blobs to be eliminated by relating size with intensity.) Blobs of size smaller than *r* pixels are then eliminated from the current image. Blobs bigger than 255 pixels are always retained
Switch images	Yes
Typical uses	Removing noise from binary images
Remarks	Also see *cur*, *dth*, *kgr*, *kbb*

41.103 dth

Format	r = *dth*(*a*, *b*)
Arguments	None
Output values	r Intensity value
Image type	Grey
Type	Dynamic threshold
Function	Threshold the input image using the cursor to select the threshold parameter
Switch images	Yes
Typical uses	Image segmentation (i.e., isolating an object silhouette from its background). Reducing data content in an image, to make subsequent analysis easier
Remarks	*dth* is an interactive thresholding operator and is useful for exploring the effects of varying the threshold parameter Also see *hgm*, *thr* and *tha* – *thg*

Illustration

The image below is typical of that displayed in *Figure 1* during the execution of *dth.* The user double clicks in the colour bar to select the threshold parameter. The result is shown, almost immediately, in the Alternate Image (on the right). The user can then select a new threshold, or double click elsewhere in *Figure 1* to finish. The final threshold value selected in this way is then returned by *dth.* The program then switches the images, so that the resulting thresholded image is displayed in the Current Image. As usual, the original is displayed in the Alternate Image.

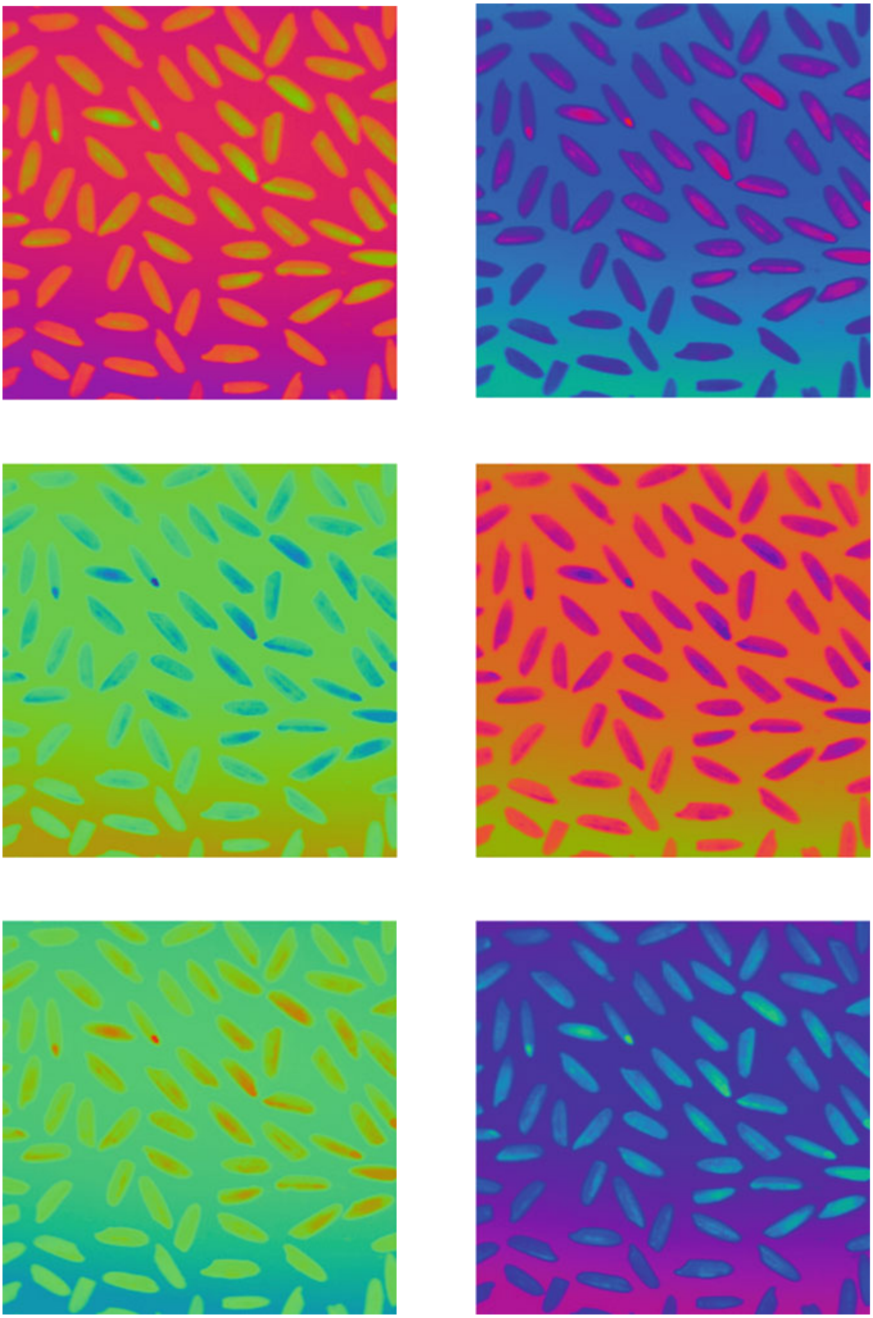


41.104 ecc

Format	*ecc*(*a*, *b*, *c*)	
Arguments	*a*	Colour channel *a* defines new R channel
	b	Colour channel *b* defines new G channel
	c	Colour channel *c* defines new B channel
Default values	*a* = 2 (R channel takes values originally specified by the G channel)	
	b = 3 (G channel takes values originally specified by the B channel)	
	c = 1 (B channel takes values originally specified by the R channel)	
Output values	None	
Image type	Colour	
Type	Monadic	
Function	The RGB channels are exchanged	
	ecc(1, 2, 3)	No change
	ecc(2, 1, 3)	R and G channels are interchanged. B channel is not changed
	ecc(1, 3, 2)	G and B channels are interchanged. R channel is not changed
	ecc(3, 2, 1)	R and B channels are interchanged. G channel is not changed
	Further examples are illustrated below	
Switch images	Yes	
Typical uses	Increasing contrast produced by the pseudo-colour operator (*psc*)	
Remarks	This function has little practical value when processing colour images. However, it is great fun to use; it often produces interesting surreal effects, especially on faces. Also see *aic*	

Illustration

Input image	Rice grains
File number	73
Commands	
Top-left	*rci(73), enc, psc*
Top-right	*rci(73), enc, psc, ecc(2, 3, l)*
Centre-left	*rci(73), enc, psc, ecc, ecc(3, l, 2)*
Centre-right	*rci(73), enc, psc, ecc(l, 3, 2)*
Bottom-left	*rci(73), enc, psc, ecc(2, l, 3)*
Bottom-right	*rci(73), enc, psc, ecc(3, 2, l)*



41.105 ecy

See *bpa.*

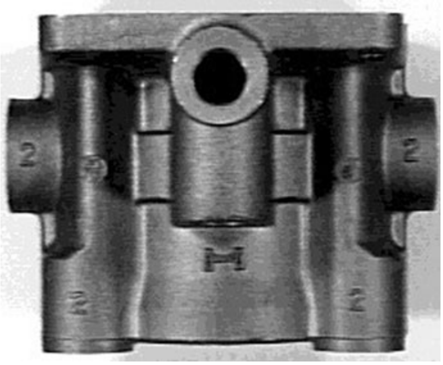
41.106 edd

Format *edd*(*a*)
Arguments *a* Function selector
Defaults *a* 0
Output values None
Image type Grey
Type Edge detector
Function Morphological edge detectors
Definition See MATLAB listing below
Switch images Yes
Typical uses Highlighting edges (i.e., regions of large intensity gradient)
Remarks A range of edge detectors can be constructed by subtracting a dilated/eroded image from the original:

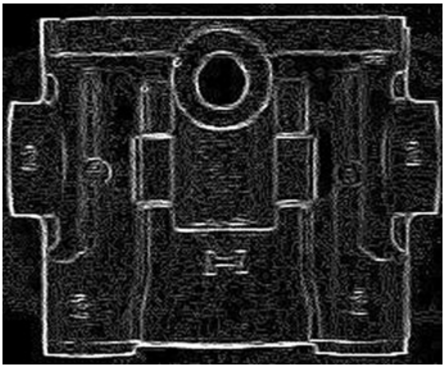
Input parameter *a*	Function
0	Contour is on dark side of dark-bright boundary
1	Contour is on bright side of dark-bright boundary
2	2-pixel wide contour spans dark-bright boundary

Illustration
Input image Hydraulics component
File number 38
Command *edd*

Left: original



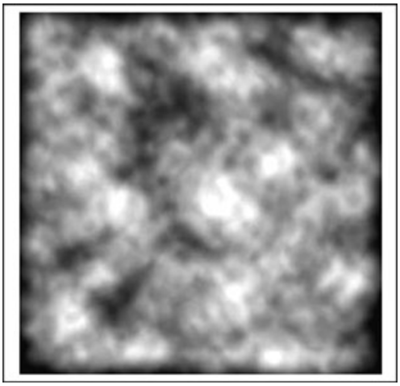
Right: after processing



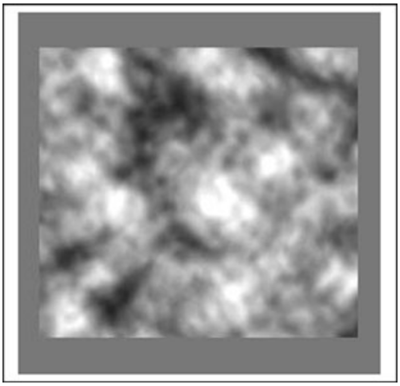
41.107 edg

Format	*edg*(*a*, *b*, *c*)	
Arguments	*a*	Width of the border at the sides of the image
	b	Width of the border at the top and bottom
	c	Intensity value of the border
Defaults	No arguments:	*a = 1*; *b = 1*; *c = 0*
	One argument:	*b = a*; *c = 0*
	Two arguments:	*b = a*; *c* is equal to the second argument supplied
Output values	Not applicable	
Image type	Any	
Type	Drawing	
Function	Set the edge pixels to a defined value	
Definition	A band of pixels of width *a* is set to level *c* at the left- and right-hand sides of the image. Bands of width *b* are also set to this level at the top and bottom	
Switch images	Yes	
Typical uses	Masking edge effects created by local and morphological operators, such as *sed, caf, dil*, etc.	
Remarks	Also see *rbe*	
Input image	Coffee beans (file number 4), after applying a severe blurring filter (*caf*)	
Image generation	*rni*(*4*), *enc*, *caf*(*15*), *enc*	
Command	*edg*(*15*, *25*, *128*)	

Left: original (Notice the edge effects)



Right: after processing



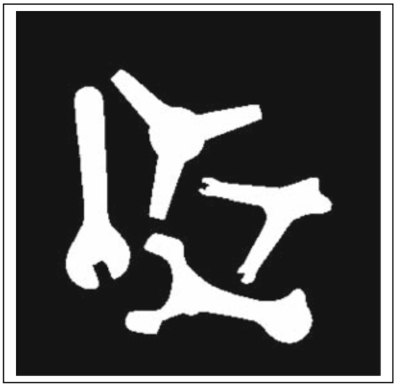
41.108 edx/lrx/tbx

Format	*lrx* *tbx* *edx*
Arguments	None
Defaults	Not applicabale
Output values	None
Image type	Grey
Type	Monadic
Function	*lrx:* Row maximum, going from left-to-right. Result is *I1* Row maximum, going from right-to-left. Result is *I2* Combine *I1* and *I2* using *mni* *tbx:* Column maximum, going from top-to-bottom. Result is *I3* Column maximum, going from bottom-to-top. Result is *I4* Combine *I3* and *I3* using *mni* *edx:* Combine images *I1*, *I2*, *I3* and *I4* using *mni*
Switch images	Yes
Typical uses	Compensating for uneven lighting by removing slow intensity changes in the back-ground
Remarks	These are three rather crude operators. However, they do occasionally produce interesting and useful results. Illustration I shows how these operators behave on a simple binary image. Illustration II demonstrates the practical benefit on a simple grey-scale image. Notice how the background shading is improved by subtracting the result of *edx* from the original image, thus making thresholding simpler

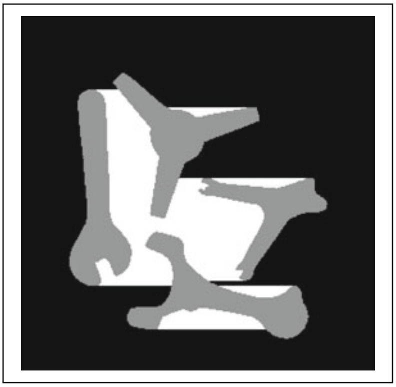
Illustration

Input image	4 piece parts
File number	46
Commands	*lrx* *tbx* *edx*

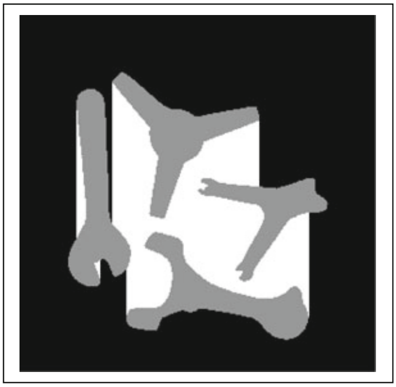
Top left: original



Top right: after *lrx*



Centre left: after tbx



Centre right: after *edx*

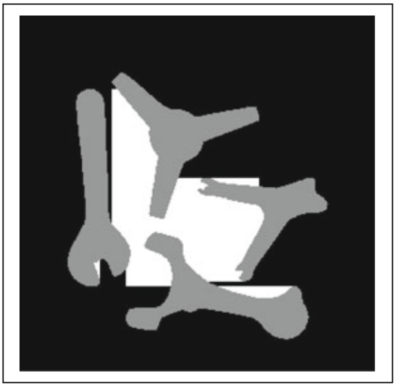


Illustration II

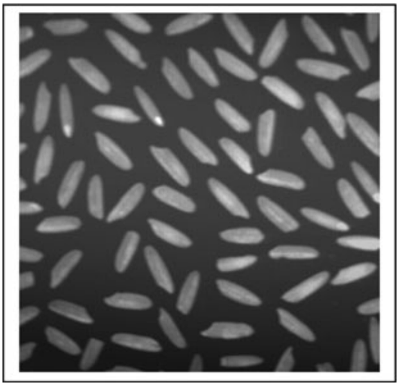
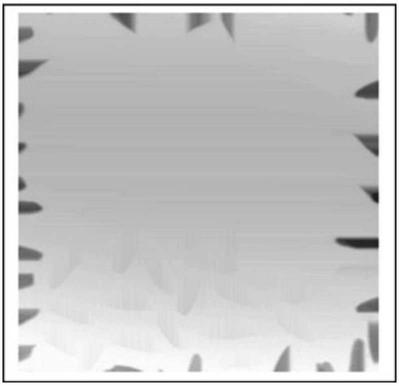
Input image	rice
File number	3

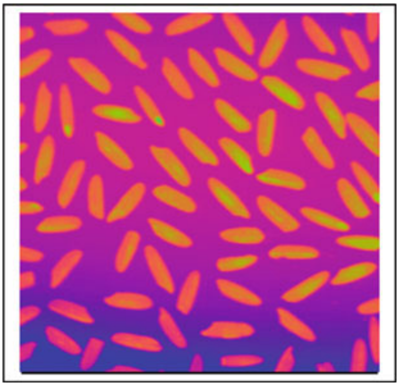
Top left: original



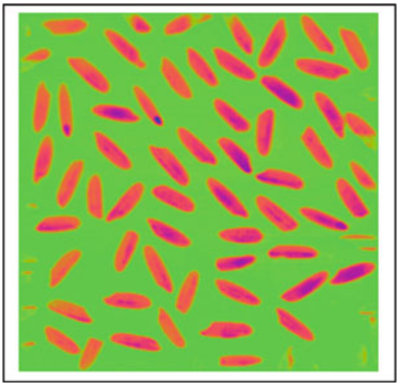
Top right: after *enc*, *neg*, *edx*



Centre left: after *enc*, *psc*



Centre right: after *enc*, *neg*, *edx*, *sub*, *enc*, *psc*



41.109 emn

See *emx*.

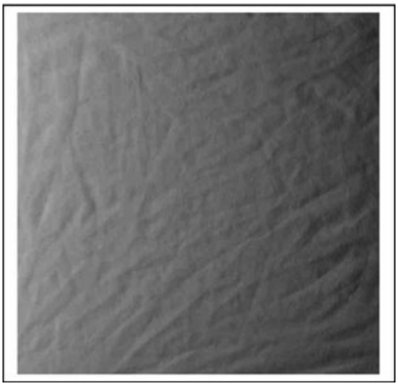
41.110 enc

Format	*enc*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Monadic
Function	Enhance contrast by applying a shift and linear stretch to the intensity scale. In the resulting image, the darkest pixel is black and the brightest pixel is white
Definition	$C \Leftarrow 255*(A - A_{min})/(A_{max} - A_{min})$
Switch images	Yes
Typical uses	Increasing contrast
Remarks	*enc* is functionally equivalent to *[a, b] = gli, air*(*a, b*). Notice that *enc* performs a linear stretching of the intensity scale, while *heq* is non-linear. Also see *blo*, *acn*, *din*, *hin*

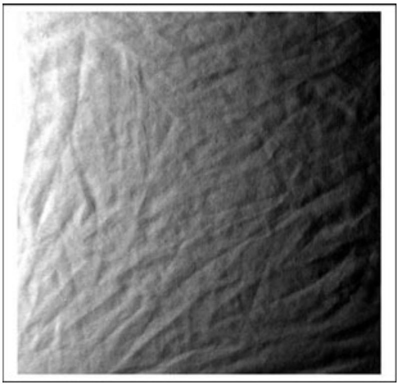
Illustration

Input image	Creased fabric
File number	28
Command	*enc*

Left: original



Right: after processing



41.111 eqd

See *bpa*.

41.112 eri

See *dri*.

41.113 ero

See *dil*.

41.114 ersf

Format *ersf*(*a*, *b*, *c*)

Arguments *a* URL for a remote script file

b Time limit (in seconds). Execution automatically terminates after *b* seconds

c Time delay (in seconds) before the next cycle begins

Defaults None

Output values None

Image type Any

Type Program control

Function Execute the script in a defined file (URL *a*), repeatedly, until a specified time limit (*b*) has been reached. At the end of each cycle, wait for a defined time (*c*), before executing the script again. The program recovers automatically if a faulty script is defined and then corrected

Switch images Undefined; operation depends on the script defined by *a*

Typical uses Prototype interfacing function

Remarks The user can modify the function(s) being executed, at any time, by altering the contents of the file specified by input parameter *a*. This is the URL for a script file, which may held be locally (i.e., same computer as QT), or on a remote computer. If the first parameter (*a*) is simply a number, the file name is built automatically and a local file is consulted. In either case, the contents of the script file can be changed 'on the fly', either by a remote user with a simple text editor, or an autonomous program, running asynchronously with MATLAB. Consider the command

```
ersf('file:///Users/bruce/MATLAB/QT/QT_work_files/script1')
```

The following actions ensue:

(i) Start the timer. This will run from this moment for *b* seconds

(ii) Read the file specified by parameter (*a*)

(iii) Execute the command sequence in file *script1*

(iv) Display the results in MATLAB's *Command Window*

(v) Wait for *c* seconds before continuing

(vi) One of two possible actions follows next:

(a) If the time delay specified by parameter *b* has not yet been reached, return to step (ii) and repeat

(b) Otherwise terminate execution

Notice that execution can be terminated at any time by the user pressing CTRL/C

Example

Command

```
ersf('file:///Users/bruce/MATLAB/QT/QT_work_files/script1',
10,0.5)
```

URL of script file

'file:///QT_work_files/script4532'

Contents of that script file

```
grb(3); enc; thr(200); dil; blf; exr; big; blf; [x, y] = cgr;
display(['Centroid:', int2str([x, y])]);
display(['End of loop']);
```

Output

```
Centroid: 316 228
End of loop
Centroid: 296 187
End of loop
Centroid: 265 168
End of loop
Timer has signalled that the time limit allowed for execution has been
reached – this loop will be completed before execution stops
Centroid: 242 198
End of loop
```

41.115 esr

Format [*c*, *d*] = *esr*(*a*, *b*)

Arguments *a* Synchronisation code (integer, not used internally)
b Command sequence to be evaluated

Defaults *a* *12345*

Output values *c* Results vector. Consists of 7 elements:
1 No. of valid output values generated
2–7 Results obtained by performing operation *b*
d Output results string

Image type Any

Type Program control

Function Execute a command defined by *b*. The following results are then stored in the folder specified by the global variable *results_url*:

Current image	File *current.jpg*
Alternate image	File *alternate.jpg*
Results, formatted text	File *results* (See example below)

Switch images Undefined. Operation depends on the operation defined by *b*

Typical uses Inspecting the results of a free-running QT program using web browser
Interfacing to another program

Remarks Normally, *esr* runs inside an infinite loop. (Execution can be terminated at any time by the user pressing CTRL/C.) *esr*(*a*, *b*) performs operation *b*. Outputs *c* and *d* are made available for debugging purposes but would not normally be used otherwise. The resulting *current* and *alternate* images and a text file containing the time-stamped, numeric results of that operation are then saved. These three files can then be examined using a standard web browser. Viewing the results does not affect the execution cycle. Alternatively, the results of operation *b* can be analysed further, by another program (*P*), running asynchronously locally, or on a remote computer. In order to facilitate synchronisation between QT and *P*, the first parameter (*a*) is simply copied into the text file (*results*). When the command

esr(*3582*,‘*mar*’)

was executed. the following data was generated and stored in the *results* file:

Code:	3582						
Command:	mar						
Date and time:	2004	11	25	16	51	48	
Results:	4	1	13	2	14	0	0

(The first element in this list indicates that there are 4 valid answers (1 13 2 14) for the operation *mar.*) Notice that commands that calculate numeric answers (e.g., *mar*, *avg*, *gli*, *cbl*, *cwp*, *eul*, etc.) are included in the call, without specifying output parameters. (The command *esr*(*3582*, ‘[*a*, *b*, *c*, *d*] = *mar*’) works perfectly satisfactorily but does not assign values to any output variables (*a*, *b*, *c* or *d*).) Individual QT commands that do not calculate output values (e.g., *neg*, *thr*, *enc*, *heq*, etc.) generate output lists in *results* consisting of seven zeroes. Compound commands are permitted but commands that return values must be executed individually. Thus, we may use

esr(*123*, ‘*rni*(*4*), *enc*, *thr*, *dil*, *ero*’)

However, the command

esr(*123*, ‘*rni*(*4*), *enc*, *thr*, *dil*, *ero*, *cbl*’) performs the desired calculation but does not return any significant values. Instead, we should use two commands:

esr(*123*, ‘*rni*(*4*), *enc*, *thr*, *dil*, *ero*’), *esr*(*124*, *cbl*)

41.116 eul

Format	$b = eul(a)$
Arguments	a Connectivity (4- or 8-connected. Hence, $a \in \{4, 8\}$)
Defaults	a 8
Output values	b Euler number
Image type	Binary
Type	Binary image measurement
Function	Calculate the Euler number for a binary image
Switch images	No
Typical uses	Counting blobs or lakes
Remarks	The Euler number is the number of blobs minus the number of holes. Hence, if it is known that there are no holes, the number of blobs can be estimated. On the other hand, if there is just one blob, then the number of holes can be found. Notice that *cbl* computes the number of blobs directly

41.117 exm

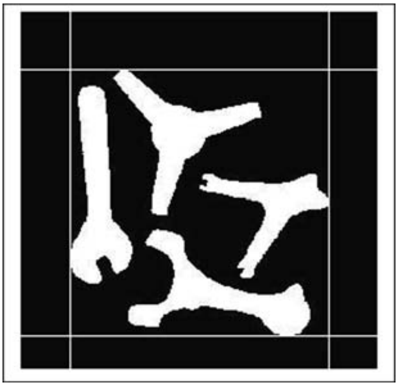
Format	$[x1, x2, y1, y2] = exm(a)$	
Arguments	*a*	Control
Defaults	*a*	1 (Draw *X* and *Y* limits)
Output values	*x1*	Minimum value of *X*
	x2	Maximum value of *X*
	y1	Minimum value of *Y*
	y2	Maximum value of *Y*
Image type	Binary	
Type	Image measurement	
Switch	Yes	
Function	*a = 1*:	Calculate and draw the minimum and maximum *X* and *Y* bounds, considering all white points
	a = 2:	Calculate and draw the minimum and maximum *X* and *Y* bounds. Then, crop the image at these limits
Switch images	Yes	
Typical uses	Reducing execution time for subsequent by limiting processing to a region of special interest	
Remarks	*exm* can find the limits for multi-blob images, whereas the related functions *bbx* and *mar* operate on just one blob at a time. Use the following command sequence to calculate the *X*- and *Y*-limits from a binary image and then crop the grey-scale image from which it was derived: $thresh, [x1, x2, y1, y2] = exm(0), swi, crp(x1, y1, x2 - x1, y2 - y1)$ The unspecified function *thresh* might, for example, be *thr*(*Q*), where *Q* is some positive integer. The important point to note is that the grey-scale image is held in the alternate image and the binary image derived from it is in the current image	

Illustration

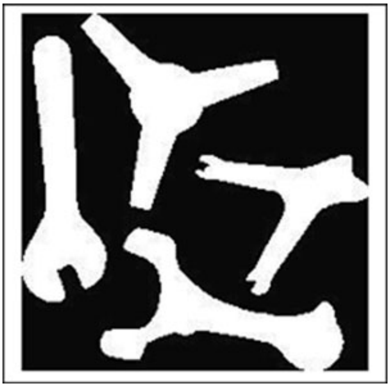
Input image	Four metal parts
File number	46
Command	*thr*, *exm*(*1*) and *thr*, *exm*(*2*)

Top-left: original

Top-right: after *thr*, *exm*(*1*)



Bottom-left: after *thr*, *exm*(*2*)



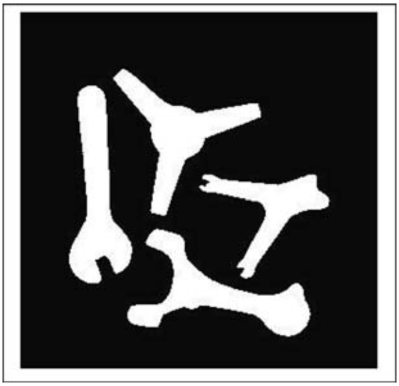
41.118 exr

Format	*exr*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Dyadic
Function	Exclusive OR of pixels at corresponding addresses in the current and alternate images
Switch images	Yes
Typical uses	Comparing binary images
Remarks	Applying the following command sequence selects the *second* largest blob in a binary image: *big*, *exr*, *big*

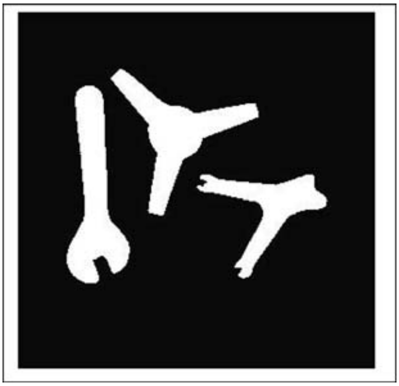
Illustration

Input images	Four metal components and the same image with the largest blob isolated using *big*
File number	46
Command	*big, exr*

Left: original



Right: after processing



41.119 ext

See *bpa.*

41.120 fap

Format	*fap*(*x*, *y*, *z*)	
Arguments	x	Vector containing X-coordinates of pixels to be set to level z
	y	Vector containing Y-coordinates of pixels to be set to level z
	z	Vector containing intensity values
Defaults	None	
Output values	None	
Image type	Grey or binary image is generated	
Type	Data display	
Function	Set the pixels addressed by the vectors *x* and *y* to intensity values defined by *z*. All other pixels are set to black	
Switch images	Yes	
Typical uses	Converting edge contour data (e.g., filtered chain code) into an image	
Remarks	Also see *gap*	

41.121 far

See *bpa*.

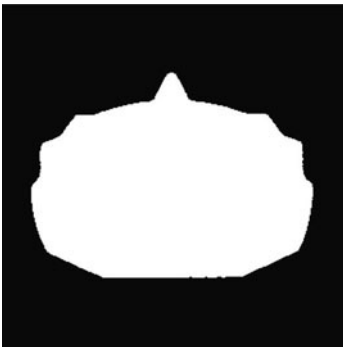
41.122 fbl

Format	*n* = *fbl*
Arguments	None
Output values	*n* Rotation angle that achieves the best fit
Image type	Binary
Type	Binary image analysis
Function	1. The current and alternate images are both normalised so that the centroid of each image is moved to the middle of the image 2. The current image is then rotated so that it achieves the best fit on the alternate image (Angle *n*) 3. The angle for best fit defines the output variable
Switch images	Yes
Typical uses	Fitting a binary template
Remarks	

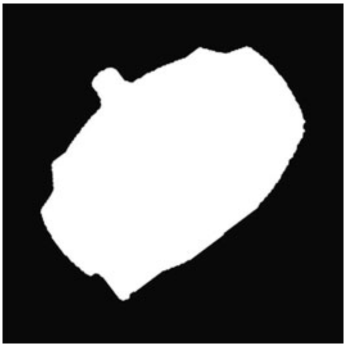
Illustration

Input image	Automobile break pads
File number	40 (split in two, to separate the brake pads)
Command	*fbl, adi*

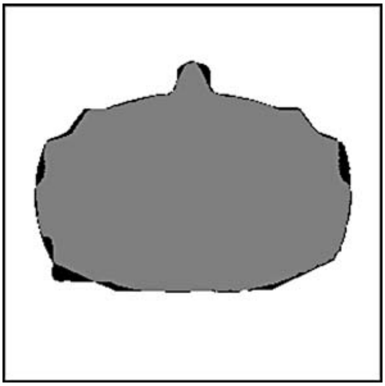
Top-left: binary image: metal base-plate for an automobile brake pad. Call this Part A



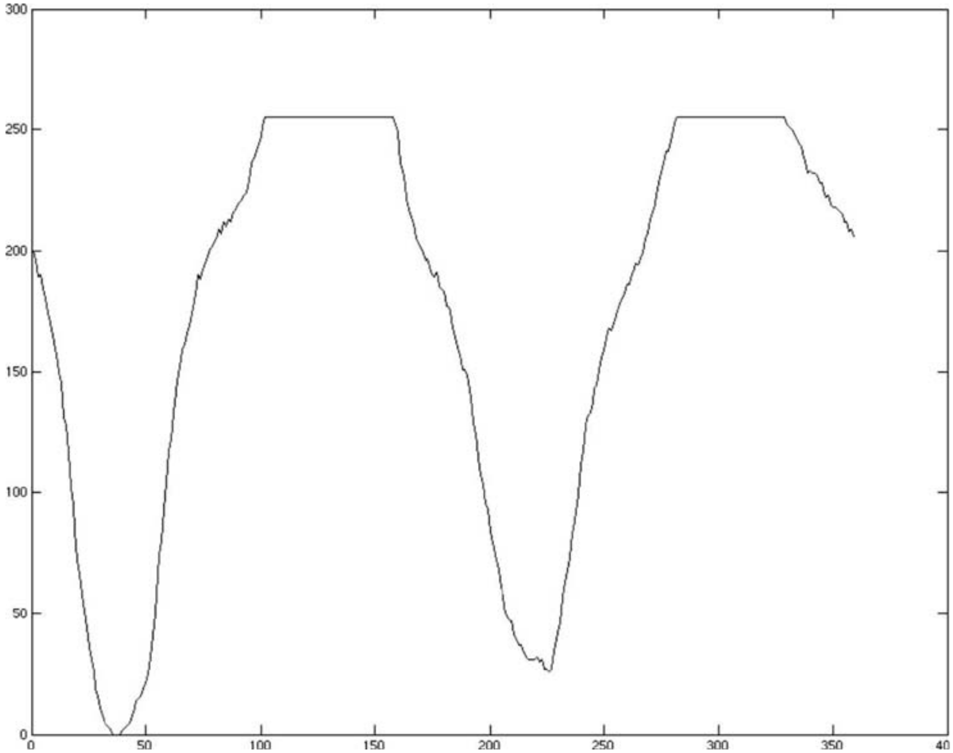
Top-centre: binary image from another slightly different object, Part B



Centre: after applying [*rei*('*B*'), *rei*('*A*'), *fbl*], Part B has been rotated and shifted so that it 'fits' Part A
Black areas indicate the differences between the two objects



Bottom: goodness of fit (ordinate), plotted against angle of rotation (abscissa). This graph is plotted in an additional MATLAB window: *Figure 5*



41.123 fcc

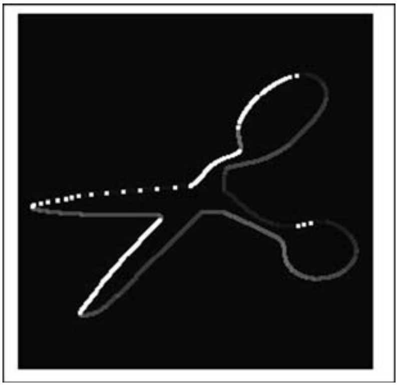
Format	*[x, y, z] = fcc*	
Arguments	*None*	
Output values	*x*	Vector containing X-coordinates of edge pixels
	y	Vector containing Y-coordinates of edge pixels
	z	Vector of chain-code values
Image type	Binary	
Type	Blob transform	
Function	Shade the image to indicate the chain-code value for each edge pixel. The chain code indicates the path taken to exit that pixel to visit an adjoining edge pixel. The edge follower travels clock-wise around the blob. All pixels other than those on the edge are set to black. The starting point is the top-left-most, non-black pixel. Only the largest blob is analysed and the edges of any lakes are ignored; other blobs and/or lakes must be analysed separately	
Switch images	Yes	
Typical uses	Analysing blob shape. Further analysis is performed on the vector z, not the image	
Remarks	A single blob can be processed using *seb*. If any other blobs are present, the result is an error. Other blobs and any lakes must analysed separately. Also see *seb*	

Illustration

Input image	Scissors (after applying *thr* to eliminate JPEG artifacts)
File number	49
Commands	*thr*, *fcc*, *lnb* (*ln*b broadens the edge contour, making it easier to see)

Left: original

Right: after processing



41.124 fce

Format *[x, y, r] = fce(u, v, w)*

Arguments *u* Vertical position of first scan line, relative to the top of the blob

v Vertical position of second scan line, relative to the first one

w Vertical position of third scan line, relative to the second one

Defaults Not applicable

Output values *x* X-coordinate of centre of the fitted circle

y Y-coordinate of centre of the fitted circle

r Radius of the fitted circle

Image type Binary

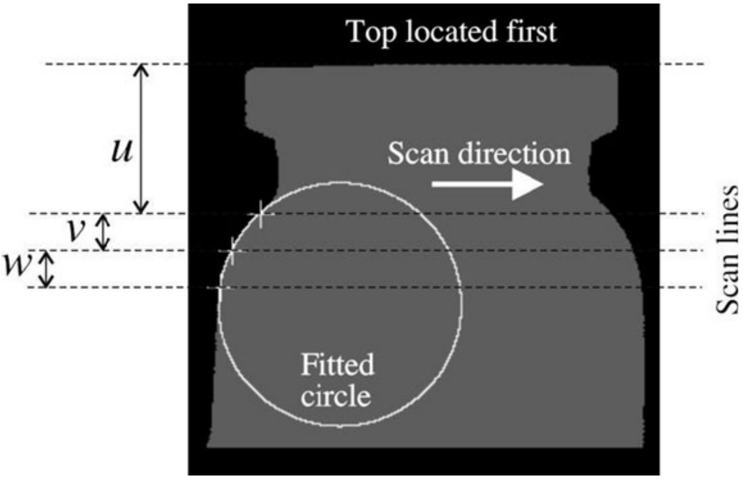
Type Drawing

Function Fit a circle to 3 edge points, found by scanning along 3 rows of the image

Switch images Yes

Typical uses Inspecting bottles, loaves, where radius of curvature is to be calculated

Remarks The algorithm used in this function is explained in the following diagram. First, the top of the blob is found. Then, the 3 scan lines are positioned *u*, ($u + v$) and ($u + v + w$) lines below it. The left-most intersection of each scan-line with the blob is then found. This identifies three edge points, which are then used for fitting the circle. Finally, the circle is drawn

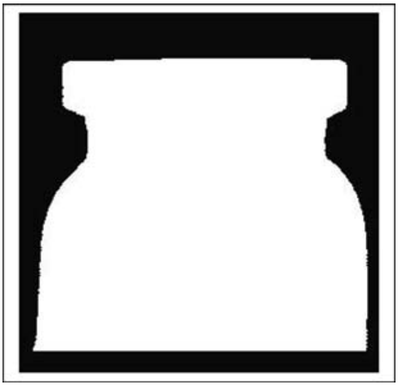


Also see *rbe* and *fcd*

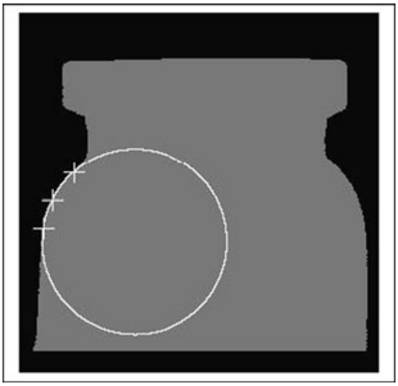
Illustration

Input image	Glass vial (file number 32) with processing to create binary silhouette
Image generation	*rni*(*32*), *rox*, *wri*, *swi*, *lrt*, *rox*, *lrt*, *rei*, *mni*, *thr*(*16*)
Command	*fce*(*90*, *22*, *22*)

Left: original



Right: after *fce*(*90*, *22*, *22*)



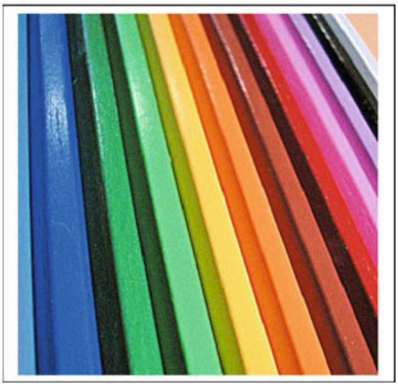
41.125 fcf

Format	*fcf*(*a*)	
Arguments	*a*	Function selection
Defaults	*a*	1
Output values	None	
Image type	Colour	
Type	Colour filter	
Function	Apply one of a set of standard programmable colour filters	
Switch images	Yes	
Typical uses	Segmentation of colour images	
Remarks	See *pcf* for a more detailed explanation	

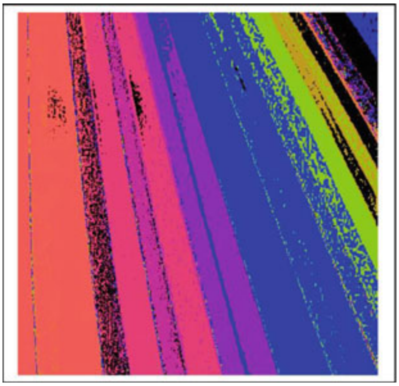
Illustration

Input image	Pencils
File number	270
Command	*fcf*(7)

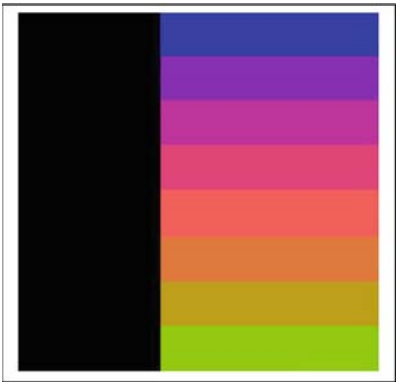
Top-left: original



Top-right: after processing



Bottom-left: mask image



41.126 fcl

Format *[x, y, r] = fcl*

Arguments None

Output values *x* X-coordinate of the centre of the circle

y Y-coordinate of the centre of the circle

r Radius of the circle

Image type Binary

Type Binary image analysis

Function Fit a circle to a set of points, using the least-squares algorithm

Switch images Yes

Typical uses Analysing binary images with 'broken' edge contours derived from circular features

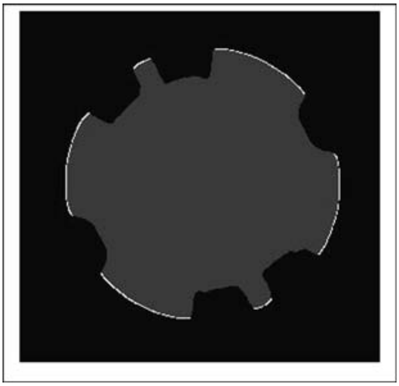
Remarks In the illustration below, a set of disjoint arcs was derived from the outer edge contour of a metal cam, using the perimeter of its convex hull as a mask. The circle found by *fcl* provides an accurate approximation to the outline of the cam

Illustration

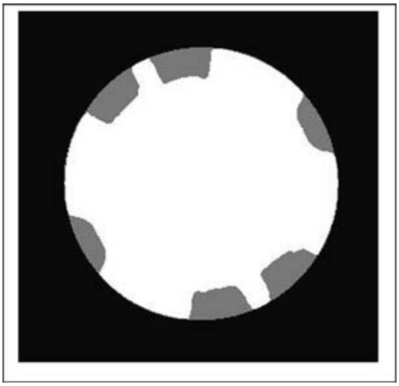
Input generation *rni*(*169*), *enc*, *thr*, *neg*, *blf*, *bed*, *wri*, *swi*, *chu*, *bed*, *rei*, *mni*

Commands *fcl*, *adi*, *mxi*, *sqr* (Generated the white arcs in the image below, left)

Left: original image (white) superimposed on the cam.



Right: circle fitted by *fcl* using the least-squares algorithm, superimposed on the cam



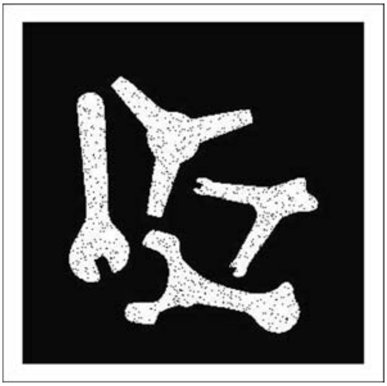
41.127 fib

Format	*fib*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Binary image filtering
Switch	Yes
Function	Fill isolated black pixels
Switch images	Yes
Typical uses	Noise reduction in binary images
Remarks	When there are very few black pixels, it may be advantageous to use *fib* rather than *blf*

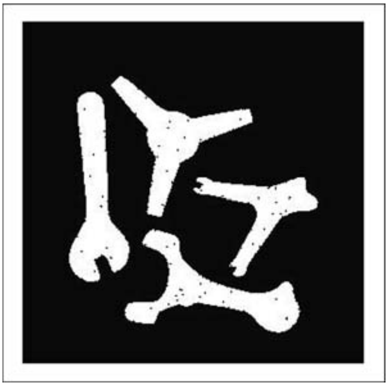
Illustration

Input image	Four metal parts with salt-and-pepper noise added
Image generation	*rni*(*46*), *spn*(*0.1*), *mni*
Command	*fib*

Left: original



Top-right: after processing



41.128 force

Format *force*(*a*, *b*)

Arguments *a* First command/command sequence

b Second command/command sequence

Defaults None

Output values None

Image type Not relevant

Type Program control

Function Execute command/command sequence *a*. If this generates an error, then execute command/command sequence *b*

Switch images Depends upon input arguments

Typical uses Useful when interfacing QT to other software, as the outcome can be predicted

Remarks The following are all valid commands

orce(‘rni(4)’,‘qwerty’) % Nonsense second parameter

force(‘qwerty’,‘neg’) % Nonsense first parameter

x = ‘rni(34)’; y = ‘qwerty’; force(x,y) % Command sequence

x = ‘rni(34)’; y = ‘qwerty’; force(y,x) % Command sequence

x = ‘rni(34),neg,thr’; y = ‘qwerty’; force(y,x) % Assigned variables

force(‘qwerty’,‘ ’) % Successful execution (but does nothing)

41.129 fov

Format *fov*

Arguments None

Output values None

Image type Not applicable

Type Design tool (*fov* is not intended to be used with other QT commands)

Function *fov* (*field-of-view Calculator*) is a design tool that estimates the following parameters for a target vision system:

Function *Field-of-view Calculator. fov* is a design tool that estimates the following parameters for a target vision system:

- The minimum dimensions of the camera's field of view
- The optical magnification required to achieve this
- The pixel size

The width of the smallest linear feature that can be detected reliably. The target system is assumed to perform inspection/measurement functions on piece-parts (widgets) that produce a reasonably high positive contrast with their back-ground. During inspection by the target system, the widgets can be in any orientation but are limited to lie within a defined positional tolerance region [±δx, ±δx]. The user is asked to specify the following input values via the key-board:

- Diameter of the calibration disc (mm, explained below)
- Camera resolution (pixels; the sensor array is assumed to be square)
- Camera sensor size (measured along its diagonal, mm)
- δx, positional tolerance along the X-axis (mm)
- δy, positional tolerance along the Y-axis (mm)

The user is not asked to specify the dimensions of the widget, as these are derived automatically by the QT software. Instead, the user presents the following to QT's camera:

- A circular disc of known diameter (This is called the *Calibration Disc*)
- A sample widget

The calibration disc should be about the same size as the widget (An exact match is not critical and can be judged by eye)

Sample dialogue and output

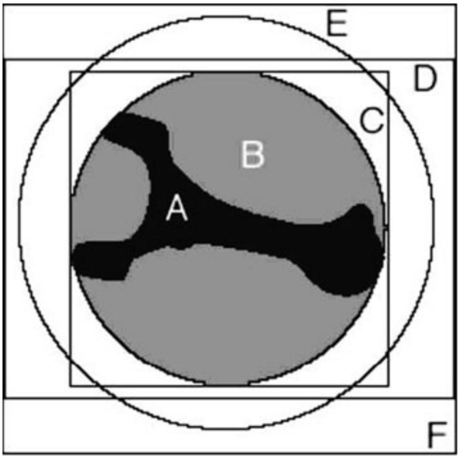
```
FIELD OF VIEW CALCULATOR

Diameter of the calibration disc (mm):157
Camera resolution (pixels):           512
Camera sensor size (diagonal, mm):    6.25
Delta X (mm):                         25
Delta Y (mm):                         5
```

Place the calibration disc fully within the field of view of the camera All activity is suspended until the user clicks on the 'OK' button Place a sample widget fully within the field of view of the camera All activity is suspended until the user clicks on the 'OK' button

RESULTS	
Field of view:	102.75 × 102.75 mm^2
Magnification required:	16.44
Pixel size:	0.20068 × 0.20068 mm^2
Minimum feature width:	0.80273 mm

Image generated by fov



A (black blob):	Widget silhouette
B (inner circle):	Minimum-area-circle enclosing the widget
C (inner rectangle):	Minimum-area-rectangle enclosing B
D (outer rectangle):	Essential pixels
E (outer circle):	Calibration disc
F (outermost square):	Field of view required for square sensor array

N.B. Those pixels in F but not in D are 'wasted' as they will never be used. In this example, only 9.2% of the field-of-view (F) is covered by the widget

41.130 frz

Format	*frz*(*a*, *b*)
Arguments	*a* Switches conversion to grey-scale ON/OFF
Defaults	*a* *1* (*Do not convert to a grey-scale image*)
Output values	*None*
Type	Image acquisition
Function	Acquire an image from a free-running USB camera
Switch images	Yes
Remarks	The operator *frz* illustrates how images from an asynchronous camera may be captured by QT. The camera driver software is set up to load a new image file, called ‘*camera.jpg*’, in the folder ‘QT_work_files’ periodically (typically every second, or so). The previous image file with that name is overwritten. The camera is not synchronised to QT/MATLAB. The author uses a *DinoEye* USB camera (AnMo Electronics, URL *http://www.dino-lite.com*) in conjunction with *EvoCam* software (Evological, URL *http://www.evological.com/*)

41.131 ftm

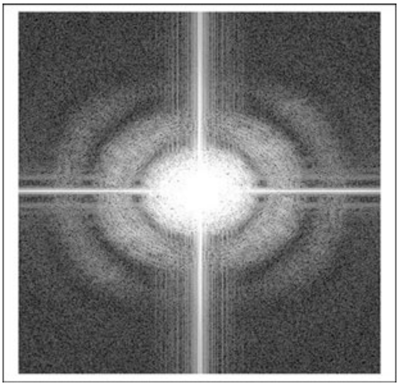
Format	*ftm*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale or binary
Type	Integral transform
Switch	Yes
Function	Log-magnitude Fourier transform (FT)
Typical uses	Analysis of particle size, periodic image structures, texture
Remarks	This version of the Fourier transform is intended as a means of describing images. Other applications, such as correlation, filtering and deblurring are better performed in MATLAB, since they require the use of complex numbers, which the designer of QT has ignored. The Fourier phase image can be calculated by changing line 5 to $a = angle(fft2(current));$ Two examples are shown below. In the first one, the FT of a spiral image, derived from an internal screw thread using a conical mirror, is shown. The spacing between the circular rings indicates the thread pitch. The second example shows the isophotes of the FT derived from the image of a pile of coffee beans. The FT image is merely a bright fuzzy spot, whose diameter is an indicator of the size of the coffee beans. This can be estimated by calculating the area enclosed within one of the contours (function *iso*), or by measuring the width of the peak in the intensity plot (*plt*). In both examples, the median filter (*mdf*(*7*)) was applied before *ftm*, to reduce the effects of noise

Illustration

Input image	Screw thread (file number 20) Coffee beans (file number 4)

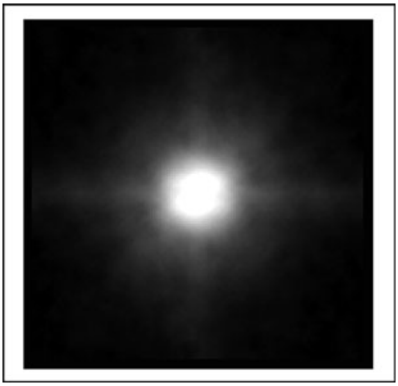
Top-left: screw thread image (file number 20)

Top-right: after *rni*(*20*), *mdf*(*7*), *ftm*

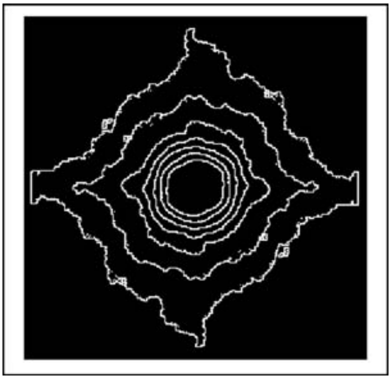


Centre-left: coffee beans image (file number 4)

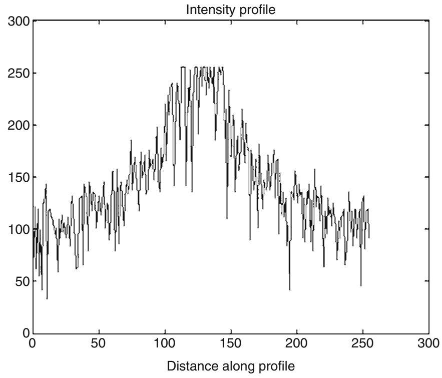
Centre-right: after *rni*(4), *mdf*(*7*), *ftm*, *enc*



Bottom-left: after *mdf*(*7*), *ftm*, *enc*, *sca*(3), *sed*, *thr*(4)

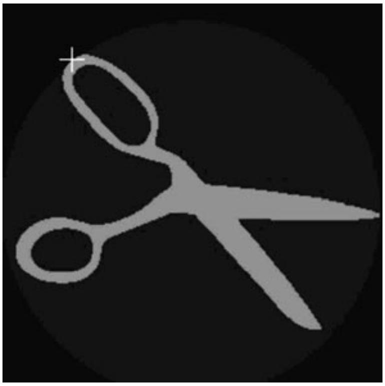


Bottom-right: after *mdf*(*7*), *ftm*, *enc*, *plt*



41.132 fwp

Format	$[u, v, w] = fwp(x, y)$	
Arguments	x	X-coordinate of point
	y	Y-coordinate of point
Defaults	$[x, y]$	Centroid of the object: [*Xcentroid*, *Ycentroid*].
Output values	u	X-coordinate of the white point furthest from *[x, y]*
	v	Y-coordinate of the white point furthest from *[x, y]*
	w	Distance between *[x, y]* and *[u, v]*
Image type	Binary, single object	
Function	Find *[u, v]*, the coordinates of the white point that is furthest from point $[x, y]$. Draw the circle of radius w centred on $[u, v]$, where w is the distance between $[x, y]$ and $[u, v]$.	
Switch images	Yes	
Typical uses	Finding the orientation of a binary object. The orientation of the line joining [*Xcentroid*, *Ycentroid*] and $[u, v]$ is an alternative to the Principal Axis as a means of finding orientation. (The Principal Axis is found by *lmi*)	
Remarks	In its present form, *fwp* will only work properly if $w \leq 255$ pixels	
Illustration		
Input image	Scissors	
File number	48	
Command	$[u, v] = Jwp, adi, hin, dcl(u, v)$	



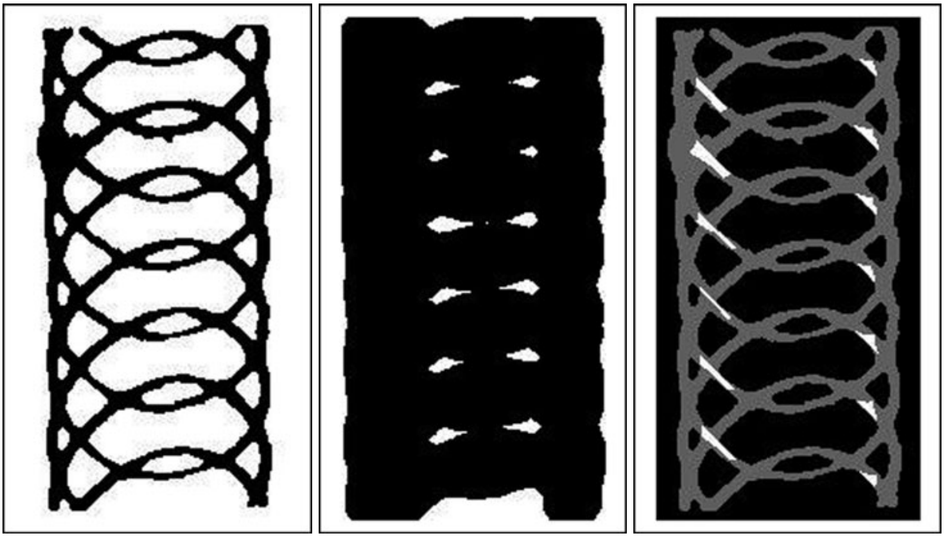
41.133 gap

Format	[*x*, *y*, *z*] = *gap*
Arguments	None
Output values	*x* Vector containing X-coordinates of non-black pixels *y* Vector containing Y-coordinates of non-black pixels *z* Vector containing intensity values of non-black pixels
Image type	Grey or binary
Type	Image measurement
Function	Get the [X, Y]-coordinates and intensity values for all non-black pixels and store them in three separate output vectors
Switch images	No
Typical uses	*gap* can be used in conjunction with *bed*, *ult*, *shk*, etc. to reduce an image to just a small amount of (non-image) data
Remarks	The sequence *[a, b, c]* = *gap*; *fap*(*a*, *b*, *c*) was tested on a 256∗256 pixel image that contains no black pixels. The image was copied successfully but the operation is very slow

41.134 gbd/gbe

Format	*gbd*(*a*) *gbe*(*a*)
Arguments	*a* Structuring element: a 2-dimensional array consisting of 0 s and 1 s
Defaults	None
Output values	None
Image type	Binary
Type	Morphology
Function	General binary dilation (*gbd*)/erosion (*gbe*)
Switch images	Yes
Typical uses	Analysing textured and patterned surfaces. Detecting specific features in an image
Remarks	The function *cse* can be used to generate several frequently used structuring elements: lines (at 0, ± 45° and 90°), upright and diagonal crosses. The MATLAB function *strel* can be used instead, to create structuring elements
Illustration	
Input image	Cake decoration pattern, with thresholding *(thr)* applied to avoid JPEG artifacts
File number	55
Command	Sequence 1: *c* = *cse*(*13*, *21*), *gbe*(*c*) Sequence 2: c = *cse(3, 23), gbe(c), adi*

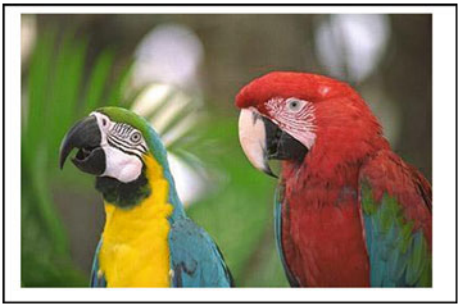
Left: original *Centre*: after sequence 1 *Right*: after sequence 2



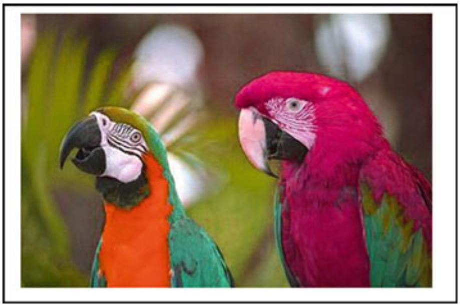
41.135 gcc

Format	*gcc*(*a*, *b*, *c*)
Arguments	*a* Additive adjustment made to the *H* channel *b* Multiplicative adjustment made to the *S* channel *c* Multiplicative adjustment made to the *V* (or I, intensity) channel
Defaults	None
Output values	None
Image type	RGB colour image
Type	Image enhancement
Function	General colour control; adjust the hue, saturation and intensity for each pixel
Definition	$hue = hue + a$, mod 1.0 $saturation = saturation * b$ (Hard limit applied at level 1) $intensity = intensity * c$ (Hard limit applied at level 255)
Typical uses	Image enhancement for visual examination of a scene with low visibility features
Remarks	Also see *gma*, *cga*
Illustration	
Input image	Birds
File number	144
Command	*test1*(−*0.08*, *1.3*, *1*)

Left: original



Right: after processing



41.136 gft

Format *gft*(*a*)

Arguments *a* Choose distance metric. ($0 \leq a \leq 3$)

Defaults *a* 0 (Euclidean distance metric)

Output values None

Image type Input image is binary. The output is a grey-scale image

Type Blob transform

Function Grass-fire transform (Also called *Prairie Fire Transform*)

Description Imagine that the blob is made of combustible material. A fire is ignited simultaneously at all edge points, including inner edges surrounding holes. The intensity in the grass-fire transform image indicates how long the fire takes to reach a given point within the blob

Switch images Yes

Typical uses Blob shape analysis

Remarks The grass-fire transform indicates the distance to the nearest edge pixel. Hence, it is useful for designing morphological operators (i.e., deciding on the size of dilation/erosion structuring elements.) Distance can be measured in a number of ways:

Input parameter, a	Distance metric
0	Euclidean
1	City Block or Manhatten
2	Chessboard
3	Quasi-Euclidean

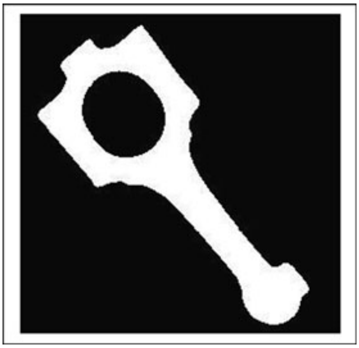
Illustration

Input image Con-rod

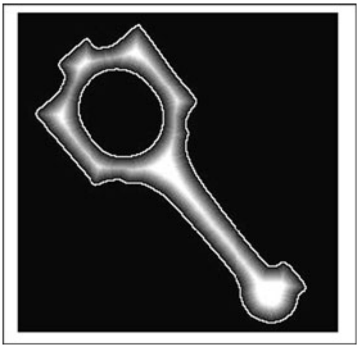
File number 47

Command wri(1), *gft*, *enc*, *wri*(*2*), *rei*(*1*), *bed*, *rei*(*2*), *mxi* (The outer edge was superimposed for clarity)

Left: original



Right: after processing



41.137 gis

Format *gis*(*n*, *d*, *u*, *l*)

Arguments
n No. of images to be stored
d Delay in seconds between successive images
u URL of a web-enabled camera
l Image label

Output values None

Image type Not relevant

Type Image acquisition

Function Capture a series of *n* images from camera *u* at intervals of *d* seconds. The images are stored with labels defined by *l* (e.g., *image1*, *image2*, *image3*, . . .)

Switch images Yes

Typical uses Capturing experimental data from a factory for off-line analysis later

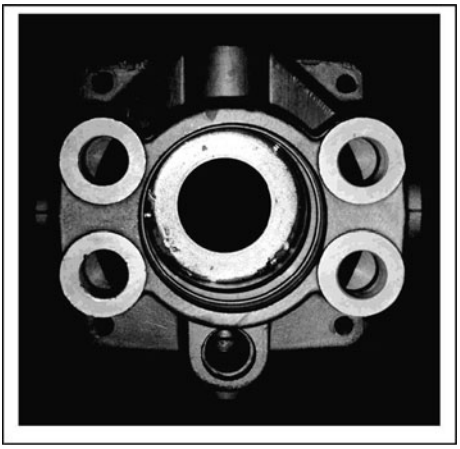
Remarks Precise timing may be a problem when network traffic is heavy and/or the camera is heavily loaded. Provided the parameter *d* is greater than the delay in updating the camera image, the best that can be accomplished is capturing one new image within each *d* second time slot

Sample image sequence captured from a camera in New York City, USA. The computer capturing the images was in Cardiff, Wales, UK. Default values were used for all parameters.

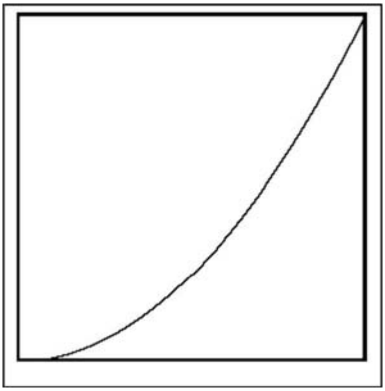
41.138 git

Format	*git*(*a*)
Arguments	*a* Mapping function, specified as a 1D array
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	General intensity transform, using a 256-element look-up table
Switch images	Yes
Typical uses	Image enhancement
Remarks	The input vector, *a*. should have 256 elements and be within the range [0, 255]. Also see *sqr*, *sqt*, *nlg*, *alg*, *enc*, *heq*, *blo*
Illustration	
Input image	Hydraulics manifold
File number	441
Commands	*Centre*: *rni*(*441*), *for i = 1:256*, *x1*(*i*) = (*i* − *1*)∗(*i* − *1*)/*255*; *end*, *git*(*x1*) *Bottom*: *gsn*, *gsn*, *x2* = *hqx*; *rni*(*441*), *git*(*x2*)

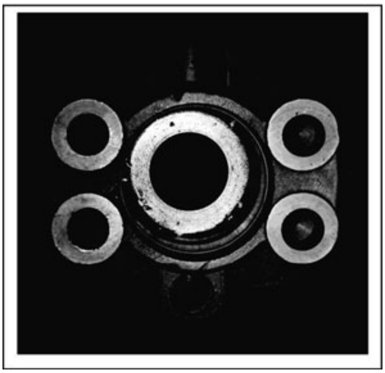
Top: original image



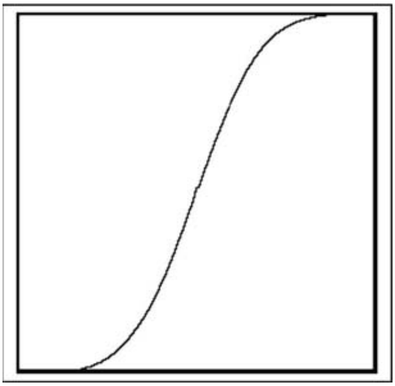
Centre-left: mapping function (*for i = 1:256, x1*(*i*) = (*i* − *1*)∗(*i* − *1*)*/255*; *end* This produces the same result as *sqr*.)



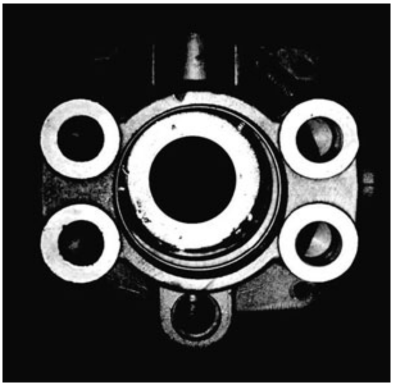
Centre-right: after *git*(*x1*)



Bottom-left: mapping function (*gsn*, *gsn*, *x2* = *hqx*)



Bottom-right: after *git*(*x2*)



41.139 glc

In some versions of QT for MS-Windows, the mnemonic *con* causes problems and is renamed *glc*. See *con*.

41.140 gli

Format	[*a*, *b*] = *gli*	
Arguments	None	
Defaults	Not applicable	
Output values	*a*	Lower intensity limit
	b	Upper intensity limit
Image type	Grey-scale	
Type	Grey-scale image measurement	
Function	Calculate the upper and lower intensity limits	
Switch images	No	
Typical uses	Finding a suitable threshold parameter	
Remarks	Also see *enc*	

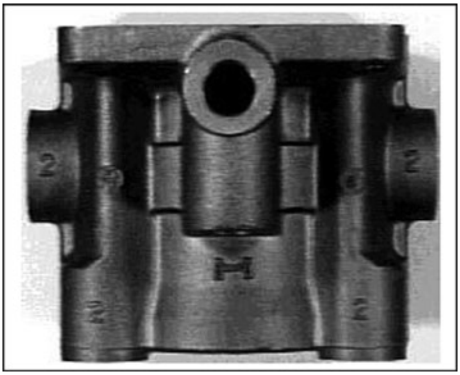
41.141 gma

Format	*gma*(*a*)
Arguments	a Gamma (γ)
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Square of intensities in the current image
Definition	$C \Leftarrow 255*(A/255)^{\gamma}$, where γ is a constant, typically in the range $0.5 \leq \gamma \leq 2$
Switch images	Yes
Typical uses	Correcting for camera non-linearity
Remarks	The function *gma* is used to improve contrast in bright/dark regions of the image. If $\gamma < 1$, dark regions are enhanced, while bright regions are enhanced if $\gamma > 1$. Photographers (and video engineers) are familiar with the concept of gamma correction: a non-linear mapping of intensity is applied to an image to compensate for film (or video sensor) non-linearity. The function *sqr* is equivalent to *gma*(*2*) and *sqt* to *gma*(*0.5*). Clearly, *gma* provides finer control of contrast than either of these. Also see *alg* and *nlg*

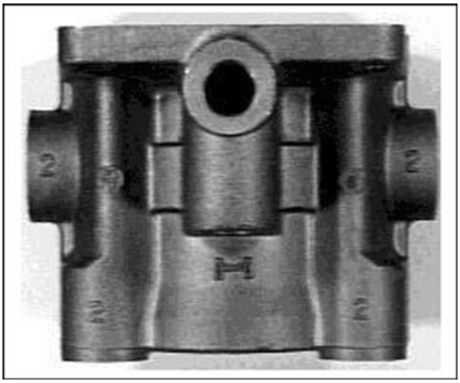
Illustration

Input image	Hydraulics component (side view)
File number	38
Command	*gma*(*0.7*)

Left: original



Right: after processing



41.142 gpt

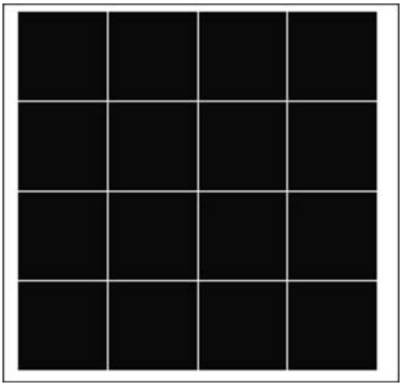
Format	*c* = *gpt*(*a*, *b*)	
Arguments	*a*	X-coordinate of a point
	b	Y-coordinate of a point
Defaults	None	
Output values	c	Intensity at [x, y]
Image type	Greyscale or binary	
Type	Grey-scale/binary image measurement	
Function	Find the intensity (*c*) at the point *[a, b]*	
Switch images	No	
Remarks	Also see *pxv*, and *blp/brp/lbp/...*	

41.143 grb

Format	*grb*(*a*, *b*)	
Arguments	*a*	*Integer, camera selection*
	b	*Grey-scale* (*0*)*/colour* (*1*) *selection*
Defaults	*a*	*0*
	b	*0* (*Convert image to grey-scale format*)
Output values	*None*	
Type	Image acquisition	
Function	Acquire an image from a local camera from an external webcam	
Switch images	Yes	
Remarks	The present version of *grb* illustrates how the M-file is structured. Some of the cameras are outside the author's control, so their availability cannot be guaranteed. From time to time, some of these cameras may be replaced and/or others added. For a good source of information about web cameras, visit *http://www.earthcam.com/* Also see *gwi*	

41.144 grd

Format	*grd*
Arguments	None
Defaults	Not applicable
Output values	None
Type	Drawing and image generation
Switch	Yes
Function	Generate a simple grid pattern
Switch images	Yes
Typical uses	Testing various image processing functions, such as filters
Remarks	Also see *grd*
Illustration	
Commands	*grd*



41.145 grip1 – grip4

The functions *grip1*, *grip2*, *grip3* and *grip4* are included here merely to illustrate the use of QT in robot vision and do not purport to provide comprehensive coverage of this subject. Our intention is to show that an image processor with a few simple graphics functions can be used to good effect in determining where best to place a robot gripper so that it can lift an object and checking whether it is safe to attempt to do so. Four situations are considered and are summarised in the table below.

QT function	Gripper fingers	Inputs	Outputs/draws
grip1	2 rectangular	XY position of gripper	No data output
		Orientation of gripper	Draws gripper as 2 rectangles
grip2	2 rectangular	XY positions of 2 points	XY position of gripper
			Orientation of gripper
		Size of gripper fingers	Draws gripper as 2 rectangles.
grip3	2 circular	Radius of gripper fingers	Positions of 2 fingers
			Draws gripper as 2 circles
grip4	1 circular (suction or magnetic)	None	Position of gripper
			Orientation of gripper
			Draws largest possible gripper

It is assumed that, in each case, one, or more, objects are lying on a plain smooth table that provides a high-contrast background. An overhead camera views the objects, which will then be picked up by a robot. To do so properly, the robot requires the following information:

1. XY coordinates for the centre axis of the robot's gripper.
2. Angular position of the robot's gripper.

No consideration is given here to converting camera coordinates to robot coordinates, nor the initial calibration of the 'hand-eye' system. The task is thus reduced to its simplest form as an exercise in 2D image intepretation.

41.145.1 grip1

Format	*grip1(x, y, z, d, N1, N2)*	
Arguments	*x*	X-coordinate of the centre axis of the gripper
	y	R-coordinate of the centre axis of the gripper
	z	Orientation of the gripper
	d	Separation of the finger of the gripper
	N1	Width of the fingerprint (one finger)
	N2	Length of the fingerprint (one finger)
Defaults	None	

Outputs None

Function *grip1 draws* two rectangles to indicate where the fingers will be placed

Switch images Yes

Typical uses Checking that the intended placement of the robot gripper will not cause a crash

Remarks This is a simple graphics operator, which draws two rectangles to indicate where the fingers will be placed. The gripper is in the *open* position. *grip1* is a component of *grip2*. An illustrative example of its output is shown later (*grip2*)

Illustration See *grip2*

41.145.2 grip2

Format *[x, y, z]=grip2(x1, y1, x2, y2, N1, N2)*

Arguments

Arguments	*[x1, y1]*	Coordinates of one point
	[x2, y2]	Coordinates of another point
	N1	Width of the fingerprint (one finger)
	N2	Length of the fingerprint (one finger)
Defaults	None	
Outputs	*[x, y, z]*	Position and orientation of the gripper

Function *grip2* accepts the coordinates of two points on any object and then calculates the following:

Coordinates of the centre of the gripper *[x, y]*

Orientation of the gripper *(z)*

It then draws the fingerprint of the gripper as two rectangles (Same as *grip1*)

Switch images Yes

Typical uses Checking that the intended placement of the robot gripper will not cause a crash

Remarks The image below shows an electrical inductor (coil) with two flying leads. Our objective is to design a visually guided robot that can locate and then grasp the end of one of the wires. In practice, this application requires 5 cameras, with computer-controlled lighting, and a robot with 6 degrees of freedom. However, we shall simplify the task by considering only the plan view of the coil. In order to take variations of back-ground intensity into account, the following preprocessing sequence may be used:

```
enc,            % Enhance contrast
mdf,            % Median filter
crk,            % ‘Crack detector’: grey-scale closing operator
thr(123)        % Threshold at some appropriate value
```

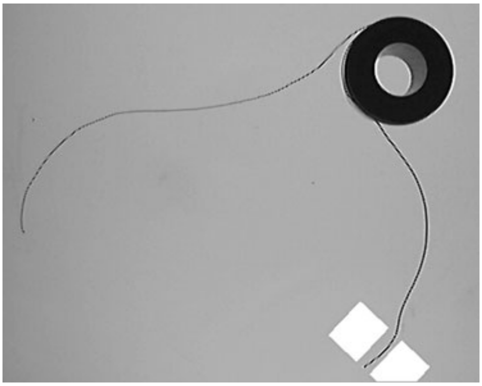
We then use the following sequence applied to the binary image generated above:

```
thn,            % Thinning operator
spr(15),        % Recursively remove the limb-end pixels (15 loops)
exr,            % Exclusive OR - isolates the ends of the wires
```

```
big,                  % Select one blob (i.e., tip of one of the wires)
lmb,                  % Select limb ends
x=gap;
a=angle([x(1), y(1)],[x(2), y(2)])
                      % Orientation of the end of wire 1
grip2((x(1)+x(2))/2, y(1)+y(2))/2, a, 10, 15, 20)
```

The result of processing a typical image of a coil is shown below. The white rectangles show the positions of the finger tips when the gripper is '*open*' (The simple version of *grip1* listed below draws only the outline of the lower rectangle, because it overlaps the edge of the image. This rectangle was 'filled in' manually, to make the illustration clearer)

Illustration The image below shows the coil with two flying leads. Superimposed on this are two white rectangles representing the fingerprints of the gripper in the 'open' state. These were calculated by *grip2*



41.145.3 grip3

Format	*[u1, v1, u2, v2]=grip3(a)*	
Arguments	*a*	Radius of gripper fingers
Defaults	a	24
Outputs	*[u1, v1]*	Coordinates of one of the gripper fingers
	[u2, v2]	Coordinates of the other gripper finger

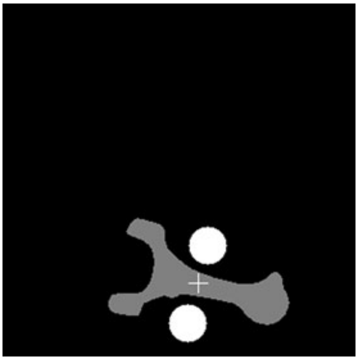
Function *grip3 draws* two solid circles to indicate where the fingers will be placed and returns 4 numeric values indicating their positions. The finger positions are calculated automatically from the centroid and the orientation of the principal axis

Switch images Yes

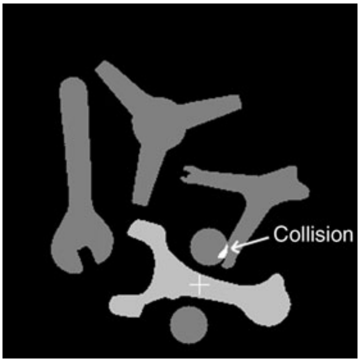
Typical uses Checking that the intended placement of the robot gripper will not cause a crash

Remarks This is a simple graphics operator, which draws two circles to indicate where the fingers will be placed. The gripper is in the *open* position

*Bottom-left***:** Image generated by *grip3*

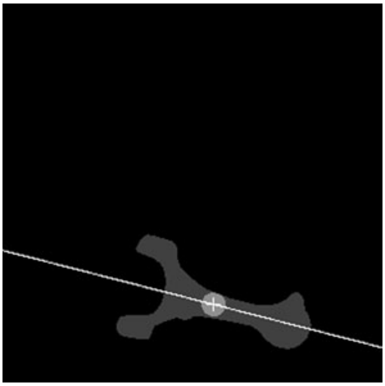


Bottom-right: grip3. Collisions ca detected



41.145.4 grip4

Format	*function [x, y, r]=grip4*
Arguments	None
Outputs	*[x, y, r]* Position and orientation of the gripper
Function	Calculate the coordinates of the centroid and orientation. Then, find the largest circular gripper that can be placed at the centroid without overlapping the edge of the object
Switch images	Yes
Typical uses	Checking that a robot with a magnetic or suction gripper will provide safe lifting
Remarks	This is a simple graphics operator that draws a white disc to show where the gripper wil be placed
Illustration	The light grey disc represents the largest suction or magnetic gripper that can be placed at the centroid (white cross). (To ensure safe lifting, these types of gripper must not overlap the edge of the object.) The orientation of the object is determined by the principal axis (white line)



41.146 grp

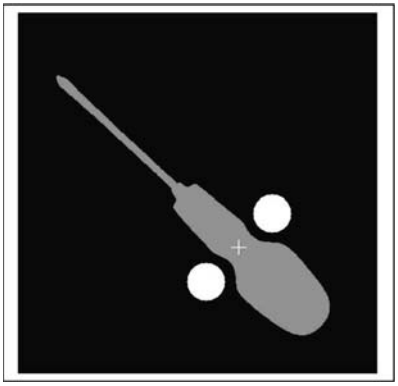
Format	$[u1, v1, u2, v2] = grp(a)$	
Arguments	*a*	Controls gripper spacing and size
Defaults	*a*	24
Output values	*[u1, v1]*	Coordinates of the first gripping point
	[u2, v2]	Coordinates of the second gripping point
Image type	Binary (single blob)	
Type	Robot vision	
Function	Calculate and display the gripping points for 2-finger robot gripper	
Switch images	Yes	
Typical uses	Demonstrates how QT can be used in conjunction with a multi-axis robot	
Remarks	The gripping points are displayed as circular discs. They are located on that line lying at 90° to the axis of minimum second moment (the principal axis) and passing through the centroid. The gripper size is adjusted automatically, to ensure that there will be some space between the object and the gripper. The simple algorithm implemented by *grp* does not always produce good gripping points. For example, on a 3-pointed star, the axis of minimum second moment is not well defined. As a result, the positions of the gripping points are highly variable as they are strongly dependant on edge quantisation effect	

Illustration

Input image	Screwdriver
File number	43
Commands	*thr, neg,*$[x1, y1, x2, y2] = grp(32)$

Left: original

Right: after processing



41.147 grs

Format [*x*, *y*, *u*] = *grs*

Arguments None

Output values *[x, y]* Coordinates of the gripping point (centroid)

u Maximum radius of the gripper to ensure good grip

Image type Binary (single blob)

Type Robot vision

Function Calculate and display the gripping point for a suction or magnetic gripper

Switch images Yes

Typical uses Demonstrates how QT can be used in conjunction with a multi-axis robot

Remarks The position of the gripper is indicated by a small white cross (i.e., the centroid of the blob) and its orientation by a white line (i.e., the axis of minimum second moment). The 'footprint' of the largest gripper that can safely be used to pick up this object is displayed as a circular disc. The simple algorithm implemented by *grs* does not always produce a good gripping point. For example, the axis of minimum second moment of a 3-pointed star is not well defined, so the orientation of the gripper is highly variable

Illustration

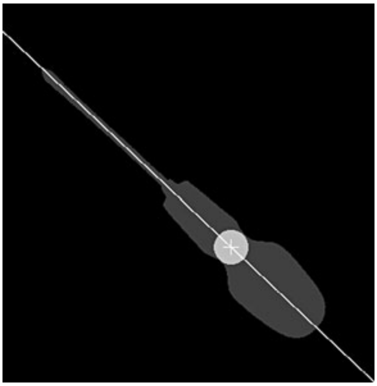
Input image Screwdriver

File number 43

Commands *thr*, *neg*,[*x*, *y*, *u*] = *grs*

Left: original

Right: after processing



41.148 gry

Format	*gry*
Arguments	None
Output values	None
Image type	Colour
Type	Colour transformation
Function	Convert a colour image to grey
Switch images	Yes
Typical uses	Discarding colour information to simplify processing
Remarks	Also see *hsi* and *rgb*

41.149 gsi

Format	*gsi*
Arguments	None
Output values	*None*
Image type	None
Type	System control
Function	Set up Stack Mode so that the user can recover a stack image simply by clicking on it
Switch images	No
Remarks	*gsi* alters the internal configuration but does not have any visible effect

Illustration

Screen layout, Stack Mode (i.e., Image Stack is active and part of it is displayed here). *Top-left*: Command Window; *Centre-left*: command History; *Top-right*: window labelled '*Figure 1*', contains the Current Image (left) and Alternate Image (right); *bottom*: window labelled '*Figure 2*', shows the top 8 elements of the stack and that image which was previously at the top of the stack (labelled '−1'). The user can recover any of the images displayed in *Figure 2*, simply by clicking on it.

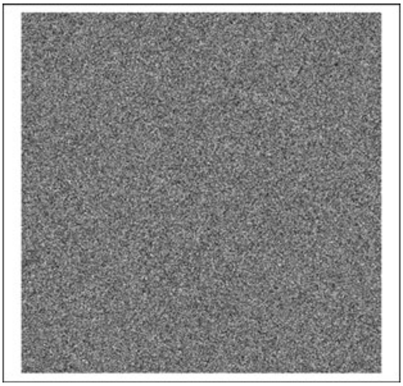
41.150 gsn

Format	*gsn*(*a*)
Arguments	*a* Determines the level of noise added to the image (0 ≤ a ≤ 1)
Defaults	*a* 1
Output values	None
Type	Drawing and image generation
Switch	Yes
Function	Generate an image array containing random numbers with a Gaussian distribution and add this to the current image. The standard deviation of the noise is determined by the input parameter, *a*
Switch images	Yes
Typical uses	Testing prototype image processing functions. Generating other test patterns
Remarks	Use *gsn* and a low-pass (blurring) filter to create a cloud-like pattern. Use a low-pass (blurring) filter and thresholding to create useful a binary test pattern

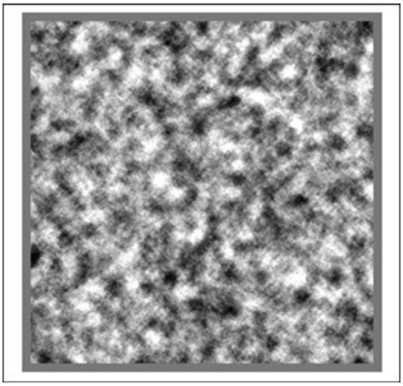
Illustration

Commands Left image: *gsn*. Right image: *gsn*, *caf*, *edg*(*8*, *128*), *enc*

Left: Gaussian noise image



Right: noise image after low-pass filtering and contrast enhancement



41.151 gwi

Format	$[b, c] = gwi(a)$
Arguments	*a* URL of the image file to be loaded (Include *http*:// at the beginning)
Defaults	Not applicable
Output values	*b* Image width (number of columns)
	c Image height (number of rows)
Image type	Image files in BMP, JPEG, PNG or TIFF formats can be read. Colour images are converted to grey-scale, using the intensity component
Type	Input/output
Function	Grab a web image given its URL
Switch images	Yes
Typical uses	Loading images from a web-cam
Sample call	*gwi*(‘*http://gemini.cs.cf.ac.uk/eyeimage.jpg*’)
Remarks	Frequently used web-cams can be accessed more conveniently by re-programming *grb*

41.152 hbt/hbt1/hbt2

Format *hbt*(*n*. *p*)
hbt1(*n*, *p*)
hbt2(*n*, *p*)

Arguments *n* Determines the size of the sampling 'snake' (*length* = *2n* + *1*)
p New image size(after normalising to produce a square image)

Defaults 8

Output values None

Image type Grey scale

Type Image filter

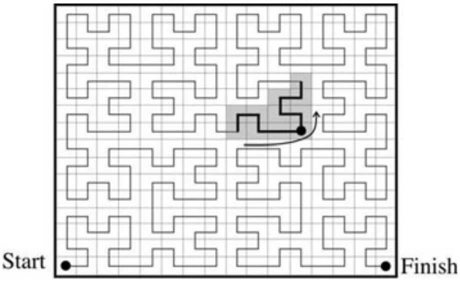
Function *hbt*

1. Reformat the input image so that it is square of size p × p pixels, *p* integer
2. Derive the path followed by the mth order Hilbert curve where $m = log_2(p)$
3. Using a 'snake' of length 2n + 1 pixels, calculate the local average intensity
4. Progressively move the 'snake' one position along the Hilbert curve and repeat step 3, for all pixels along the Hilbert curve (See diagram below)

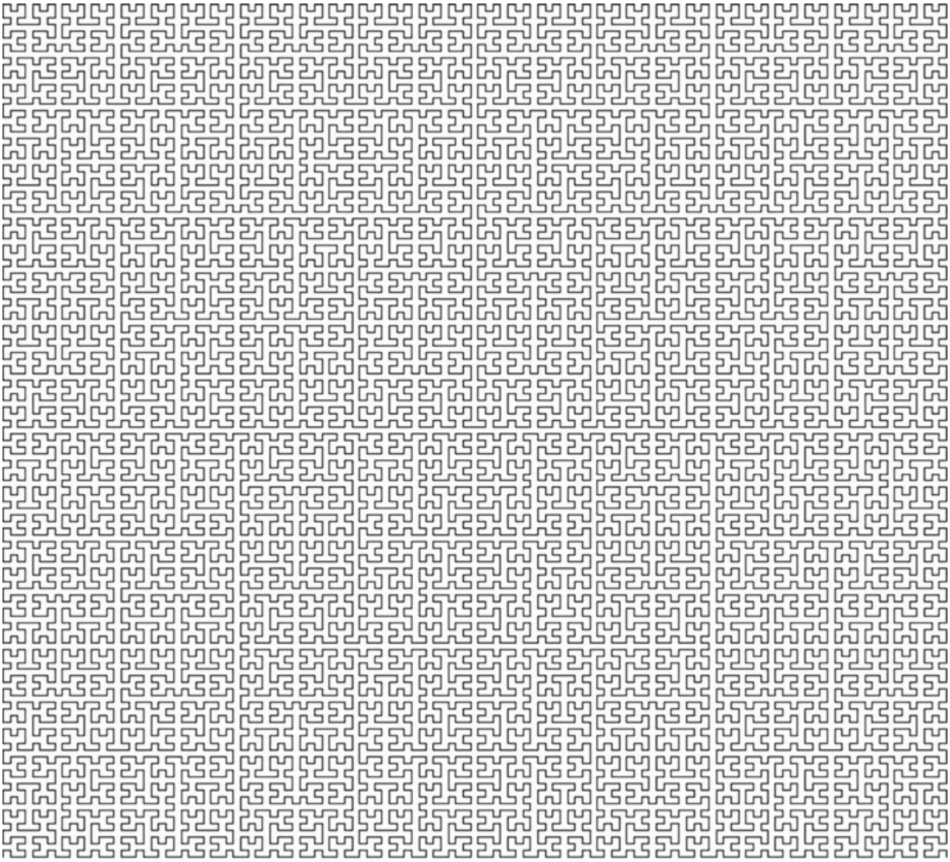
hbt1 As for hbt, except that the maximum intensity is found along the 'snake'.

Switch images Yes but the picture displayed in the Alternate Image is reformatted to be square and of size $2^m \times 2^m$, where *m* is an integer and is equal to $log_2(p)$

Remarks Filtering with the Hilbert curve is relatively crude but it does lend itself to implementation in fast hardware using shift registers. Also see *scr*



Smoothing by averaging along the Hilbert curve. In this simple example the intensities in 11 pixels (shaded) are averaged. That value is then stored, in the output image, at the position indicated by the black spot. The process is repeated by moving the sampling 'snake' progressively along the Hilbert curve. Notice that the region contributing to the estimate of local average intensity changes shape as the 'snake' moves around the Hilbert curve.

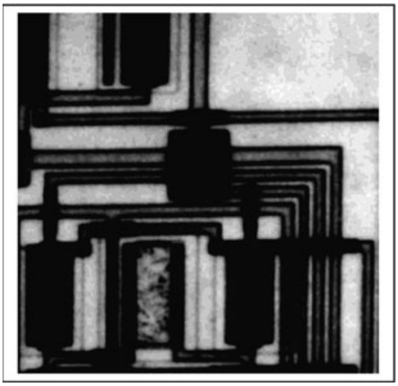


Hilbert curve, 10th order

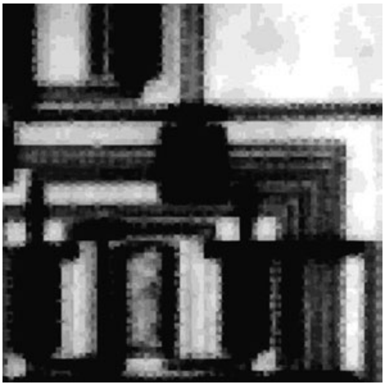
Illustration

Input image	Thick film circuit
File number	136

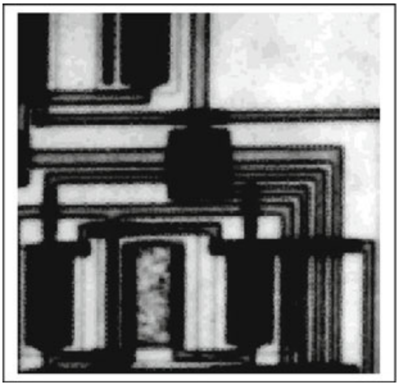
Top-left: original image



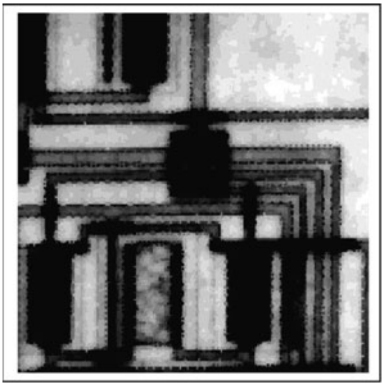
Top-right: after *hbt*(*11*, *256*)



Bottom-left: after *hbt*(*11*, *512*)



Bottom-right: after *hbt1*(*11*, *512*)



41.153 hcd

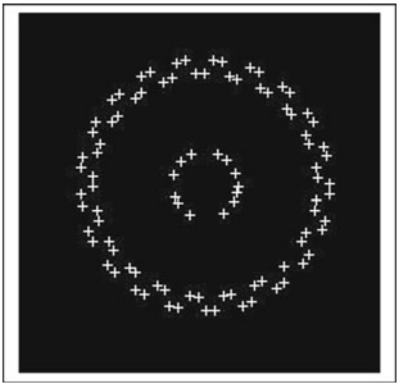
Format	*[d, e] = hcd(a, b, c)*	
Arguments	*a*	Standard deviation of smoothing Gaussian filter
	b	Threshold
	c	Radius of region considered in non-maximal suppression
Defaults	*a*	2
	b	1000
	c	2
Output values	*d*	Row coordinates of corner points
	e	Column coordinates of corner points
Image type	Grey or binary	
Type	Image analysis	
Function	Detect corners	
Switch images	Yes	
Typical uses	Feature detection, prior to measuring distances and angles based on corners. Corners may also be useful in constructing a 'line drawing' from the image	
Remarks	It may be necessary to experiment to obtain the best set of parameter values This operator tends to be 'generous' in detecting subtle features, which can reduce the speed of operation	

Illustration

Input image	Gear
File number	171
Command	*hcd*, *dil*(*3*), *crs*(*3*)

Top-left: original image

Right: after processing

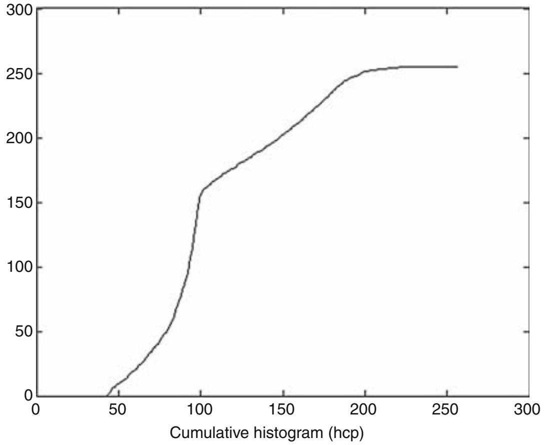


41.154 hcp

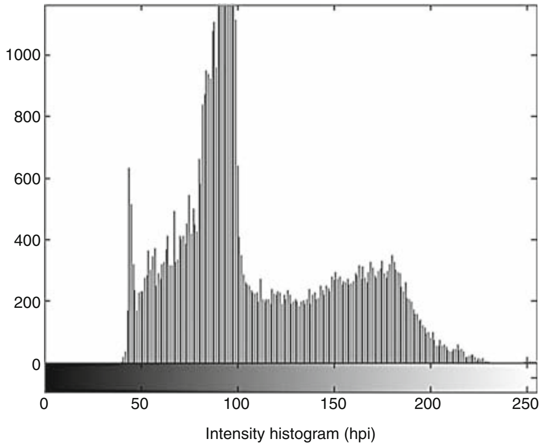
Format	*a* = *hcp*
Arguments	None
Defaults	Not applicable
Output values	*a* Cumulative histogram, rescaled to the range [0, 255]
Image type	Grey
Type	Histogram analysis
Function	Calculate and plot the cumulative intensity histogram. Strictly speaking, this is the function *H*(*X*), where $H(X) = \int_{x=0}^{x=X} h(x).d(x)$ However, this is approximated, in the discrete-variable arithmetic used in QT, by $H(X) = \sum_{i=0}^{X} h(i)$ The output (*a*) generated by *hcp* is the 1-dimensional array: $a(X) = \frac{W.\sum_{i=0}^{(X)} h(i)}{W.H}$ a(X) is the function that performs histogram equalisation on the input image
Switch images	Yes
Typical uses	*hcp* provides useful way to generate the histogram equalisation mapping function. This can be used in a variety of ways, such as contrast enhancement by hyperbolisation. That is, the histogram of the resulting picture has a histogram that has the form *1/X*
Remarks	Also see *hpi*, *hqx*, *mit*

Illustration

Left: histogram equalisation mapping function



Right: intensity histogram



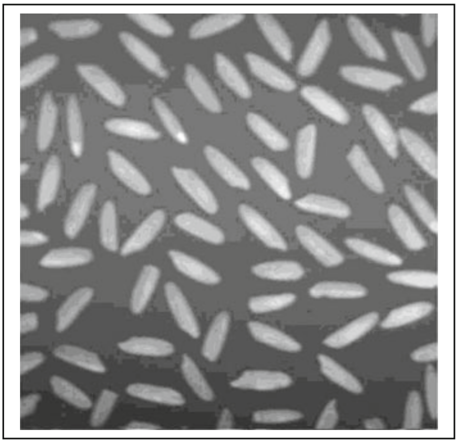
41.155 heq

Format	*heq(a)*
Arguments	*a* Control parameter for plotting the mapping function
Defaults	a 0 Do not plot the mapping function
Output values	None
Image type	Grey
Type	Monadic
Function	Enhance contrast by applying histogram equalisation to the intensity scale. This results in an image whose intensity histogram is nearly flat.
Switch images	Yes
Typical uses	Increasing contrast.
Remarks	The darkest pixel in the output image is black and the brightest pixel is white. However, notice that *enc* performs a linear stretching of the intensity scale, whereas *heq* is non-linear. Also see *blo*, *acn*, *din*, *hcp, hin.*

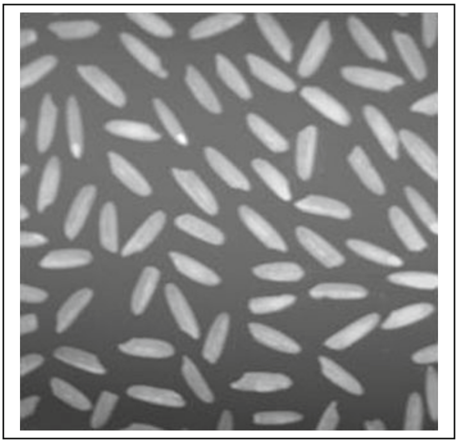
Illustration

Input image	Rice grains
File number	3
Command	*heq*

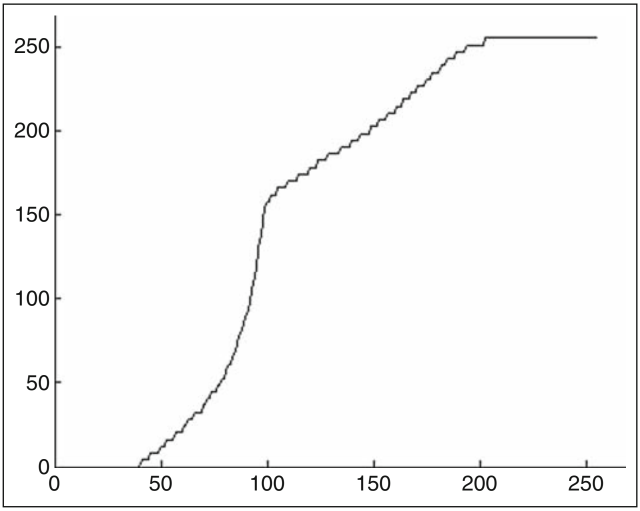
Left: original



Right: after processing



Bottom: Mapping function. Abscissa, input intensity. Ordinate, Output value



41.156 hgm

Format	$b = hgm(a)$	
Arguments	a	Select type of histogram display
Defaults	a	1
Output values	b	Intensity value selected by the user
Image type	Grey	
Type	Histogram	

Function: Plot the intensity histogram of the current image. There are four options, as indicated in the following table

Input	Plotted in	Colour bar (wedge)	Ordinate axis	Interactive	Switch Images
None	Figure 1	No	Linear	No	No
1	Figure 1	Yes	Linear	No	No
2	Figure 1	Yes	Linear	Yes	Yes
3	Figure 1	Yes	Logarithmic	Yes	Yes
4	Figure 3	Yes	Linear	No	No
5	Figure 1	Yes	Cumulative	No	Yes

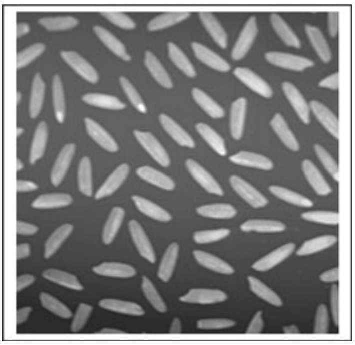
Remarks: *hgm* is used principally as an aid to understanding the structure of an image and particularly in helping the user to select an appropriate threshold parameter. (Thresholding is performed separately, probably using *thr*.) The image of the histogram created by *hgm*(*1*) can be processed like any other grey-scale image. *hgm*(*2*) allows the user to relate peaks and valleys to the intensity scale and then estimate where to place a threshold *hgm*(*3*) is similar but uses a logarithmic vertical scale, to compress very high peaks, so that lower peaks can be examined more closely. *hgm*(*4*) produces a pretty annotated diagram that is suitable for insertion into a report, thesis, book, etc. Also see *dth*, *cur*

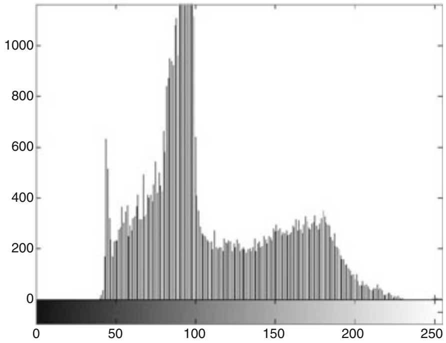
Illustration

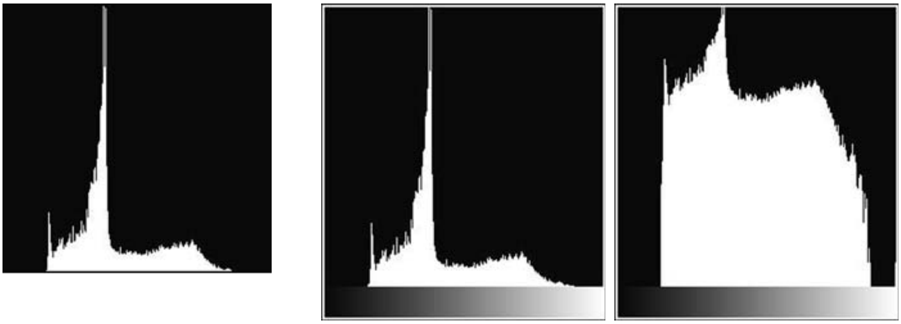
Input image: Rice grains

File number: 3

Command:
Top-left: Original image
Top-right: *hgm*(*4*)
Bottom-left: *hgm*(*1*)
Bottom-centre: *hgm*(*2*)
Bottom-right: *hgm*(*3*)







41.157 hgr

See *con.*

41.158 hil

Format *hil*(*a*, *b*, *c*)

Arguments *a* Lower intensity threshold limit

b Upper intensity threshold limit

c New intensity value

Defaults *c* 255

Output values None

Image type Grey

Type Monadic

Function Highlight a given range of intensity values; all pixels whose intensities lie within the range *[a, b]* are mapped to level c. All other pixels remain unchanged

Switch images Yes

Typical uses Image segmentation (i.e., isolating an object silhouette by suppressing unwanted intensity variations in its background)

Remarks To novice users, thresholding (*thr*) and highlighting are obvious functions to use in many applications. However, both are sensitive to lighting variations and will not produce reliable image segmentation in any but the simplest applications. For this reason, they are almost always used where manual setting of the input parameters is possible, or in conjunction with a suitable filter, edge detector, or intensity-normalisation function

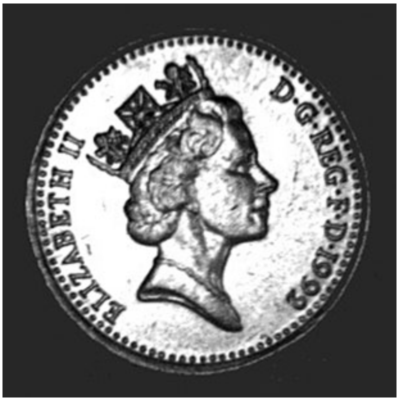
Illustration

Input image Coin

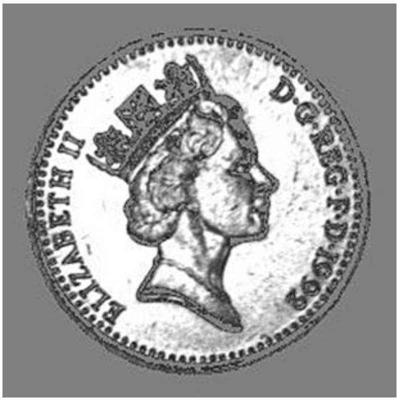
File number 23

Command *hil*(*0*, *50*, *128*)

Left: original



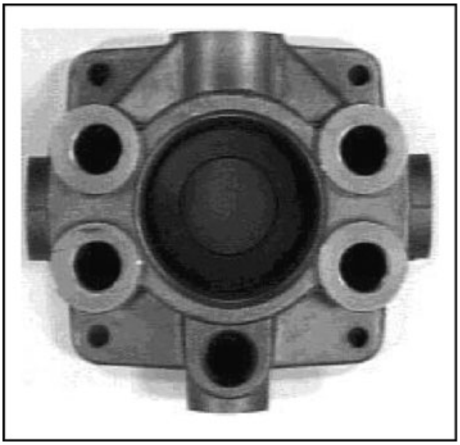
Right: after processing



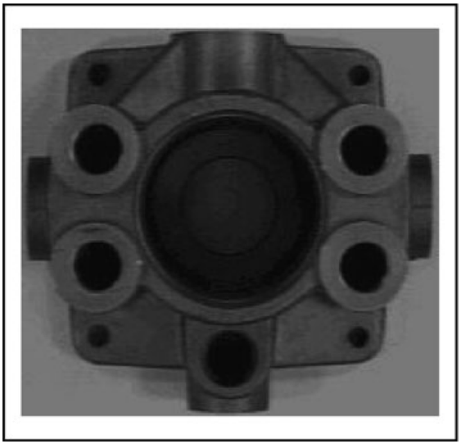
41.159 hin

Format	*hin*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Monadic
Function	Halve all intensities
Definition	C ⇐ A/2
Switch images	Yes
Typical uses	Reducing intensity so that white annotation features can be superimposed (using *mxi*)
Remarks	Also see air, *blo*, *din*, *enc* and *heq*
Illustration	
Input image	Hydraulics component
File number	37
Command	*hin*

Left: original



Right: after processing



41.160 hlp

Format	*hlp*('*topic*') or *hlp topic*
Arguments	topic Character sequence
Defaults	No topic supplied: *hlp* lists all of the M-files in the scripts folder
Output values	None. Data is printed on the screen, in MATLAB's *Command Window*
Type	Miscellaneous
Function	Help facility. QT and MATLAB's own M-files are listed. See example below
Switch images	No
Remarks	The reader is also referred to MATLAB's *help*, *which* and *what* functions
Output:	no argument supplied

```
aab.m     Area of all blobs in a binary image. [1/0]
abd.m     Absolute value of difference in intensities between current and lternate
abv.m     Absolute value of the intensity in the current image. [0/0]
.........
zed.m     Zero-cross edge detector. [1/1]
zer.m     Set all pixels to black. [0/0]
```

The brief explanation listed opposite each command is derived from the first comment line in the MATLAB listing. (The MATLAB documentation refers to this as the *H1* line.)

Typical output: command hlp('radon') or *hlp radon*

```
dlr.m:    % Draw one line identified from a peak in the Radon transform image [0/4]
drp.m:    % Dominant Radon projection [0/0]
irt.m:    % Inverse Radon Transform [0/0]
rdn.m:    % Radon transform [0/0]
IRADON Compute inverse Radon transform     N.B. This is a MATLAB function
RADON Compute Radon transform              N.B. This is a MATLAB function
RADONC Helper function for RADON           N.B. This is a M function
```

41.161 hpf

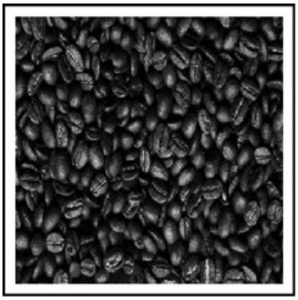
See *lpf*.

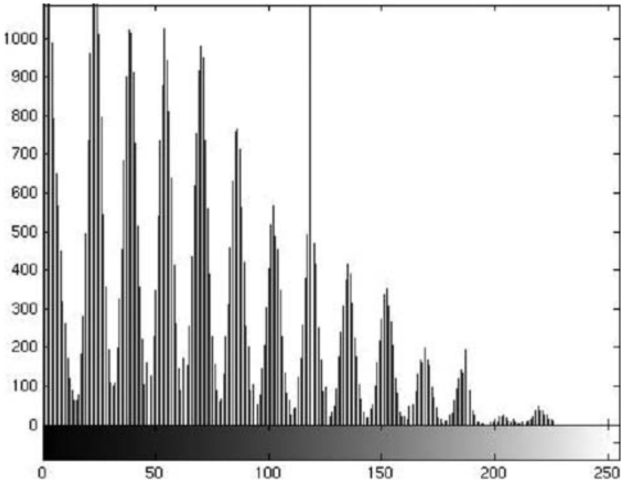
41.162 hpi

Format	*hpi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Histogram
Function	Calculate and plot the intensity histogram of the current image in Figure 4 (full screen). The user closes Figure 4 by clicking anywhere on it
Switch images	No
Typical uses	*hpi* is used principally as an aid to understanding the structure of image and in guiding the design of an algorithm. It is commonly used is to assist in the choice of a threshold parameter. For example, a bimodal intensity histogram often results from back-lighting an opaque object. A threshold point close to the bottom of the valley between the two peaks in the histogram is often able to isolate the object silhouette
Illustration	
Input image	Coffee beans
File number	4
Command	*hpi*
Remark:	The multiple peaks in the histogram below arise as a result of saving the image in JPEG format (The image was originally stored in JPEG format and later converted to TIF format for this book.)

Left: input image

Right: intensity histogram Abscissa, intensity. Ordinate, frequency (no. of pixels)





41.163 hqx

Format *a* = *hqx*

Arguments None

Defaults Not applicable

Output values *a* Histogram equalisation mapping function, derived from the Alternate image

Image type Current and Alternate images should both be grey

Type Histogram adjustment

Function The mapping function that would perform histogram equalisation on the Alternate image is computed. (This function is returned in the 1-D output array *a*.) This mapping function is then applied to the Current image

Switch images Yes

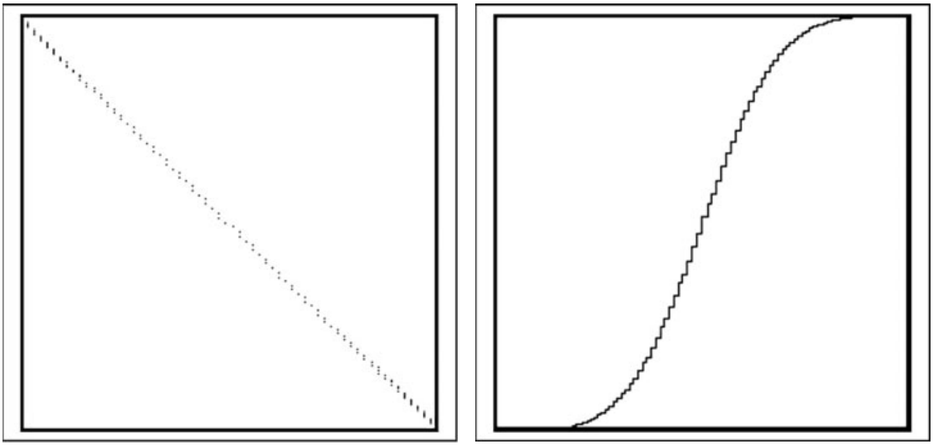
Typical uses *hqx* is useful as a way of modelling near real-time histogram equalisation, where the mapping function derived from frame *I* of a video sequence is applied to frame (*I* + *1*) or (*I* + *2*), not to frame *I*

Remarks The following command sequence should produce a straight line *gsn*, *heq*, *wri*, *swi*, *cpy*, *hqx*, *rei*, *imf*

In fact, [*cpy*, *hqx*] generates an image that differs slightly from that produced directly by *heq*; the differences are slight and appear to be due to rounding errors. (See illustration below.) Also see *hcp* and *hpi*

Illustration

Left: *gsn*, *heq*, *wri*, *swi*, *cpy*, *hqx*, *rei*, *imf* *Right*: mapping function, ‘Gaussian noise’ image



41.164 hsb

Format	*[c, d] = hsb(a, b)*	
Arguments	*a*	Number indicating which row is to be scanned
	b	Minimum intensity value to be detected
Defaults	None	
Output values	*c*	X-coordinate of point found
	d	Intensity of point found
Image type	Grey scale or binary	
Type	Image measurement	
Switch	No	
Function	Scan horizontally along a given row until a bright pixel is found	
Definition	Scan row *a* from left to right. When a pixel with intensity value greater than or equal to *b* is found, stop and return the X-coordinate (*c*) and intensity (*d*)	
Switch images	No	
Typical uses	Fitting curves to edges or other contours	
Remarks	For an example of use (fitting a circle to three edge points), see *fce*	

41.165 hsi/hue/ity/sat

Format *hsi*(*a*)
hue
ity
sat

Arguments *a* Select one of the *H*, *S*, *I* channels (*hsi* only)
hue None
ity None
sat None

Defaults *a* 0 (Display *H*, *S* and *I* components separately. Do not alter the current image)

Output values None

Image type Colour

Type Image display and channel separation

Function *hsi*
a = 0: Separate and display the *H*, *S* and *I* channels
a = 1: Set the current image to be equal to the *hue* channel
a = 2: Set the current image to be equal to the *saturation* channel
a = 3: Set the current image to be equal to the *intensity* channel
hue Same as *hsi*(*1*) (select hue channel)
ity Same as *hsi*(*3*) (select intensity channel)
sat Same as *hsi*(*2*) (select saturation channel)

Switch images *hsi*
a = 0, No
a ≠ 0, Yes
hue, *ity*, *sat*
Yes

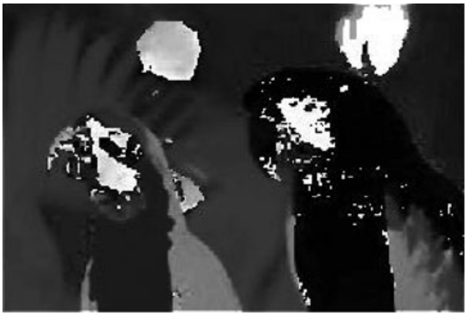
Typical uses Simplifying colour image processing, by reducing it to grey-scale processing

Remarks *hsi*(*0*) displays the 4 images in Figure 4 which is automatically scaled to fill the screen. Figure 4 closes when the user clicks on it. Also see *rgb*

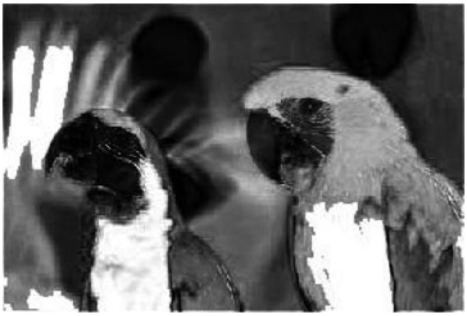
Illustration

Input image	Birds
File number	144
Command	*hsi*

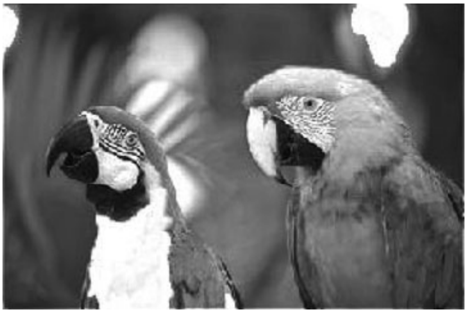
Top-left: hue



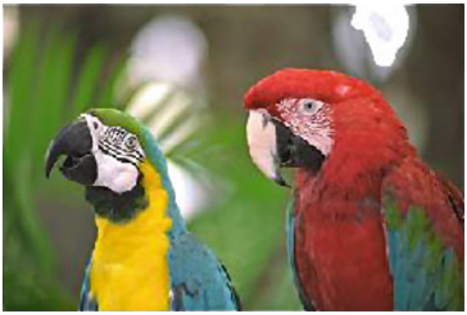
Top-right: saturation



Bottom-left: intensity

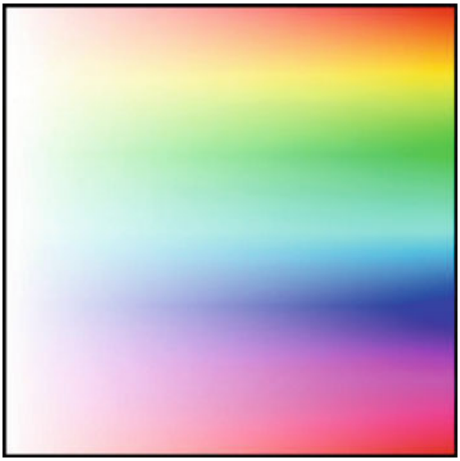


Bottom-right: original colour image



41.166 hsp

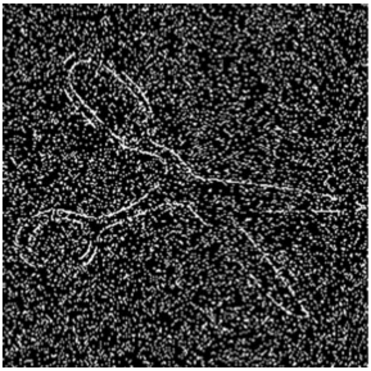
Format	*hsp*
Arguments	*None*
Output values	None
Image type	Colour image generator
Type	Colour image generator
Function	Generate a synthetic image in which the hue and saturation vary linearly with vertical and horizontal position, respectively.
Switch images	Yes
Typical uses	As an aid to interpreting and processing the output from *shs*
Remarks	Also see rgb
Illustration	
Command	*hsp*
Axes	Saturation varies along the horizontal axis. Low saturation at the left. Hue varies along the vertical axis. Notice the cyclic nature of hue



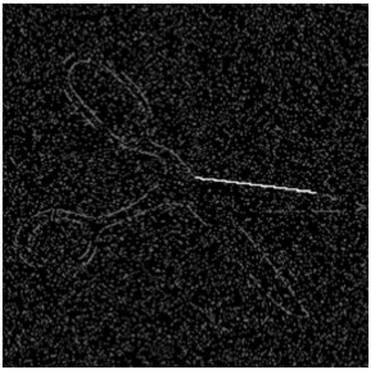
41.167 huf/fsl

Format	*huf*(*a*, *b*, *c*) [*x1*, *y1*, *x2*, *y2*] = *fsl*(*a*, *b*, *c*)		
Arguments	*huf*	*a*	Pseudo-colour display ON/OFF
		b	RhoResolution. See MATLAB documentation, function *hough*
		c	ThetaResolution. See MATLAB documentation, function *hough*
	fsl	*a*	Peak selection. See MATLAB documentation, function *houghpeaks*
		b	*FillGap* in the documentation for MATLAB function *houghlines*
		c	*MinLength* in the documentation for MATLAB function *houghlines*
Defaults,	*huf*	*a*	0
		b	2
		c	0.5
Output values	*huf*	None	
	fsl	[*x1*, *y1*, *x2*, *y2*]	End-point coordinates of the line found from the HT
Image type	Binary		
Type	Feature detection and location		
Function	*huf*	Hough Transform (HT)	
	fsl	Uses HT to extract line segments from a binary image	
Switch images	Yes		
Typical uses	Finding linear segments in noisy images and those where contours demarking large intensity gradients (i.e., found using an edge detector) are ‘broken’		
Remarks	In the image generated by *huf*, the horizontal axis represents angular position. The vertical axis determines distance from the centre of the image. *fsl* was adapted from a program given in the documentation for the MATLAB function. This is a complex function to operate most efficiently. The reader is therefore referred to the following MATLAB function descriptions: *hough*, *houghpeaks*, *houghlines*. The Hough and Radon Transforms (*rdn*) perform similar functions		
Illustration			
Input image	Scissors, deliberately corrupted by noise, generated using *gsn* and *spn*		
File number	48		

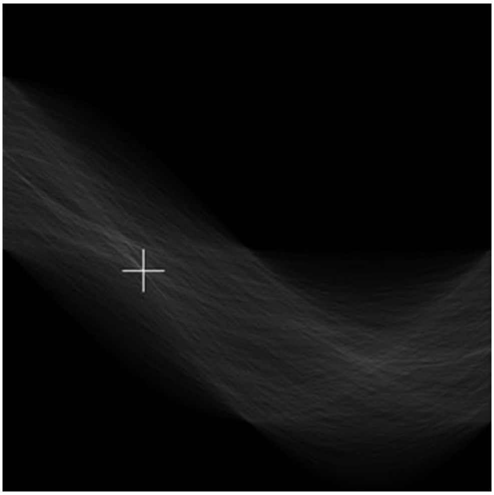
Top-left: original



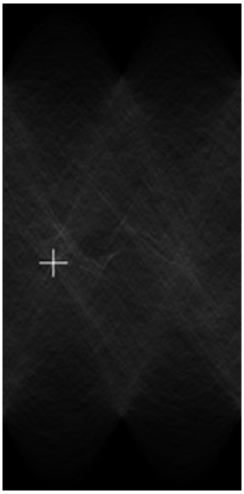
Top-right: after *fsl*



Centre-left: hough transform(huf) (Crosses indicate points of maximum intensity)

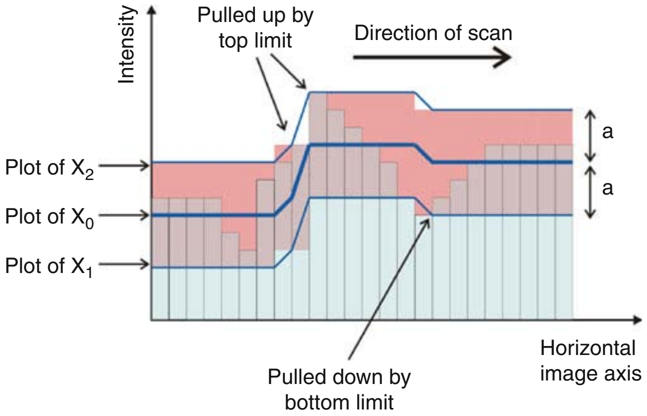


Bottom-right: radon transform (*rdn*)



41.168 hys/hs4

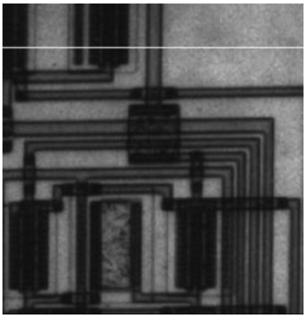
Format	*hys*(*a*) *hs4*(*a*)
Arguments	a Filter control parameter
Defaults	8
Output values	None
Image type	Grey scale
Type	Image filter
Function	*hys*: 1-dimensional hysteresis smoothing (See diagram below) *hs4*: apply *hys* 4 times, scanning in the 4 principal directions. Add the results
Switch images	Yes
Typical uses	*hys* is suitable for processing non-isotropic images generated by laser scanners and line-scan sensors inspecting web product. It may also be suitable where there is strong directional lighting
Remarks	Hysteresis smoothing is a rather crude 1-dimensional method for low-pass filtering. However, this may well suit applications where there is a marked difference between the two image axes, as explained above. It can be implemented in low-cost hardware capable of real-time operation



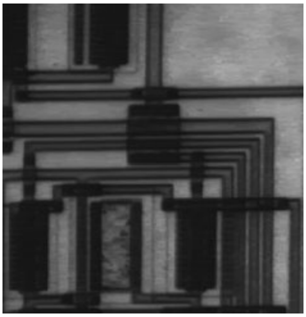
Illustration

Input image	Thick film circuit
File number	136

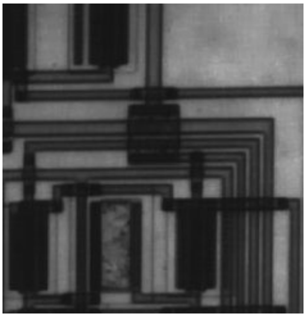
Top-left: *Original image*



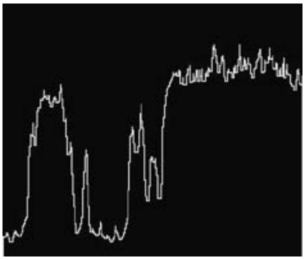
Top-center: *hys*(*8*)



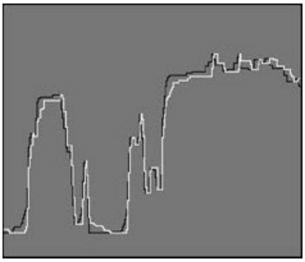
Top-right: *hs4*(*8*)



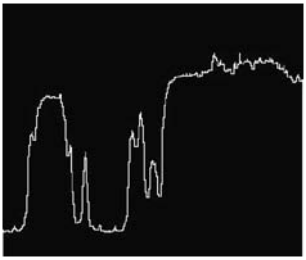
Bottom-left: *intensity profile, original*



Bottom-centre: *intensity profile, hys*(*8*)



Bottom-right: *intensity profile, hs4*(*8*)



41.169 hzs

Format $[x, y] = hzs(a, b, n)$

Arguments *a* Row number indicating start of scan

b Row number indicating end of scan

n Number of scan lines

Defaults None

Output values *x* X-coordinates of points found

y Y-coordinates of points found

Image type Binary

Type Image measurement

Switch No

Function Scan horizontally along a given set of rows. In each case, find the left-most point where the intensity is white (non-black for grey-scale images)

Definition *n* horizontal scan lines are calculated between rows *a* and *b*. Then, for each scan line, find the coordinates of the left-most white pixel

Switch images No

Typical uses Fitting curves to edges, or other contours

Remarks See *pft* and *hsb*

Illustration

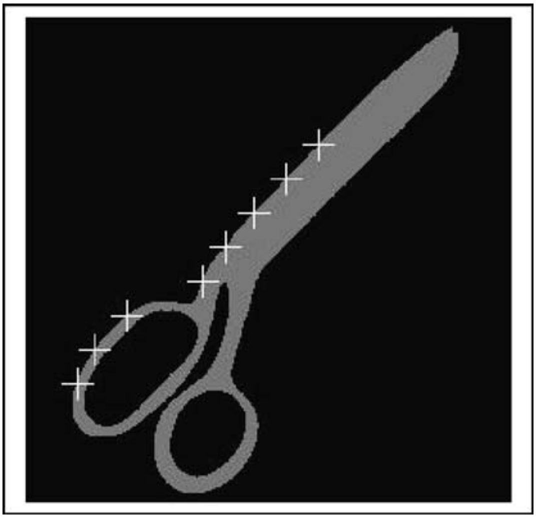
Input image Scissors

File number 50

Command *thr*, [*a*, *b*] = *hzs*(*50*, *200*, *8*)

(*thr* ensures that the image is binary and thereby avoids JPEG coding artifacts)

Left: points found by *hzs*



41.170 icc

Format	a = *icc*	
Arguments	None	
Defaults	Not applicable	
Output values	a	Correlation score. ($-1 \leq a \leq +1$)
Image type	Grey	
Type	Image analysis	
Switch	No	
Function	Cross-correlation between the current and alternate images	
Typical uses	Comparing images. Detecting 2-dimensional periodicity. Analysing texture	

41.171 idn

Format	*idn*
Arguments	None
Output values	None
Image type	Any
Type	Image display
Function	Display the current and alternate images immediately in Figure 1
Switch images	No
Typical uses	Useful during execution of long programs that do not otherwise display intermediate results

41.172 ihm

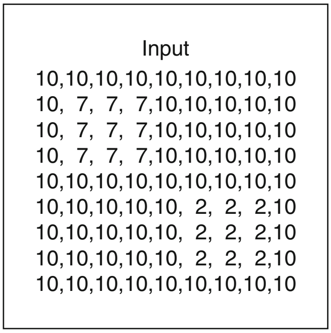
Format	$[b, c] = ihm(a)$	
Arguments	*a*	Control parameter ($a \in \{0, 1\}$. If $a \neq 0$, do not consider black level)
Defaults	a	0
Output values	*b*	Intensity value at the peak frequency in the histogram
	c	Maximum frequency value in the histogram
Image type	Grey-scale	
Type	Grey-scale image measurement	
Function	Find the position and value of the maximum in the intensity histogram. The black level can be ignored by setting $a \neq 0$	
Switch images	No	
Typical uses	Analysing the intensity histogram as part of a function for image segmentation	
Remarks	Also see *cgp* and *hpi*	

41.173 imn

See imx

41.174 imx/imn

Format *imx*(*a*)
imn(*a*)
Arguments *a* *Intensity difference limit* ($a > 0$)
Defaults *a* *128*
Output values None
Image type Grey
Type Morphology
Function Apply the H-maxima/H-minima transform
Switch images Yes
Typical uses Noise reduction, prior to image analysis
Remarks *imx* suppresses all regional maxima whose height, compared its local surroundings, is less than *a*. (A regional maximum is an 8-connected sets of pixels that all have the same intensity value and whose external boundary pixels all have a value less than that value.) Similarly, *imn* suppresses all regional minima. The following example shows the results of applying *imn(4)* to a simple image



```
Input
10,10,10,10,10,10,10,10,10
10, 7, 7, 7,10,10,10,10,10
10, 7, 7, 7,10,10,10,10,10

```

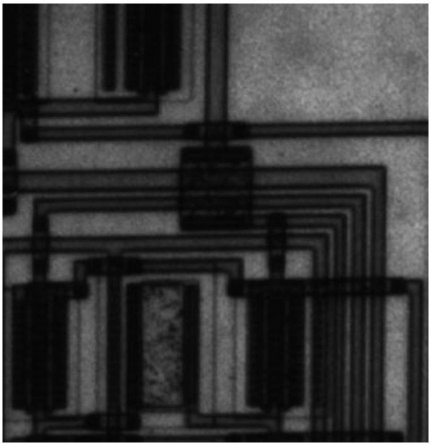
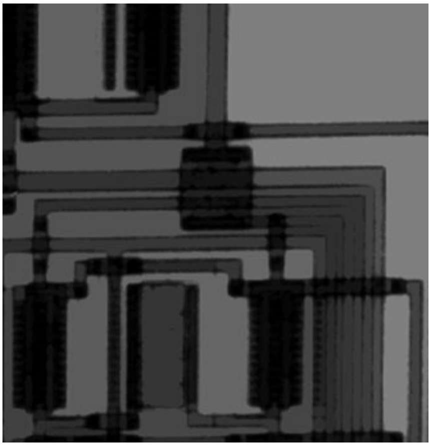
Illustration
Input image Thick film circuit
File number 136
Command *imx*(*75*)

Left: original



Right: after processing



41.175 ine

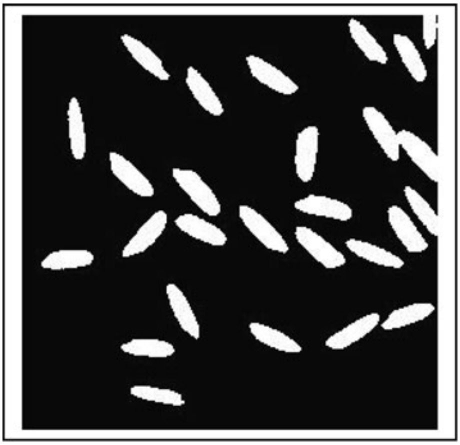
Format	$b = ine(a)$
Arguments	a Tolerance value for intensity difference
Defaults	a 0
Output values	Number of pixels
Image type	Grey
Type	Image comparison
Function	Generate an image in which white pixels indicate that the difference in the intensities between corresponding pixels in the current and alternate images is less than or equal to the given parameter, a. The output b is the number of pixels pairs that are nearly equal
Switch images	Yes
Typical uses	Image comparison
Remarks	*ine* tests for equality of intensity values

41.176 iob

Format	*iob*(*a*, *b*, *c*)	
Arguments	*a*	*X*-coordinate of a point, or a vector containing several values
	b	*Y*-coordinate of a point, or a vector containing several values
	c	Connectivity (4 or 8)
Defaults	c	*8*
Output values	None	
Image type	Binary	
Type	Blob shape analysis	
Switch	Yes	
Function	Isolate that *c*-connected blob (c = 4 or 8), which overlaps a given point [*a*, *b*].	
Typical uses	Blob analysis	
Remarks	*iob* can also be called with vector inputs, as illustrated below. Also see *cob*	
Illustration		
Input image	Rice grains (file number 3) after thresholding	
Image generation	*rni*(*3*), *enc*, *thr*	
Commands	[*h*, *w*] = *size*∗*current*;	% Image size
	i = *round*(*w*∗*rand*(*100*, *1*));	% 100 *X*-coordinates generated at random
	j = *round*(*h*∗*rand*(*100*, *1*));	% 100 *Y*-coordinates generated at random
	iob(*i*, *j*)	% Select up to 100 rice grains at random

Left: original

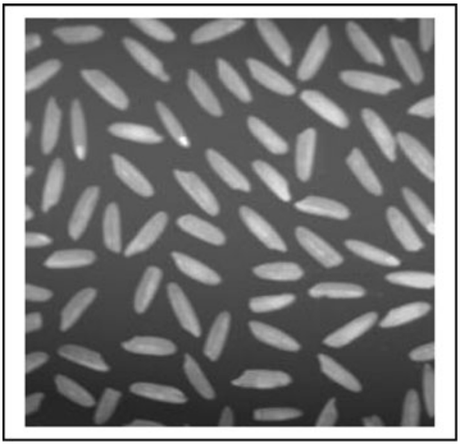
Right: after processing



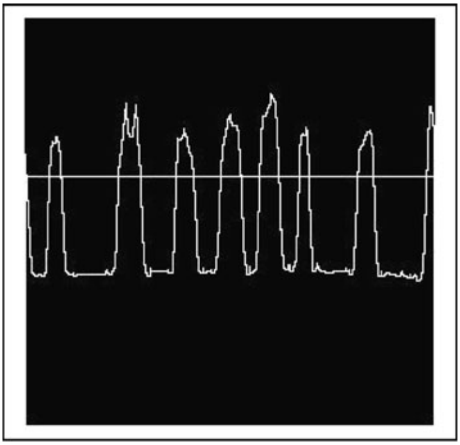
41.177 ipc/ipr

Format	*ipc*(*a*) *ipr*(*a*)		
Arguments	*a*	Column/row for plotting	
Defaults	*a*	Index number for the column/row through the centre of the image	
Output values	None		
Image type	Grey scale		
Type	Measurement and analysis		
Function	Plot the intensity profile along a defined column/row in the current image. The plot is drawn in the current image		
Switch images	Yes		
Typical uses	The two functions are used principally as aids to understanding the structure of an image and in guiding algorithm design		
Remarks	Also see *plt*. *ipc* and *ipr* are suitable for use in the remotely operated versions of QT, whereas *plt* is not. *plt* provides an annotated and more precise graph. Axes:		
	ipc	X-axis	Intensity
		Y-axis	Vertical position in the input image
	ipr	X-axis	Horizontal position in the input image
		Y-axis	Intensity
Illustration			
Input image	Rice grains		
File number	3		
Command	*ipr*(*100*)		

Left: original



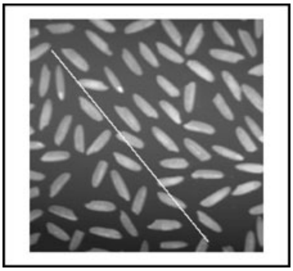
Right: after processing



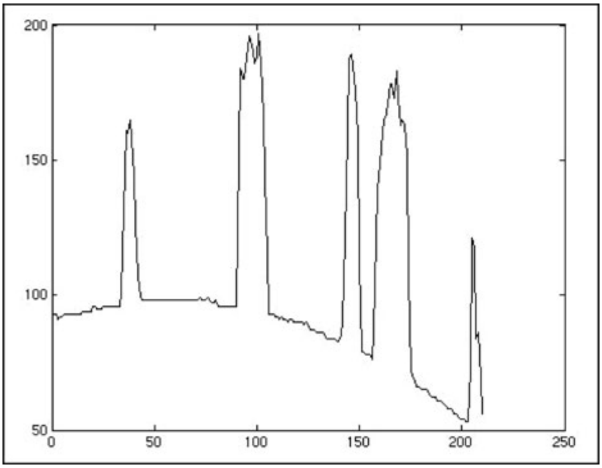
41.178 ipl

Format	*ipl*(*x1*, *y1*, *x2*, *y2*)	
Arguments	*x1*	X-coordinate of one end of the sampling line
	y1	Y-coordinate of one end of the sampling line
	x2	X-coordinate of the other end of the sampling line
	y2	X-coordinate of the other end of the sampling line
Defaults	*x1*	Half image width
	y1	1
	x2	Half image width
	y2	Height of image
Output values	None	
Image type	Grey	
Type	Drawing	
Function	Plot the intensity profile along a defined line in the current image. The plot is drawn in a new figure	
Switch images	Yes	
Typical uses	*ipl* is used principally as an aid to understanding the structure of an image and in guiding algorithm design	
Remarks	If no arguments are supplied, a graph is drawn of the intensities found along a vertical line through the centre of the image. Also see *plt*, *lsc* and *scc*	
Illustration		
Input image	Rice grains	
File number	3	
Command	*ipl*(*25*, *35*, *196*, *245*)	

Left: input image



Right: intensity profile Abscissa, horizontal position. Ordinate, intensity



41.179 ipp

Format	$b = ipp(a)$
Arguments	a Proportion of picture area ($0 \leq a \leq 1$)
Defaults	a 0.5
Output values	b Intensity level
Image type	Grey-scale
Type	Grey-scale image measurement
Function	Calculate the intensity level b such that a proportion a of the pixels have intensity values $\leq b$
Switch images	No
Typical uses	Finding a suitable threshold parameter by analysing the intensity histogram
Remarks	Also see *enc*, *air*, *pth*

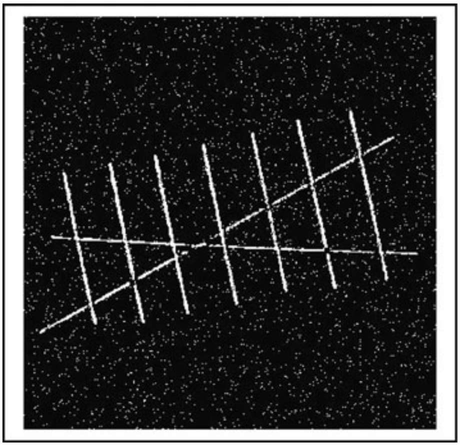
41.180 irt

Format	*irt*
Arguments	None
Defaults	None
Output values	None
Image type	Grey scale or binary
Type	Global transform
Switch	Yes
Function	Inverse Radon transform
Switch images	Yes
Typical use	Isolating individual linear streaks in noisy images
Remarks	Normally, *irt* is used in conjunction with *rdn* (Radon transform). The example shown below illustrates how a group of nearly vertical, parallel lines can be identified. The Radon transform image (RT) is first weighted by multiplying it by the intensity wedge (*wgx*, *neg*). The contrast is then adjusted by applying *sqr*. (This reduces the number of 'noise' points in the final image.) Finally, *irt* is applied (Also see *rdn* and *slf*)

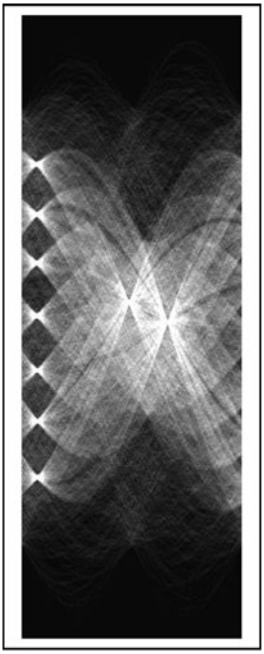
Illustration

Input image	Lines
File number	160
Command	*rdn*, *wri*, *wgx*, *neg*, *rei*, *mul*, *sqr*, *irt*

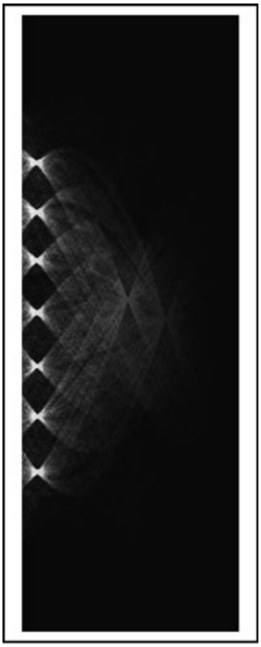
Top-left: original



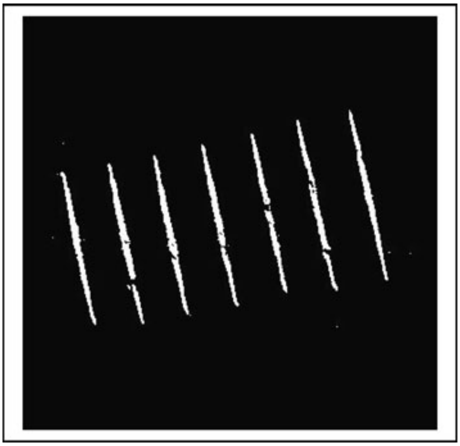
Top-right: just after *rdn*



Bottom-left: after *sqr*



Bottom-right: after *irt*



41.181 isight

Format	*isight*(*a*)
Arguments	*a* *Image file number*
Defaults	*a* *Latest* (*i.e., highest numbered*) *image file present in the folder*
Output values	*None*
Type	Image acquisition
Function	Acquire an image from an iSight camera using iStill software (Apple Computer Inc)
Switch images	Yes
Remarks	The *iSight* camera is no longer available. Use *frz* instead.

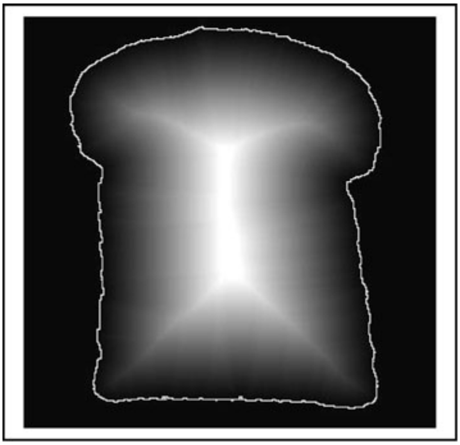
41.182 iso

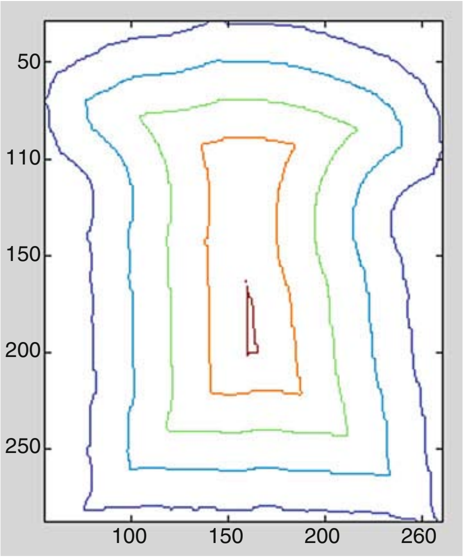
Format	*iso*
Arguments	*None*
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Image analysis
Switch	Yes
Function	Draw intensity contours (isophotes) in Figure 6
Typical uses	Visualising slow intensity variations that are difficult to see otherwise
Remarks	The contour image disappears when the user clicks anywhere in Figure 6. Also see *ctr*

Illustration

Input image	Slice of bread (file number 45), after grass-fire transform (*gft*)
Image generation	*rni*(45), *gft*, *enc*
Commands	*iso*

Left: original (slice outline added for clarity) *Right*: after processing





41.183 itl

Format	*[x, y] = M(xl, yl, x2, y2, x3, y3, x4, y4)*	
Arguments	[*xi*, *yi*]	Coordinates of the ith point (*i* = *1*, *2*, *3*, *4*)
Output values	[*x*, *y*]	Coordinates of the point of intersection
Image type	Not relevant	
Type	Geometry	
Function	Find the point of intersection of two lines, each defined by two points. Let *A* be the line joining points [*x1*, *y1*] *and* [*x2*, *y2*]. *B* be the line joining points [*x3*, *y3*] *and* [*x4*, *y4*]. *itl* finds the coordinates of the point of intersection of lines *A* and *B*	
Switch images	No	
Typical uses	Analysing feature geometry	
Remarks	Notice that is either line is vertical, an error will occur	

41.184 itx

Format *itx*(*a*, *b*, *c*)

Arguments *a* String to be displayed

b X-coordinate of the left-most point of the arrow

c Y-coordinate of the left-most point of the arrow

Defaults *b* and *c* Use the cursor to select the position

Output values None

Image type Any

Type Image annotation

Switch No

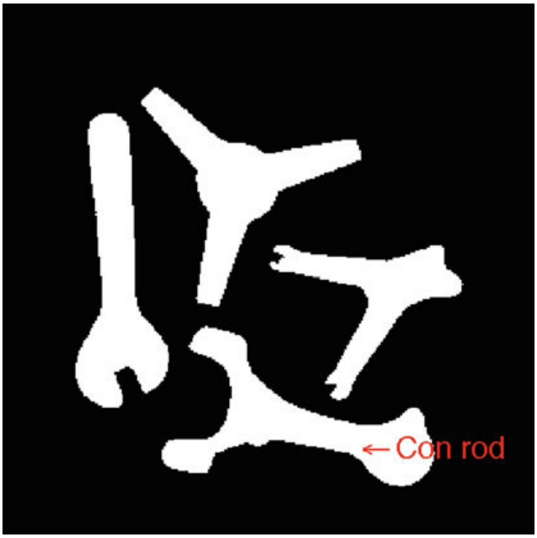
Function Superimpose text over the current image. An arrow to the left of the text allows small feature to be highlighted

Switch images No

Typical uses Annotate the current image

Remarks The text is written into an *alpha channel* associated with the Current image. It is not part of the image and will disappear when the next operation is performed. Neither the Current nor the Alternate image is altered. If only one argument (c) is specified, text with intensity *c* is placed to the right of a point selected by the cursor

Illustration



41.185 ity

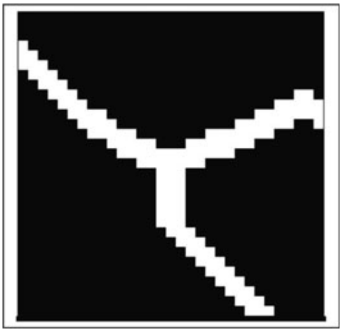
See *hsi*

41.186 jas/las

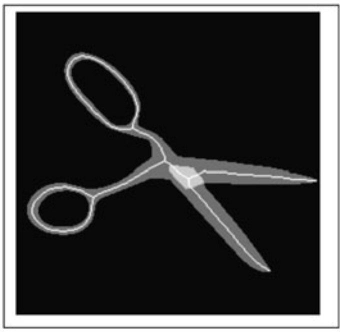
Format		d = jas(a, b, c)
		d = las(a, b, c)

Arguments	*a*	Select which skeleton junction/limb end is to be used
	b	Fixes the size of the region selected (size = $2b \times 2b$)
	c	Dilation control
Defaults	*a*	2
	b	10
	c	2
Output values	*d*	Structuring element (SE)
Image type	Binary	
Type	Designing Structuring Elements for feature recognition	
Function	1.	The *a*th skeleton junction (*jas*) or limb end (*las*) is found (The numbering is the same as that used by *ndo*)
	2.	The blob found in step 1 is shrunk to a single point
	3.	Find the position $[x, y]$ of that point
	4.	Dilate the skeleton using *dil*(*c*), where *c* is the 3rd argument supplied to *jas/las*
	5.	Place a window of size $(2b + 1)$ x $(2b + 1)$ pixels centered on point $[x, y]$.
	6.	Use the contents of this window as the Structuring Element, which is output as *d*
Switch images	Yes	
Typical uses	Noise reduction in binary images; simplifying them, prior to blob measurement/shape analysis	
Remarks	*jas* and *las* are tools for experimenting with erosion/dilation. They are not intended for batch processing. Also see *use*, *gbd*, *gbe*	
Illustration		
Input image	Scissors	
File number	48	
Command	test (See listing above)	

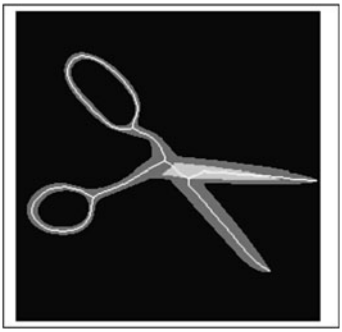
Top-left: SE generated by *jas*



Top-right: result of processing by *jas*(*4*, *15*, *2*)



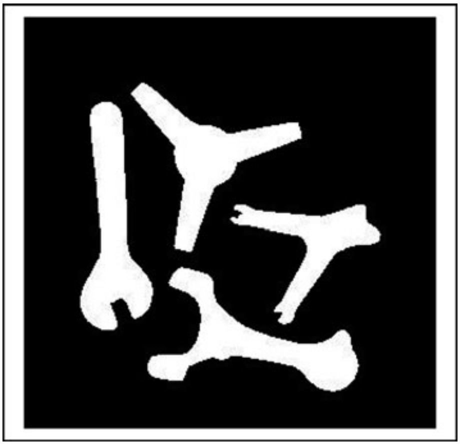
Bottom-left: result of processing by *las*(*2*, *35*, *5*)



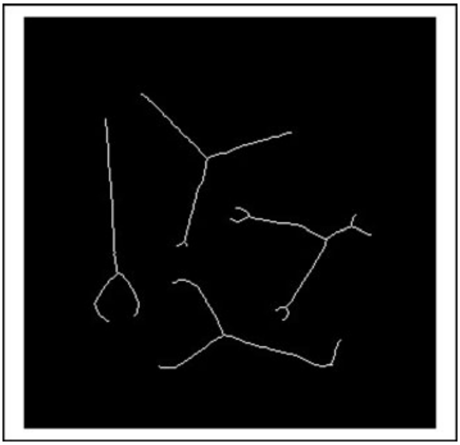
41.187 jnt/lmb

Format	*jnt* *lmb*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob shape analysis
Switch	Yes
Function	Locate the points on a ‘match-stick’ figure (the skeleton), generated by *ske* or *thn*, where three or more limbs meet (*jnt*), or where limbs end (*lmb*)
Typical uses	Representing shapes by measuring distances and angles on the ‘match-stick’ figure. These may be measured between limb ends and/or joints
Remarks	The ‘match-stick’ figure can be ‘broken’, so that each limb is separated from the others, using the command sequence *jnt*, *enc*
Illustration	
Input image	Four metal parts, with *thn* (thinning) applied to create a ‘match-stick’ figure
Image generation	*rni*(*46*), *thr*, *thn*
Commands	Joints: *rni*(*46*), *thr*, *thn*, *wri*, *jnt*, *dil*(*5*), *rei*, *mxi* *Limb ends*: *rni*(*46*), *thr*, *thn*, *wri*, *lmb*, *dil*(*5*), *rei*, *mxi*

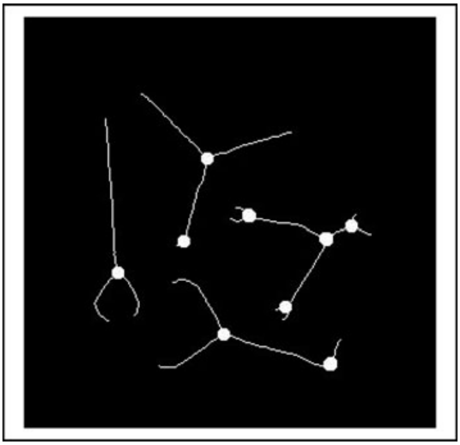
Top-left: original image (file number 46)



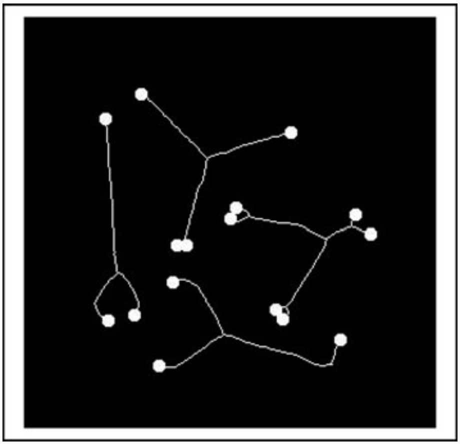
Top-right: rni(*46*), *thr, thn*



Bottom-left: enlarged joints superimposed on the 'match-stick' figure



Bottom-right: enlarged limb ends superimposed on the 'match-stick' figure



41.188 joy

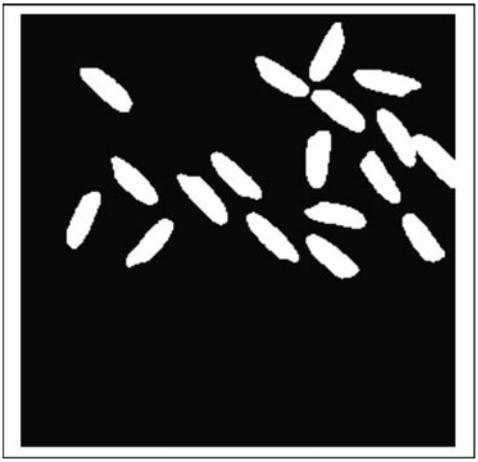
Format	*joy*(*a*)
Arguments	*a* Select recording to play
Default	a = 3, Play 'gong' sound
Output values	None
Image type	Not relevant
Type	User interface
Function	Play one of several pre-recorded sounds
Switch images	No
Typical uses	Providing an audible signal indicating the progress of program execution
Remarks	These recordings are provided as standard with MATLAB and have been played successfully on a Macintosh computer, running OS X.

41.189 kbb

Format	*kbb*(*a*)	
Arguments	a	Rank size of smallest blob to be kept
Defaults	a	2
Output values	None	
Image type	Grey	
Type	Binary image analysis	
Function	Keep the blob of rank size *a* and all blobs larger than it	
Switch images	Yes	
Typical uses	Noise reduction in binary images; simplifying them, prior to blob measurement/shape analysis	
Remarks	Also see *big*, *kgr*	
Illustration		
Input image	Rice grains	
File number	3	
Command	enc, thr, *kbb*(*17*)	

Left: original

Right: after processing

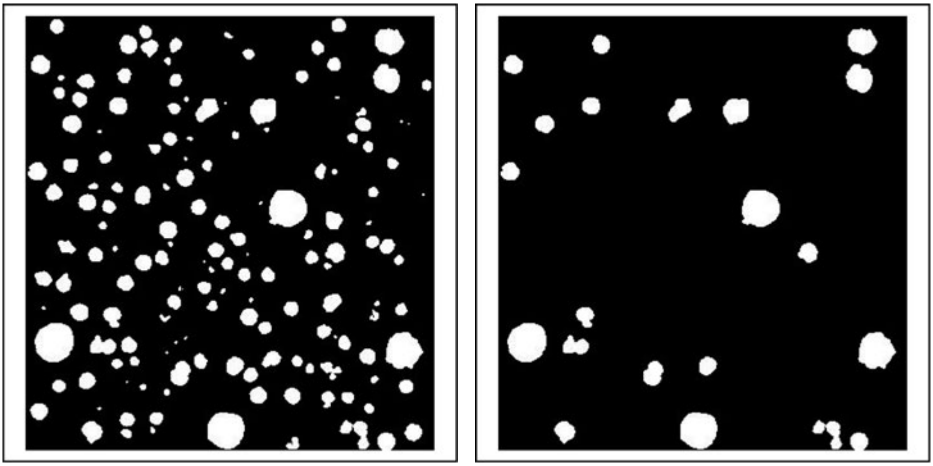


41.190 kgr

Format	*kgr*(*a*, *b*)	
Arguments	*a*	Lower size limit
	b	Connectivity (b takes only values 4 or 8)
Defaults	*b*	8
Output values	None	
Image type	Binary	
Type	Blob transform	
Function	Eliminate all *b*-connected blobs (*b* = 4 or 8) whose area is less than *a* pixels	
Switch images	Yes	
Typical uses	Reducing the effects of noise after filtering and thresholding	
Remarks	Also see *ndo* and *big*	
Illustration		
Input image	Non-standard; contrived for this illustration	
Command	*kgr*(*150*)	

Left: original

Right: after processing



41.191 las

See *jas.*

41.192 led

See *ced*

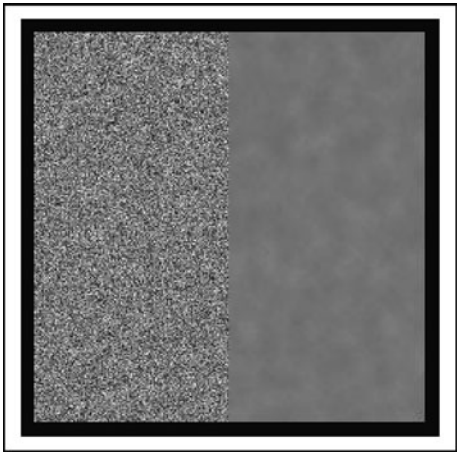
41.193 ley

Format	*ley*(*a*, *b*)
Arguments	*a* Width of the filter window
	b Height of the filter window
Defaults	One argument supplied: b = a
	No arguments supplied: a = b = 9
Output values	None
Image type	Grey
Type	Non-linear local operator
Function	The local entropy of the intensity values within each rectangular neighbourhood of size a × b defines the intensity for the central pixel
Switch images	Yes
Typical uses	Segmenting textured images
Remarks	Also see *lsd*

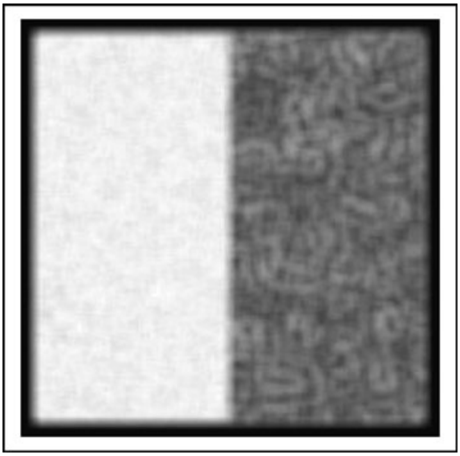
Illustration

Input image	Generated using *gsn* and *caf*. Both halves of the original image shown below have the same average intensity
Command	*ley*(*9*, *9*)

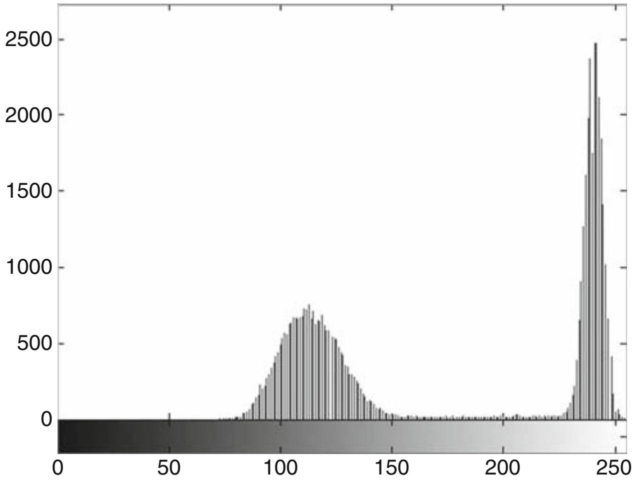
Left: original



Right: after processing



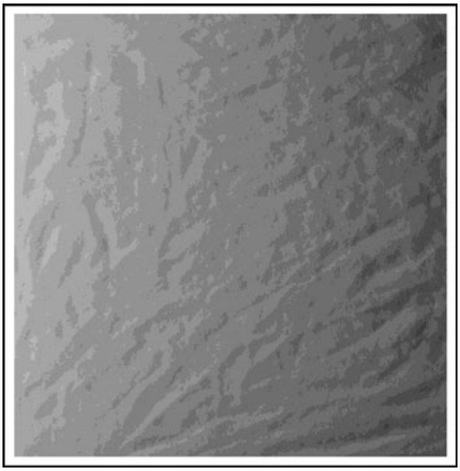
Bottom: Intensity histogram of the processed image (Edge effects were removed by masking first)



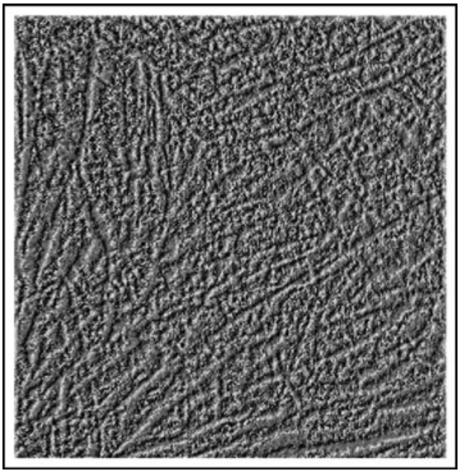
41.194 lhq

Format	*lhq*(*a*, *b*)	
Arguments	*a*	Processing window width (normally an odd number)
	b	Processing window height (normally an odd number)
Defaults	*a*	7
	b	7
Output values	None	
Image type	Grey scale	
Type	Non-linear filter	
Switch	Yes	
Function	Local-area histogram equalisation	
Definition	Within that window of size a × b pixels centred on point (*i*, *j*), *N*(*i*, *j*), the number of pixels that are darker than *A*(*i*, *j*) is computed. After rescaling, this number defines the intensity *C*(*i*,*j*) in the output image	
Switch images	Yes	
Typical uses	Pre-processing for texture analysis	
Remarks	Also see *sdm*	
Illustration		
Input images	Creased fabric	
File numbers	28	
Commands	*lhq*(*15*, *15*)	

Left: original image



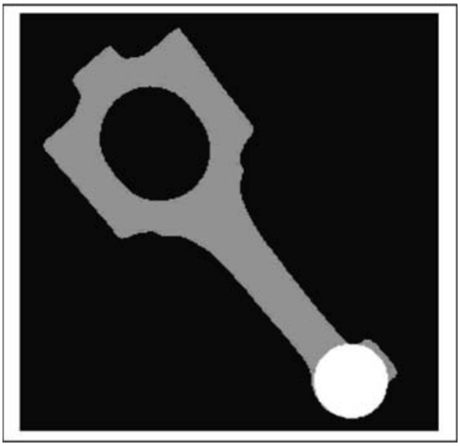
Right: after processing



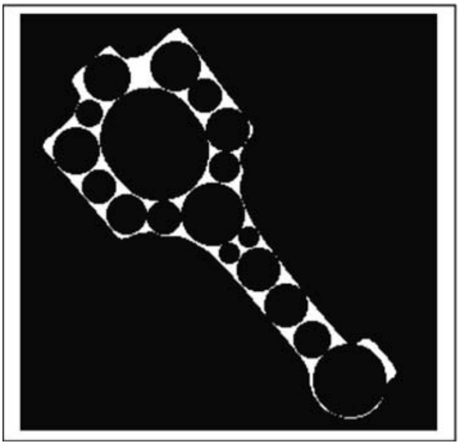
41.195 lic/mic

Format	*[x, y, z] = lic*	
	mic(a)	
Arguments	*a*	Limit on no. of white points to continue recursion (*mic* only)
Default value	a	500
Output values	*x*	X-coordinate of the inscribed circle (*lic* only)
	y	X-coordinate of the inscribed circle (*lic* only)
	z	Radius of the inscribed circle (*lic* only)
Image type	Binary	
Type	Binary image analysis	
Function	*lic*:	Fit the largest inscribed circle into the white regions
	mic:	Apply *lic* recursively
Switch images	Yes	
Typical uses	Placing a magnetic or vacuum gripper Choosing structuring element for binary erosion	
Remarks	*mic* is often slow, since applies *lic* recursively	
Illustration		
Input image	Automobile con-rod	
File number	47	
Commands	*lic*:	*lic, adi*
	mic:	*mic*

Top-left: after *lic, adi*



Top-right: after *mic(500)*



41.196 lmi

Format	$a = lmi$
Arguments	None
Defaults	Not applicable
Output values	*a* Orientation of the principal axis
Image type	Binary
Type	Blob measurement
Function	Calculate the orientation of the principal axis of a blob-like figure
Switch images	No
Typical uses	Finding the orientation of a blob
Remarks	If there is more than one blob, *lmi* computes the orientation of just one: the first blob encountered during a top-to-bottom, left-to-right raster scan. The subsidiary function *blob_parameters* is used in several other functions. The principal axis is also called the axis of minimum second moment

41.197 lnb

Format	*lnb*(*a*)
Arguments	*a* Size of processing window
Defaults	*a* 3
Output values	None
Image type	Grey scale or binary
Type	Non-linear filter
Switch	Yes
Function	Largest (i.e., brightest) neighbour in an $a*a$ window
Typical use	Noise reduction. Component of a number of other operators (e.g., *lnb*, *sub* is a highly effective edge detector)
Remarks	*lnb*(*a*) is equivalent to *dil*(*a*, *1*) and is included in QT to maintain compatability with earlier systems. Also see *snb*

41.198 lpc

See *con*

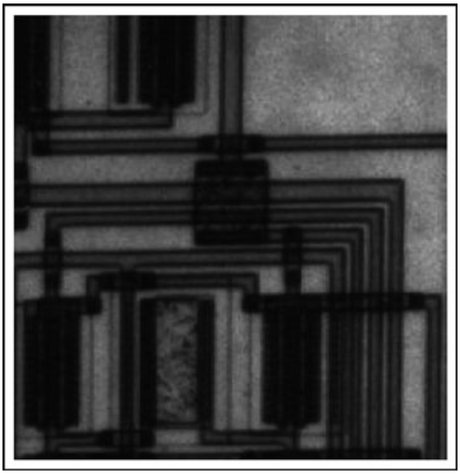
41.199 lpf/hpf

Format	*lpf* *hpf*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Image filtering
Switch	Yes
Function	*lpf* Local averaging of the intensities within each 3∗3 window *hpf* Result of applying lpf subtracted from the original image
Switch images	Yes
Typical uses	
Remarks	These two functions are included to retain compatability with earlier systems. *lpf* reduces noise slightly but also introduces a slight blurring effect, while *hpf* emphasises sharp edges, small spots, thins arcs/lines and textures. *hpf* also enhances camera noise. *lpf* may be applied repeatedly (typically 2–10 times), to produce a more pronounced blurring effect. Also see *raf*, *caf*

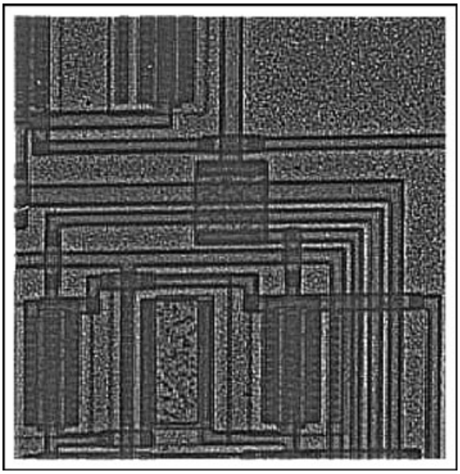
Illustration

Input image	Circuit
File number	136
Command	*hpf*, *enc* (Note: *enc* is included to improve the contrast)

Top-left: original



Top-right: after processing



41.200 lrt

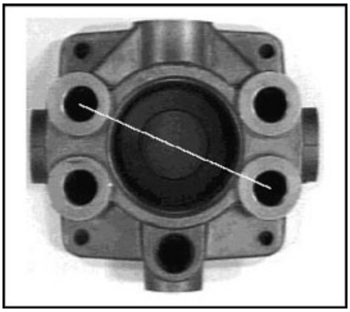
Format	*lrt*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale or binary
Type	Affine
Switch	Yes
Function	Invert the horizontal axis
Switch images	Yes

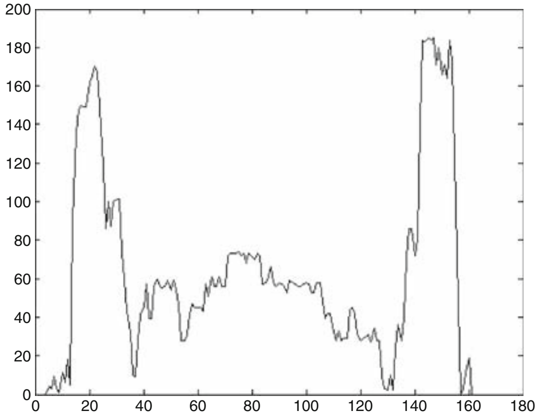
41.201 lsc

Format	*a = lsc(x1, y1, x2, y2, n)*	
Arguments	*x1*	X-coordinate of one end of the scan line
	y1	Y-coordinate of one end of the scan line
	x2	X-coordinate of the other end of the scan line
	y2	Y-coordinate of the other end of the scan line
	n	Number of sample points along this line
Defaults	*n*	Determined automatically from [*x1*, *y1*] and [*x2*, *y2*].
Output values	*a*	Vector containing *n* intensity values
Image type	Grey	
Type	Image analysis	
Switch	No	
Function	Line-scan; sample the intensities uniformly along the line [*x1*, *y1*] to [*x2*, *y2*].	
Typical uses	Reducing processing time, by converting a 2D image into 1D vector. Determining periodicity in known directions	
Remarks	Also see *scc*	
Illustration		
Input image	Hydraulics manifold	
File number	37	
Command	*rni(37), z = lsc(44, 71, 199, 139), figure(2), plot(z), figure(1), vpl(44, 71, 199, 139, 255)*	

Left: original with scan line superimposed by *vpl.* (The line ends were specified manually.)

Right: after *plot*(*z*)
Horizontal axis, scan position
Vertical axis, intensity

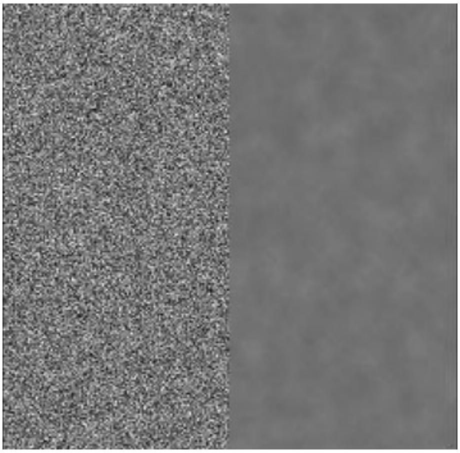




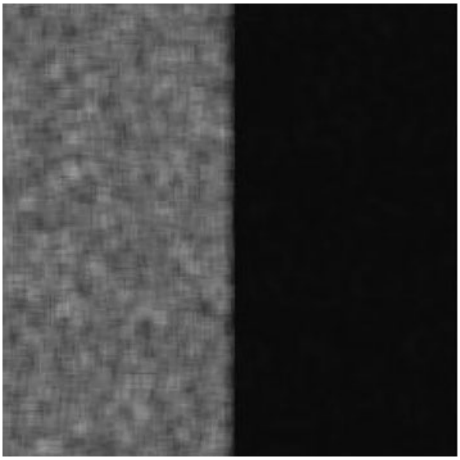
41.202 lsd

Format	*lsd*(*a*, *b*)
Arguments	*a* Width of the filter window
	b Height of the filter window
Defaults	One argument supplied: $b = a$
	No arguments supplied: $a = b = 5$
Output values	None
Image type	Grey
Type	Non-linear local operator
Function	The standard deviation of the intensity values within each rectangular neighbourhood of size a × b defines the intensity for the central pixel
Switch images	Yes
Typical uses	Segmenting textured images
Remarks	Also see *ley*
Illustration	
Input image	Generated using *gsn* and *caf*. Both halves of the original image shown below have the same average intensity
Command	*lsd*(*7*, *7*)

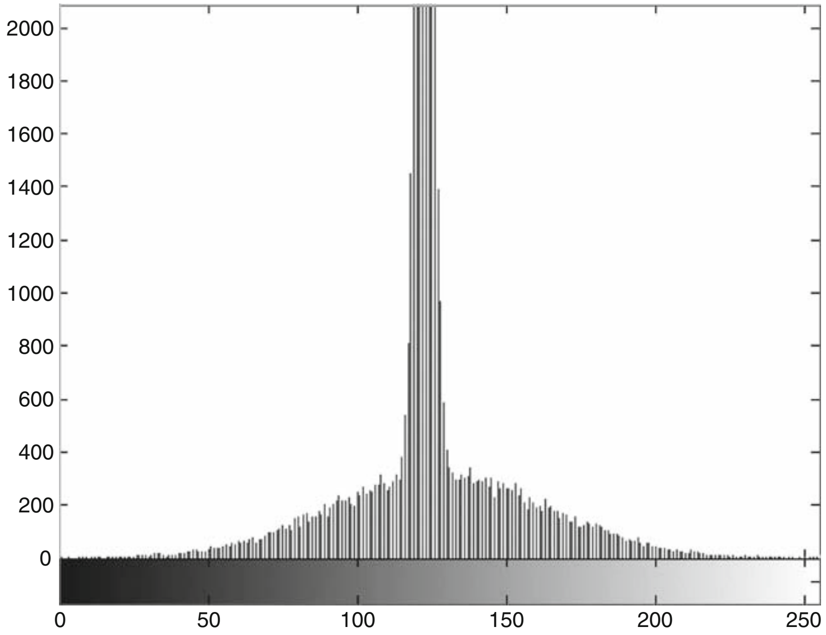
Left: original



Right: after processing



Bottom: *Intensity histogram of the original image*

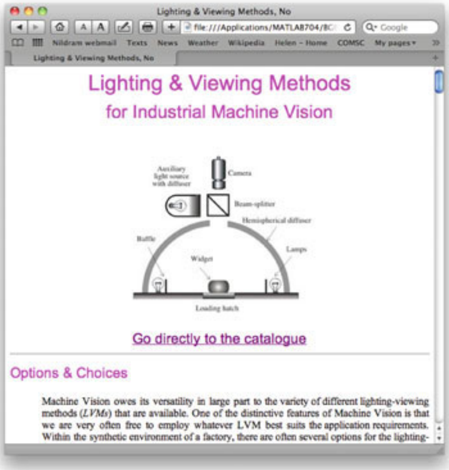


41.203 lvm/lvs

Format	*lvm*(*a*)	
Arguments	*a*	String to be used in the search
Defaults	*a*	View the home page for the Catalogue of Lighting-Viewing Methods (LVM. See Chapters 8 and 40)
Output values	None	
Image type	Not relevant	
Type	Information/advice for the user	
Function	*lvm*	Display the LVM home page
	lvm(‘*string*’)	Search each LVM page for *string*
	lvs({‘*string1*’, ‘*string2*’, . . .})	Search each LVM page for *string1 and string2 and . . .*
Switch images	No	

Typical Web Pages, user typed *lvm*

Top-left:	QT's immediate response to command *lvm*
Top-right:	User clicked on hyperlinked text, '*Go directly to the catalogue*'
Bottom-left:	User clicked on hyperlinked text, '*Omni-directional illumination*'
Bottom-right:	User clicked on hyperlinked text, '*Get it!*' (next to 'Optical set-up')



Lighting & Viewing Methods

for Industrial Machine Vision

Go directly to the catalogue

Options & Choices

Machine Vision owes its versatility in large part to the variety of different lighting-viewing methods (*LVMs*) that are available. One of the distinctive features of Machine Vision is that we are very often free to employ whatever LVM best suits the application requirements. Within the synthetic environment of a factory, there are often several options for the lighting-

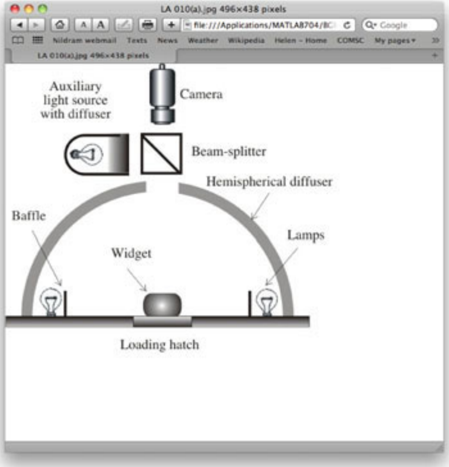
Method 10: Omni-directional Illumination

OBJECTIVES
§ To provide uniform, all-round (omni-directional) illumination.
§ To eliminate shadows
§ To reduce the effects of glinting
§ To see inside deep blind holes.

TYPICAL APPLICATIONS
- Viewing complex parts and assemblies, fibrous surfaces, etc. without casting shadows.
- Viewing bright reflecting surfaces without glinting.

EQUIPMENT Circular illumination source: circular fluorescent tube (driven by a high-frequency supply to avoid strobing), fibre-optic ring light, circular array of small bulbs, or LEDs. Hemispherical diffuser, painted matt white or stippled inside, with small viewing aperture at the centre. A cylindrical baffle prevents direct illumination of the widget.
CAMERA Array
MOTION Static
GEOMETRY Complicated shapes. Deep holes
MATERIALS Brightly polished metal, shiny plastic, porous, fibrous
REMARKS Since there are no shadows, step-like features produce very little contrast. It is possible to see inside deep holes, which would appear dark with standard (oblique) illumination. Specular reflection (glinting) is suppressed. However, changes in the reflectance and colour of a diffusing surface are clearly visible. Also see Method 186.
REFERENCE This technique was described from SIRA Institute, England, although it is similar to the "light tent" used by photographers for shiny objects, such as silver hollow-ware.
DIAGRAMS & SAMPLE IMAGE Figure S.10.

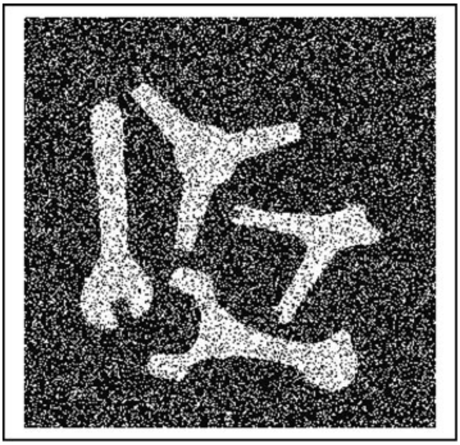
Figure S.10 Omni-directional lighting. (a) [Get it!] Optical set-up (cross-section). (b) [Get it!] Illumination diagram. (c) [Get it!] Sample image: light-grey aluminium casting, about 120 x 120 mm^2. Step-like features (82 mm) do not cast significant shadows and hence are barely visible. The large circular well is 78 mm deep and its diameter is 56 mm. [Get it!]



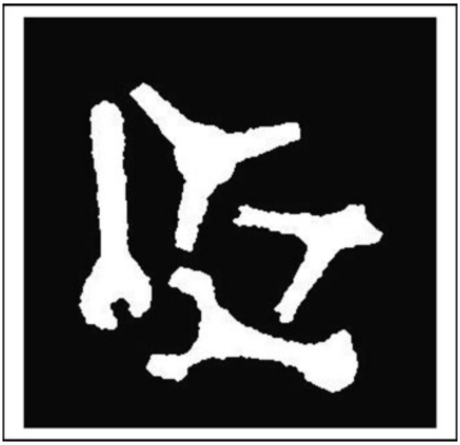
41.204 maj

Format	*maj*(*a*)
Arguments	*a* Multiplier for current image, before addition
Defaults	*a* Indefinitely large
Output values	None
Image type	Binary
Type	Binary image transformation
Switch	Yes
Function	Majority-vote edge smoothing on a binary image
Definition	Majority voting is applied within a 3 × 3 window. The central pixel is set to white, if there are more than 4 white points within the window. If there are four or fewer white pixels, the central pixel is set to black. This process is repeated *a* times. If *a* is omitted, or set to infinity, the process stops when no change takes place
Typical uses	Feature extraction in noisy images
Remarks	
Illustration	
Input image	Four metal parts with salt and pepper noise added
Image generation	*rni*(*46*), *spn*(*0.4*)
Commands	*maj*

Left: original

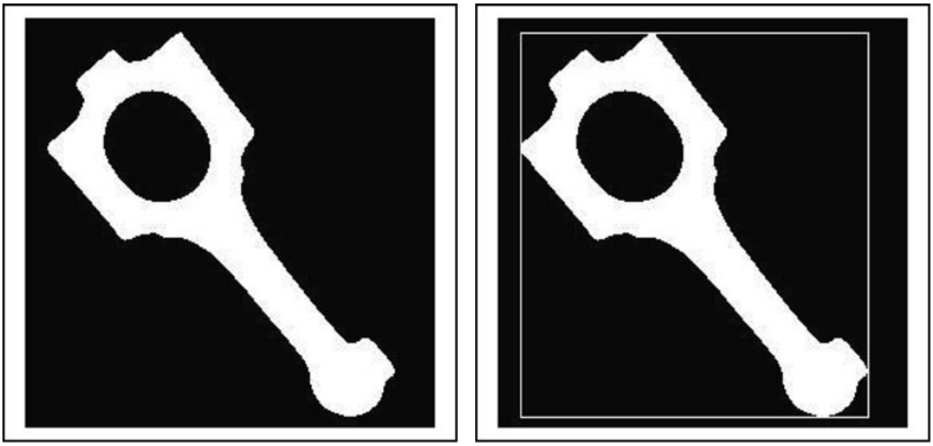


Right: after *maj*



41.205 mar

Format	[*a*, *b*, *c*, *d*] = *mar*	
Arguments	None	
Defaults	Not applicable	
Output values	*a*	Minimum X limit
	b	Minimum Y limit
	c	Maximum X limit
	d	Maximum X limit
Image type	Binary	
Type	Blob transform	
Function	Find the (X,Y)-coordinates describing the bounding box. That is the minimum area rectangle aligned with the sides of the image that encloses all white pixels	
Switch images	Yes	
Typical uses	Blob analysis	
Remarks	To obtain the 'filled' minimum-area rectangle, use *mar*, *blf*. Also see *bbx*	
Illustration		
Input image	Con-rod	
File number	47	
Command	*thr*, *mar* (N.B. *thr* avoids the artifacts created by storing a binary image in JPEG format)	



Left: original

Right: after processing

41.206 mbc

Format $[x, y, z] = mbc(a)$

Arguments *a* Limit on number of iteration cycles within the auxiliary function *mbc_many*

Defaults *a* 5

Output values *x* X-coordinate of the centre of the fitted circle

y Y-coordinate of the centre of the fitted circle

z Radius of fitted circle

Image type Binary, with a single blob

Type Blob shape analysis

Function Minimum bounding circle

Switch images Yes

Typical uses Binary image analysis

Remarks This relies on an approximate heuristic procedure. The auxiliary function *mbc2* is applied first. This finds the size and position coordinates of that circle which passes through the two most distant edge points. In many cases this is sufficient. However, in those situations where it fails to enclose all points within the blob, the function *mbc_many* is applied. Initially, this fits a circle using *ceb*, then finds the protuberances (i.e., regions outside that circle). These are then used to fit another circle, again using *ceb*. This cycle is then repeated a total of *a* times, where *a* is the input parameter

Illustration

Input image Various

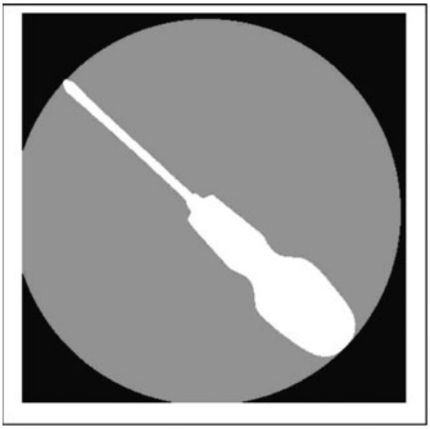
File numbers 43, screwdriver

49, scissors

175, plastic injection mouldings (6 malformed battery tops)

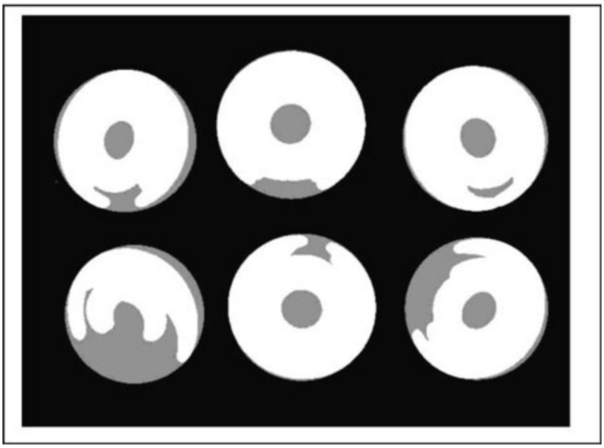
Commands After conversion to a binary image, the command sequence *mbc*, *adi* was applied

Top-left: screwdriver



Top-right: scissors

Bottom: plastic mouldings



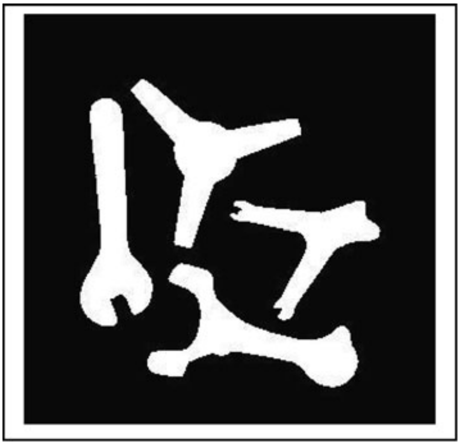
41.207 mch

Format	*mch*
Arguments	None
Output values	None
Image type	Binary
Type	Binary image analysis
Function	Detect the midpoint of each vertical chord crossing a white region
Switch images	Yes
Typical uses	Checking objects that are nominally symmetrical about a vertical axis
Remarks	*mch* provides a fast alternative to skeletonisation and is useful for certain applications where there is limited variability of form and orientation

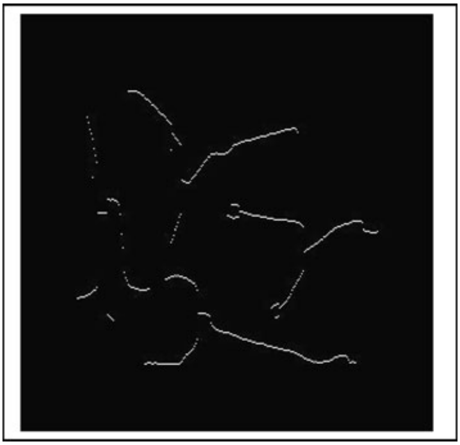
Illustration

Input image	4 piece parts
File number	46
Command	*thr*, *mch*

Top-left: original image



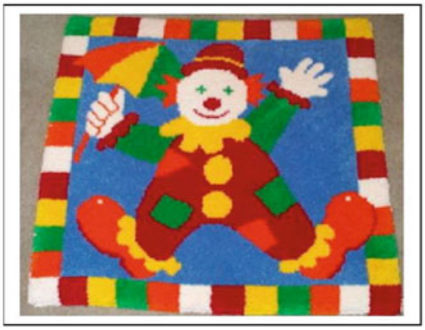
Right: after *mch*



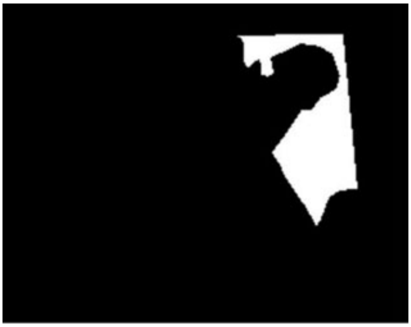
41.208 mci

Format	*mci*
Arguments	None
Defaults	Not applicable
Output values	None
Image types	Current: Colour image Alternate: Binary mask (same size as the current image)
Type	Colour image analysis
Function	Retain only those pixels in the current image that have the same address as a white pixel in the mask image. All other pixels are set to black
Switch images	Yes. The original colour image is retained
Typical uses	Selecting parts of an image for colour analysis, for example using the programmable colour filter, functions *shs and* pcf
Remarks	The binary mask image may conveniently be drawn using the function *pgn*
Illustration	
Input images	Current: image no. 354 Alternate: binary mask drawn using *pgn*
Command	*mci*

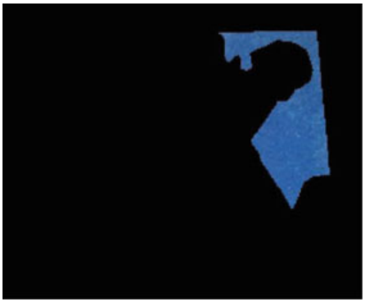
Left: colour image (current image)



Right: binary mask image (alternate image)



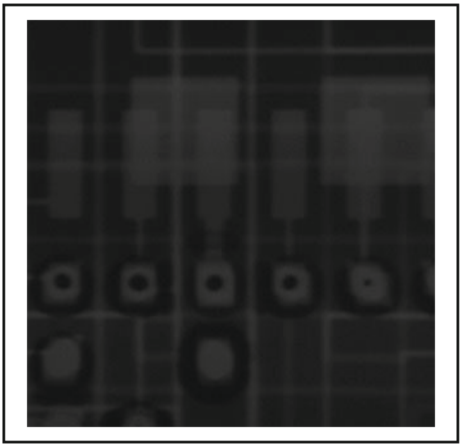
Bottom: after processing



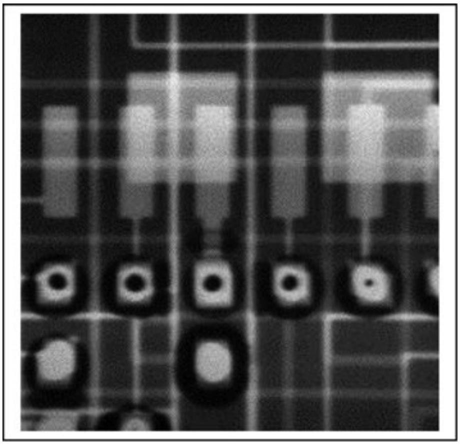
41.209 mcn

Format	*mcn*(*a*)
Arguments	a Intensity multiplier
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Monadic
Function	Multiply all intensities by a constant
Definition	C ⇐ a∗A with a hard limit placed at 255
Switch images	Yes
Typical uses	Increasing contrast
Remarks	Also see *air*, *blo*, *acn*, *din*, *hin*
Illustration	
Input image	PCB after shifting and rescaling intensities
File number	135
Command	*acn*(34), *hin*, *hin*, *hin*, *mcn*(*10*)

Left: original



Right: after processing



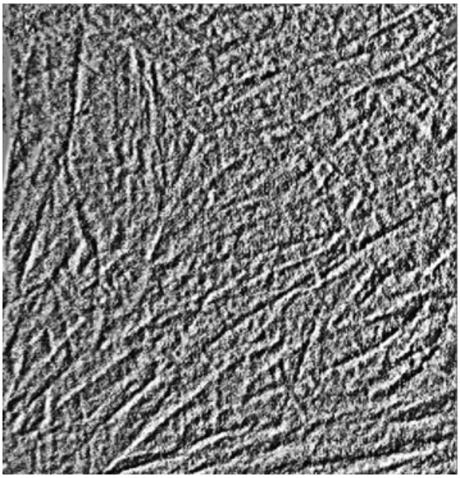
41.210 mdf

Format	*mdf*(*a*, *b*)	
Arguments	*a*	Processing window, width (normally an odd number)
	b	Processing window, height (normally an odd number)
Defaults	*a*	3
	b	3 (If only one argument is supplied, *b* = *a*)
Output values	None	
Image type	Grey scale	
Type	Non-linear filter	
Switch	Yes	
Function	Median filter	
Definition	Within that window of size a × b pixels centred on point (*i*, *j*), the median intensity value is calculated. The median value is the one placed [(ab + 1)/2] after sorting in rank order	
Switch images	Yes	
Typical uses	Pre-processing to reduce the effects of sensor noise	
Remarks	Very high spatial frequencies are attenuated. Edges are not blurred significantly	

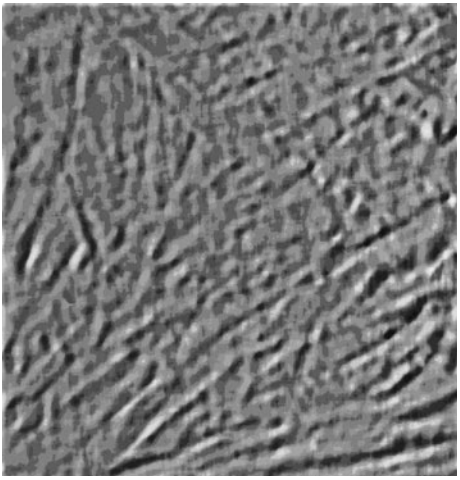
Illustration

Input images	Creased fabric, pre-processed by applying *lhq*(*15*, *15*)
File numbers	28
Command:	*mdf*(*9*, *9*)

Left: before *mdf*



Right: after *mdf*(*9*, *9*)

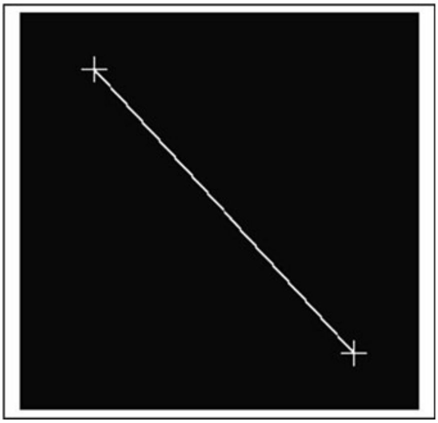


41.211 mdp

Format	[*xl*, *yl*, *x2*, *y2*] = *mdp*
Arguments	None
Output values	[*x1*, *y1*, *x2*, *y2*] Coordinates of the most distant points
Image type	Binary, single blob
Type	Object measurement
Function	Find those two points that are furthest from each other
Switch images	Yes
Typical uses	Measuring the length/diameter of a binary object
Remarks	Also see *fwp*
Illustration	
Input image	Scissors
File number	48
Command	mdp

Left: original image

Right: after *mdp*



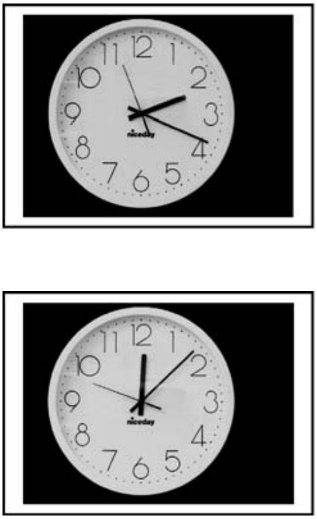
41.212 mic

See *lic*

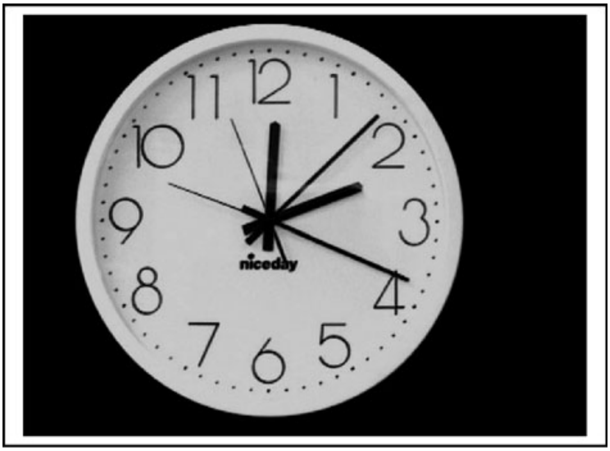
41.213 mni

Format	*mni*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Find the minimum intensity between corresponding pixels in the current and alternate images
Definition	C ⇐ *MIN*(A, B)
Switch images	Yes
Typical uses	Using one image to mask another Segmenting an image by isolating an object from its background
Remarks	*mni* is a component of numerous algorithms
Illustration	
Input images	Clocks
File number	142 and 143
Command	*mni*

Left: two originals



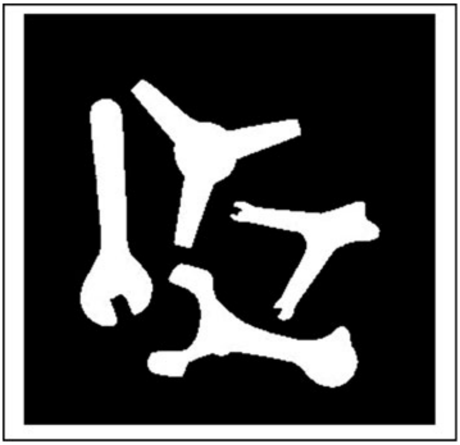
Right: after processing



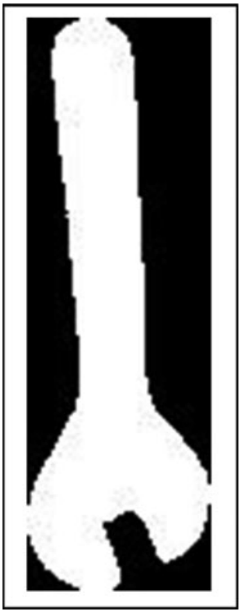
41.214 mrc

Format	*mrc*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob shape analysis
Switch	Yes
Function	Crop the image around the bounding box. (That is the minimum area rectangle aligned with the sides of the image that encloses all white pixels.) If there is more than one blob, the operation is performed on the first one found during a raster scan (searching top-to-bottom and left-to-right)
Switch images	Yes
Typical uses	Blob-shape analysis
Remarks	Notice that the image size changes as a result of applying *mrc*
Illustration	
Input image	Four metal parts
File number	46
Command	*mrc*

Left: original



Right: after processing



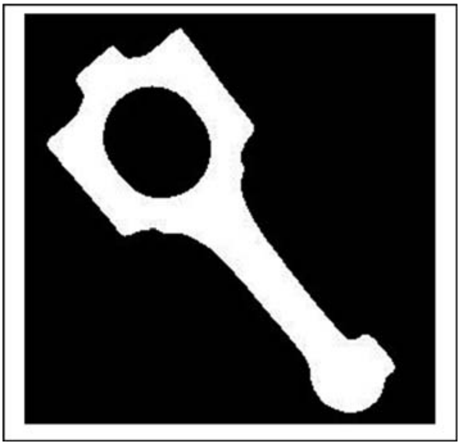
41.215 mst

Format	*mst*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Thin each blob in a binary image; reduce it to a match-stick figure
Switch images	Yes
Typical uses	Blob shape analysis
Remarks	Thinning produces a connected figure that approximates the medial axis (skeleton, *ske*) but is subtly different from it

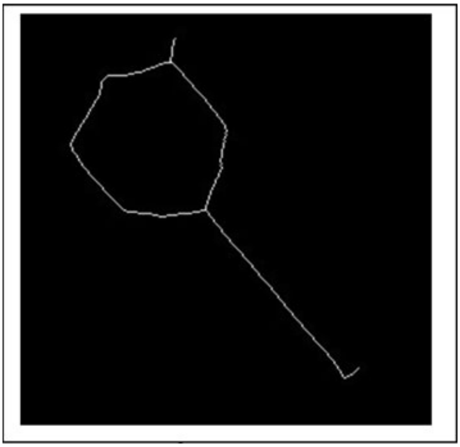
Illustration

Input image	Con-rod
File number	47
Command	*thr*, *mst* (N.B. *thr* avoids the artifacts created by storing a binary image in JPEG format)

Left: original



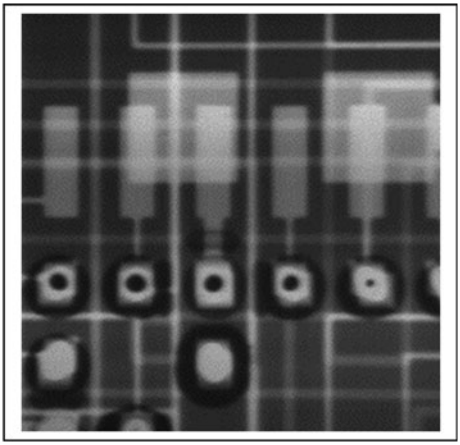
Right: after processing

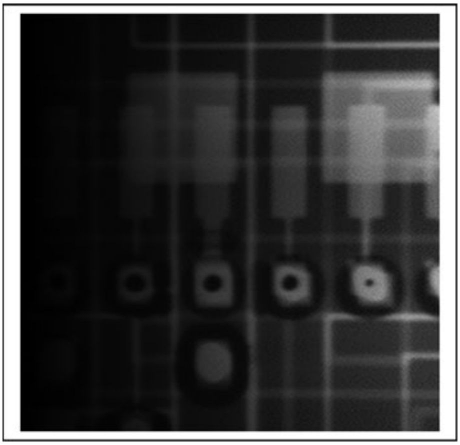


41.216 mul

Format	*mul*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Multiply the intensities in the current and alternate images
Definition	C ⇐ (A × B)/255
Switch images	Yes
Typical uses	Calculating moments
Remarks	*mul* allows the contrast to be varied in different parts of an image
Illustration	
Input images	PCB and intensity wedge (*wgx*)
File number	135
Command	*adi*

Left: original (Other one is output of *wgx*) *Right*: after processing

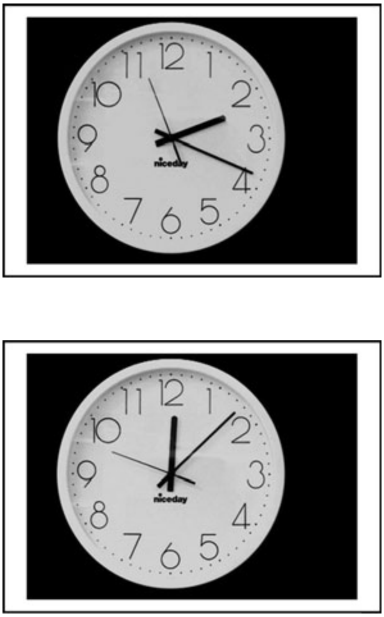




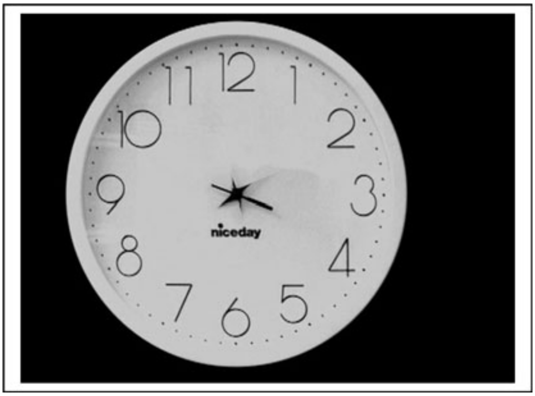
41.217 mxi

Format	*mxi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Find the maximum intensity between corresponding pixels in the current and alternate images
Definition	C ⇐ *MAX*(A, B)
Switch images	Yes
Typical uses	Superimposing (white) lettering onto an image Superimposing bright features of one image onto darker regions of the other
Remarks	*mxi* forms a component of numerous algorithms
Illustration	
Input image	Clocks
File number	142 and 143
Command	*mxi*

Left: two originals



Right: after processing



41.218 mxs

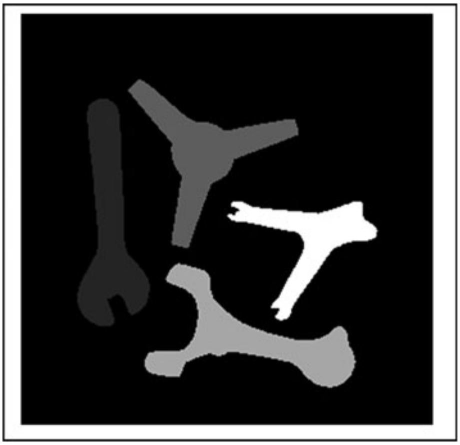
See *asi*

41.219 ndo

Format	*ndo*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Numerate distinct objects in a binary image. All pixels within a given blob are set to the same intensity. Each blob is shaded with a different intensity value. Blobs are defined by 8-connectivity of white pixels
Switch images	Yes
Typical uses	Analysing binary images containing multiple blobs
Remarks	A 4-connected version could also be defined but this is not particularly useful as human beings often find 4-connectivity difficult to distinguish from 8-connectivity. Also see *big* and *kgr*
Illustration	
Input image	Metal objects
File number	46
Command	*thr*, *ndo*, *enc* (N.B. *thr* avoids the artifacts created by storing a binary image in JPEG format. enc was included to improve visibility. The result of applying *ndo* to this image is very dark, since there are only four blobs)

Left: original

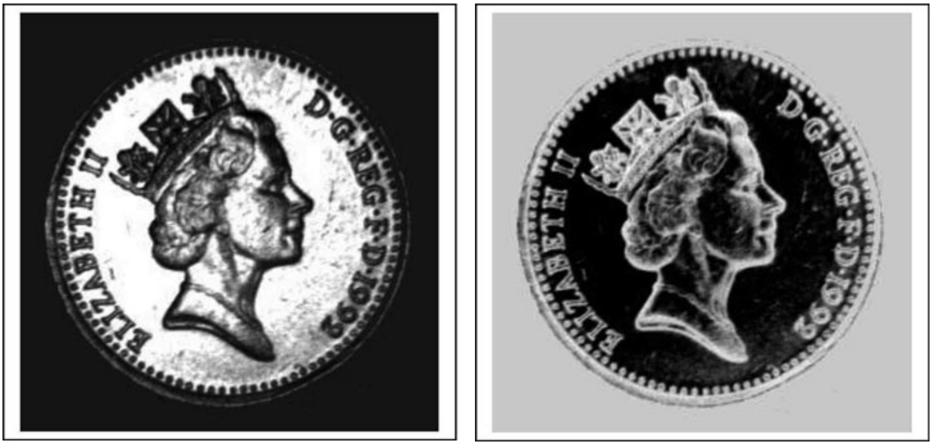
Right: after processing



41.220 neg

Format	*neg*
Arguments	none
Defaults	not applicable
Output values	none
Image type	grey
Type	monadic
Function	negate the input image
Definition	C ⇐ (W − A)
Switch images	yes
Typical uses	Preprocessing for commands that treat white and black differently (e.g., *rlc, blf, chu*)
Remarks	The function *neg* produces an image that resembles a photographic negative
Illustration	
Input image	Coin
File number	23
Command	*neg*

Left: original *Right*: after processing



41.221 news

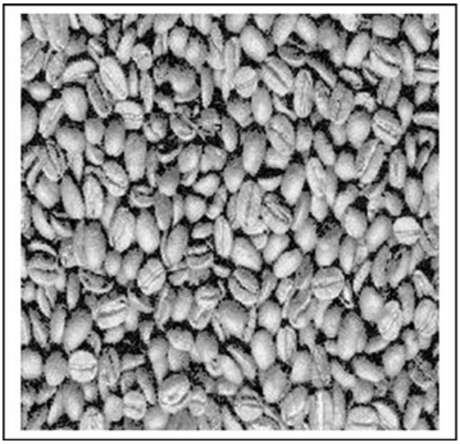
Format	*news*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Not relevant
Type	Information
Function	Visit the author’s web page providing the latest information about updates to QT
Switch images	No

41.222 nlg

Format	*nlg*
Arguments	None
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Logarithm of intensities in the current image
Definition	$C \Leftarrow 255*log(A)/log(255)$ with hard limits placed at 0 and 255
Switch images	Yes
Typical uses	Used to improve contrast in dark regions of the image
Remarks	Also see *alg*, *sqr* and *sqt*
Illustration	
Input image	Coffee beans
File number	4
Command	*nlg*

Left: original

Right: after processing



41.223 nlp

See *dil*

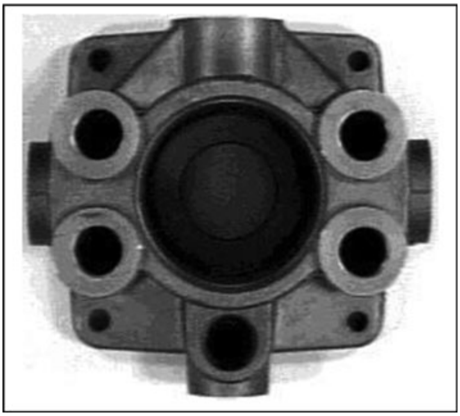
41.224 nop

Format	*nop*
Arguments	*None*
Defaults	Not applicable
Output values	None
Image type	Not relevant
Type	Dummy command
Function	Do nothing
Switch images	No
Typical uses	As a dummy command when calling functions such as *pci*

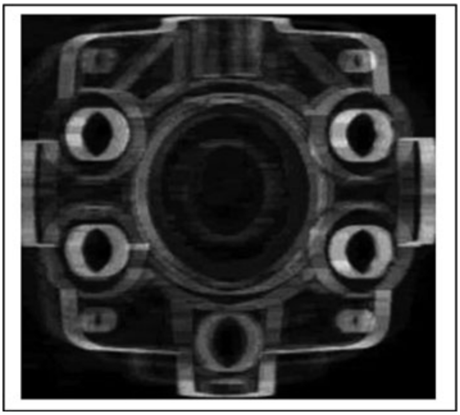
41.225 nrf

Format	*nrf*(*a*, *b*)	
Arguments	*a*	Width of the filter window
	b	Height of the filter window
Defaults	One argument supplied: b = a	
	No arguments supplied: a = b = 5	
Output values	None	
Image type	Grey	
Type	Monadic	
Function	The intensity values within each rectangular neighbourhood of size a × b are placed in rank order. The smallest value is then subtracted from the largest value	
Switch images	Yes	
Typical uses	Edge detection in images where there are no step-like intensity transitions	
Remarks	*nrf*(*a*, *b*) produces the same results as *rdf*(*a*, *b*, *1*)	
Illustration		
Input image	Hydraulics manifold	
File number	37	
Command	*nrf*(*11*, *3*)	

Left: original



Right: after processing

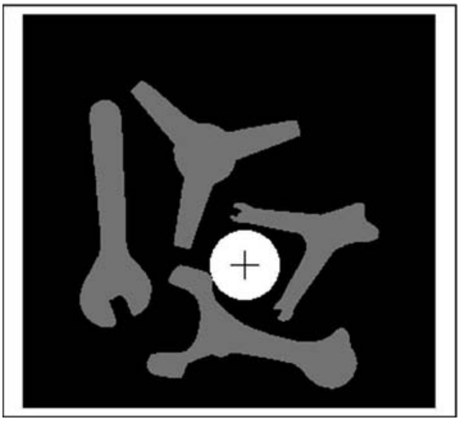


41.226 nwp

Format	[*x*, *y*, *r*] = *nwp*(*u*, *v*)	
Arguments	*u*	X-coordinate of a point
	v	Y-coordinate of a point
Defaults	None	
Output values	*x*	X-coordinate of the nearest white point
	y	Y-coordinate of the nearest white point
	r	Distance from the given point [*u*, *v*] to its closest white point, [*x*, *y*]
Image type	Binary	
Type	Binary image analysis	
Function	Draw the disc centred at [*x*, *y*] with radius *r*, where r is the distance from [*x*, *y*] to its closest white point	
Switch images	Yes	
Typical uses	Joining 'broken' contours (These are often produced when thresholding the output of an edge detector)	
Remarks	Also see *lic*, *mic*, *dic*, *fwp*	
Illustration		
Input images	Four piece parts	
File number	46	
Commands	*rni*(*46*), *thr*, [*x*, *y*] = *cur*; *nwp*(*x*, *y*), *adi*, *mxi*, *wri*, *zer*, *dcl*(*x*, *y*, *0*), *crs*(*10*), *neg*, *rei*, *mni*	

Left: original image

Right: after processing



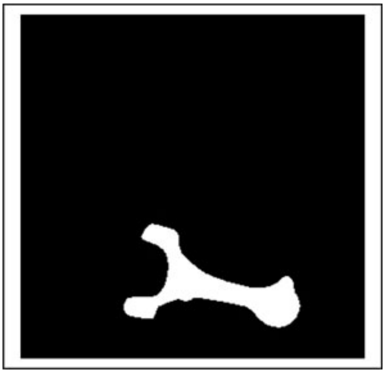
41.227 nxy/npo/nxy_all

Format	*nxy* *npo* *nxy_all*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Binary image transform
Function	*nxy*: Normalise position so that the centroid is relocated at the centre of the image *npo*: As *nxy*, plus normalisation of orientation (i.e., rotate the image so that the principal axis is horizontal) *nxy_all*: As *nxy* when there are multiple objects *npo_all*: As *npo* when there are multiple objects
Switch images	Yes
Typical uses	Analysing blob shape for a wide variety of applications in parts inspection and robot vision
Remarks	Imagine a visually guided robot whose task is to pick up flat objects lying on a table. The camera is directly overhead. Given three parameters (X- and Y-coordinates and orientation), the robot can pick up objects one a time. *npo* and *nxy* allow this process to be simulated. *nxy_all/npo_all* should be used when there is more than one binary object

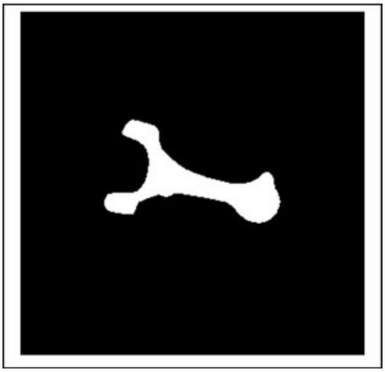
Illustration

Input image	Four metal objects with one item selected (con-rod)	
Image generation	*rni*(*46*), *thr*, *big*	
Command	npo	
	Removing blobs from only 2 sides:	*rbe*(*1*) or *rbe*(*1*, *8*)

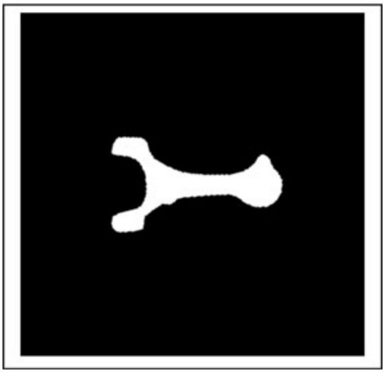
Top-left: original image



Top-right: after *nxy*



Bottom-left: after *npo*



41.228 oab

See *bpa*.

41.229 opn

See *dil*.

41.230 opr

Format	*opr*(*a*, *b*)	
Arguments	*a*	Operation to be performed
	b	Number of times operation is performed
Defaults	*b*	256
Output values	None	
Image type	Grey scale	
Type	Depends on the first argument (*a*)	
Function	Operation *a*(*i*) is performed for *i* = 1:*b*	
Switch images	Yes	
Typical uses	Training	
	Improving user understanding of image structure	
Remarks	The following examples shows how *opr* may be used	

Expanding spatial resolution

[p, q] = dgw; opr('rsz(i, i);', min(p, q))

Rotating the image

opr('tur(i)', 180)

Barrel shifting the image (Shift in X direction)

[p, q] = dgw; opr('psw(i, 0)', p)

Shifting the image (Shift in Y direction)

[p, q] = dgw; opr('psh(0, i)', q)

Variable gamma adjustment followed by pseudo-colour display

opr('gma(i/100), psc', 100)

Thresholding/Drawing intensity contours

caf, opr('thr(i-1), bed', 256)

Selecting single intensity level. Smoothing applied first

caf, opr('thr(i, i)', 256)

Intensity plot

[w, h] = dgw; opr('plt(i)', h)

Displaying blobs in order of size (biggest first)

n = cbl, opr('big(i), adi', n)

Display first N standard images

opr('rni(i)', N)

Bug tracing a binary edge

bed, n = cwp; seb, opr('thr(i, i)', n)

41.231 pad/sqi

Format *pad*(*a*, *b*, *c*)
sqi(*a*)

Arguments (*pad*) *a* Width of the left/right sides of the border
b Width of the top/bottom sides of the border
c Intensity of the padded border

Defaults *b* Equal to *a* when 1 or 2 arguments are supplied
c 0, when 1 argument is supplied

Output values None

Image type Grey or binary

Type Adjust image geometry

Function *pad* adds a border of intensity *c* and
width *a* to the left and right of the original image
width *b* to the top and bottom of the original image
sqi(*a*) automatically adjusts the aspect ratio so that the image is square. The padded area is assigned intensity value *a*

Switch images Yes

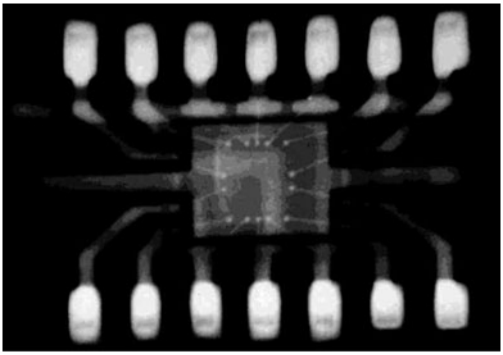
Typical uses *pad* Errors also occur if dyadic operators (*adi*, *sub*, *mxi*, *mni*, *exr*) are applied to two images of different sizes
sqi Some operation sequences, such as [*yxt*, *mxi*] *and* [*yxt*, *adi*], generate errors if the input image is not square

Remarks Also see *pex*, *psh* and *psw*

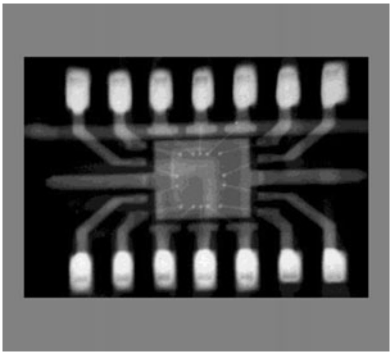
Illustration

Input image	X-ray of a DIL integrated circuit	
File number	113	
Command	*pad*(*20*, *50*, *128*)	(*Top-right*)
	sqi(*128*)	(*bottom-left*)

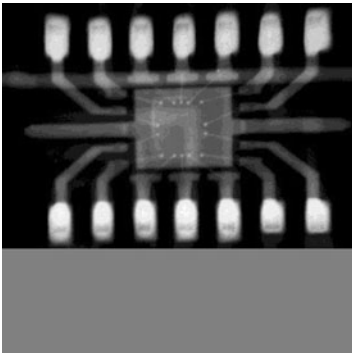
Top-left: original



Top-right: after *pad*(*20*, *50*, *128*)



Bottom-left: after *sqi*(*128*)



41.232 pbi

Format *[x, y, z1, z2] = pbi(x1, y1, x2, y2)*

Arguments *x1* X-coordinate of point 1

y1 Y-coordinate of point 1

x2 X-coordinate of point 2

y2 Y-coordinate of point 2

Defaults None

Output values *x* X-coordinate of the point mid-way between *[x1, y1]* and *[x2, y2]*

y Y-coordinate of the point mid-way between *[x1, y1]* and *[x2, y2]*

z1 Orientation of the line joining [x1, y1] and [x2, y2]

z2 Orientation of the perpendicular bisector of the line joining *[x1, y1]* and *[x2, y2]*

Image type Any

Function Calculate a point *[x, y]* on the perpendicular bisector of the line joining *[x1, y1]* and *[x2, y2]* and draw the perpendicular bisector

Switch images Yes

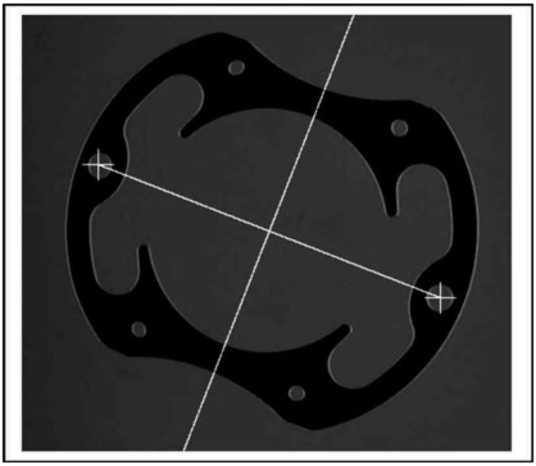
Typical uses Analysing binary images

Illustration

Input image Stator stamping for an electric motor

File number 174

Image The user defined the two points indicated by crosses with the cursor. Their coordinates were then passed to *pbi*.

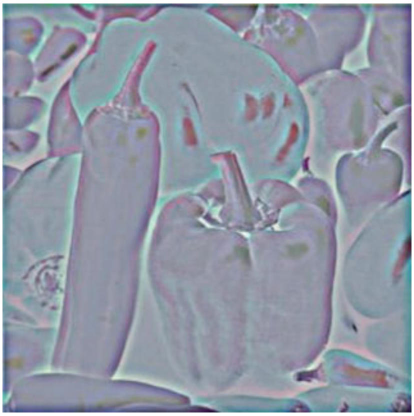


41.233 pcd/adc/mnc/mxc/suc

Format	*pcd*(*x*) *adc* *mnc* *mxc* *sue*	
Arguments	x	Dyadic operator (*pcd* only)
Defaults	None	
Output values	None	
Image type	Colour	
Type	Colour image processing	
Function	*pcd*(x)	Perform a given dyadic operator (x) to two colour images
	adc	Add two images (point-by-point, RGB channels are processed separately)
	mnc	Minimum of intensities in two images (point-by-point, RGB channels are processed separately)
mxc	mxc	Maximum of intensities in two images (point-by-point, RGB channels are processed separately)
	sue	Subtract two images (point-by-point, RGB channels are processed separately)
Switch images	Yes	
Typical uses	Filtering colour images	
Remarks	Also see *pci*, *adi*, *mxi*, *mni*, *sub*	
Illustration		
Input images	Peppers	
File number	73	
Command	*pci*(‘*caf*’), *pcd*(‘*mni*’) (High pass filter, applied to the RGB channels separately)	

Top-left: original

Top-right: after processing



41.234 pcf

Format	*pcf*
Arguments	None
Defaults	Not applicable
Output values	None
Image types	Current, colour; alternate, 255 × 255-pixel grey-scale image
Type	Colour image processing
Switch	Yes
Function	Programmable colour filter

Definition The alternate image is used as a look-up table, to transform the current image (colour) into a monochrome image in which colour sets are mapped into distinct intensity levels. Thus, a broad set of colours that a person might call 'yellow' might be mapped to level 137, while 'turquoise' is mapped to level 119 and 'mauve' to 93. The assignment can be selected arbitrarily. To understand how colour recognition can be achieved by *pcf*, consider the following. Let $A(p, q)$ denote the intensity at the pixel (p, q) in the alternate image. Also, let pixel (i, j) in the current image have hue $H(i, j)$ and saturation $S(i, j)$. These values are calculated from the RGB values generated by *pcf*. (The intensity component is not considered, since this does alter the identification of colours in the context of Machine Vision.) The pixel at address (i, j) within the output image generated by *pcf* is assigned an intensity value equal to

$$A(H(i, j), S(i, j))$$

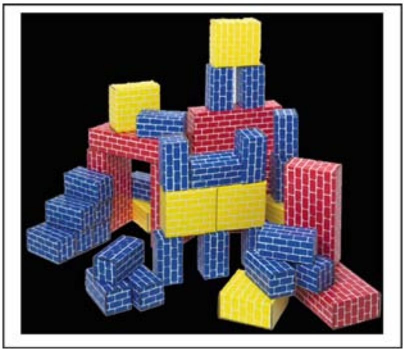
Typical uses Colour recognition; reduction of colour images to grey-scale for simplified processing

Remarks A programmable colour filter is best applied to images containing 'block colours'. These are discrete, well separated, colours that do not vary significantly over a large area and are very different from each other. (See illustration below.) Normally, the boundaries between block colour regions are typically quite sharp, with little or no blending from one block colour region to another. Block colour printing is unable to represent real scenes but is cheap to produce. As a result, many containers/labels, for food products, household cleaners, toiletries, etc. are printed using block colours. In the first illustration below, the alternate image, which defines the colour look-up table, is computed from the hue-saturation scattergram. (*shs*) Notice that low values of saturation (corresponding to the left-hand side of the image) are mapped to black. In the second example, the look-up table is a simple pattern based on an intensity wedge. Again, low values of saturation are mapped to black. Another example, showing how *shs* and *pcf* can be used together is given in the notes relating to *shs*

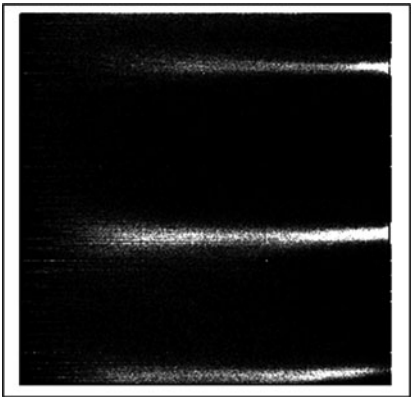
Illustration

Input image	Coloured blocks
File number	168
Command	See below

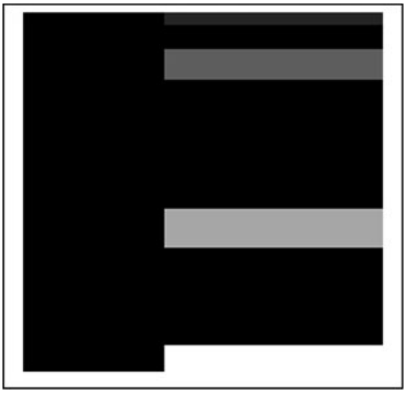
Top-left: original



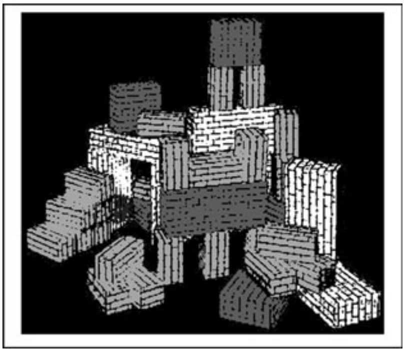
Top-right: after *shs*



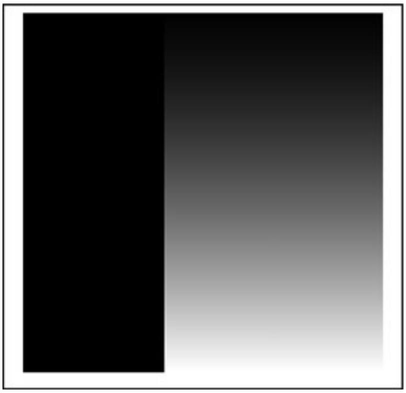
Centre-left: look-up table generated using shs, *rin*, *csh*, *thr*(*32*), *ndo enc*, *dil*(*9*). *psh*(*100*, *0*)



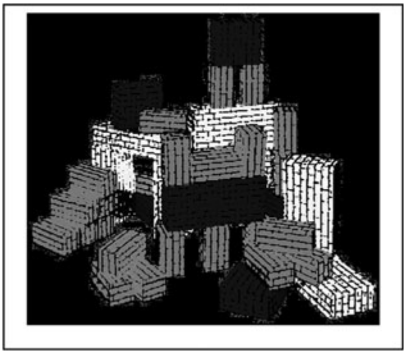
Centre-right: *pcf* using the look-up table defined by the 'bars' image to the left



Bottom-left: look-up table generated using *wgy*, *psh*(*100*)



Bottom-right: *pcf* using this look-up table (Each hue is assigned a to a different intensity value)



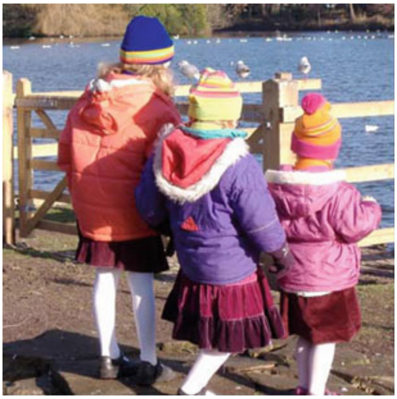
41.235 pci

Format	*pci*(*r*, *g*, *b*)
Arguments	*r* Image processing command/sequence applied to the R-channel *g* Image processing command/sequence applied to the G-channel *b* Image processing command/sequence applied to the B-channel
Defaults	*g* Same value as *r* *b* Same value as *r*
Output values	None
Image type	Colour
Type	Progam control
Function	Apply the following commands/sequences of commands *r* applied to the R-channel *g* applied to the G-channel *b* applied to the B-channel
Switch images	Yes
Typical uses	Image enhancement for visual display, or preprocessing prior to colour recognition
Remarks	The commands/sequences of commands can be chosen independently. Commands that return outputs cannot be used here (Use *pca* instead)

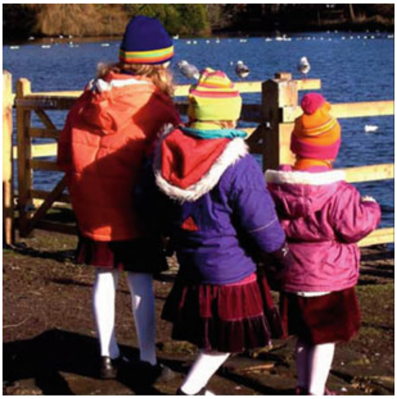
Illustration

Input image	Children
File number	264
Command	See below

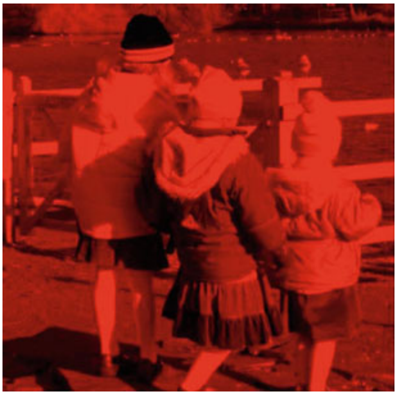
Top-left: Original



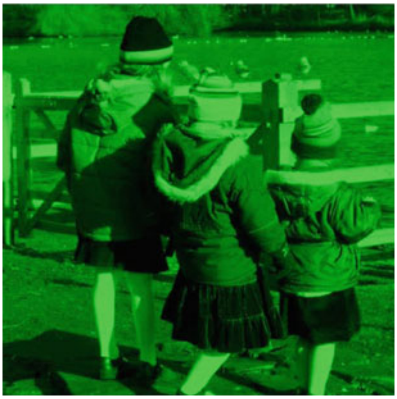
Top-right: *pci(‘sqr’)*



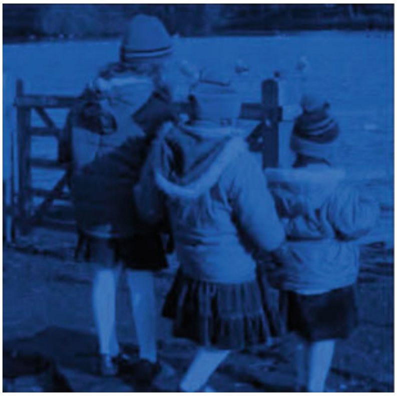
Centre-left: *pci(‘nop’,‘zer’,‘zer’) (This retains only the red channel)*



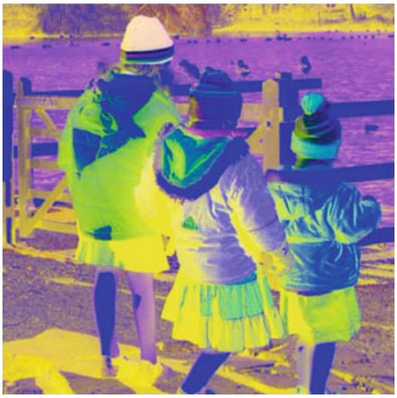
Centre-right: *pci(‘zer’,‘nop’,‘zer’) (This retains only the red channel)*



Bottom-left: *pci(‘zer’,‘zer’,‘nop’)*



Bottom-right: *pci(‘neg’,‘neg, sqr’,‘heq’)*



41.236 ped

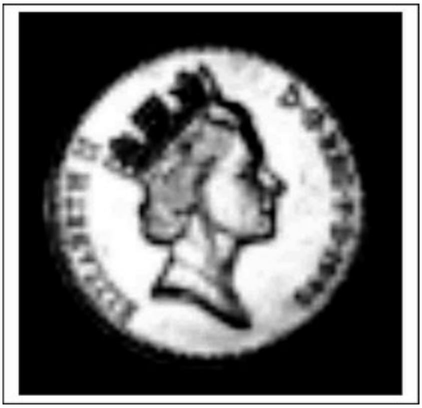
See *ced.*

41.237 pex

Format	*pex*(*x*)	
Arguments	*x*	
Defaults	*x*	2
Output values	None	
Image type	Grey	
Type	Image warping	
Function	Rescale the spatial resolution along both axes, by a given amount, *x*	
Switch images	Yes	
Typical uses	Demonstrates the effects of adjusting the spatial resolution	
Remarks	The input parameter, *x*, may be greater than 1, in which case the image resolution is reduced. If $x < 1$, the image resolution is increased, using bilinear interpolation. It is interesting to squint when viewing a reduced resolution image. This has the effect (similar to the operator *caf*) of blurring edges and may actually make it more readily identifiable visually. Also see *rsz*	
Illustration		
Input image	Coin	
File number	23	
Command	*pex*(4)	

Left: original

Right: after processing



41.238 pft

Format $p = pft(a, b, m, n)$

Arguments a Row number indicating start of scan

b Row number indicating end of scan

m Number of scan lines

n Polynomial order

Defaults None

Output values p Vector containing the coefficients of the fitted polynomial

Image type Binary

Type Image analysis

Switch No

Function Fit a polynomial curve of order n to a set of edge points, found by scanning from left to right along a series of m horizontal lines. The latter are equally spaced between rows a and b

Switch images No. A curve is drawn in Figure 6

Typical uses Defining circularly symmetric filters

Remarks Choosing an appropriate value for the polynomial order (parameter n) is crucial. In the example given below, n is too small and does not allow an accurate fit of the edge points. (See right-hand-side of the graph.) However, raising n can cause problems, due to over-fitting. As a general guide, n should be as low as possible, while ensuring a good fit. Normally, the number of data points, m, should be greater than $5n$. Furthermore, the edge should have a finite slope and be single-valued for every value of the X-coordinate. If necessary, polynomial curves should be fitted to small segments of a complicated curve

Illustration

Input image Bottle, with thresholding to create a binary image

Image generation *rni*(*31*), *thr*, *neg*

Command *pft*(*80*, *275*, *20*, *3*)

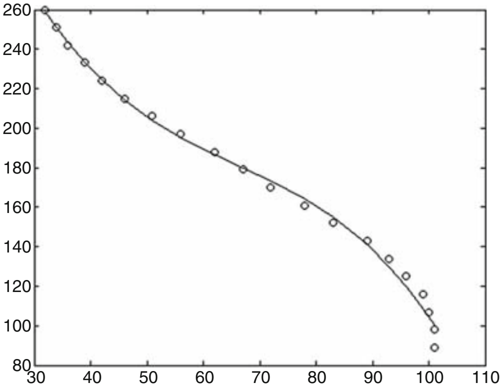
Output: $p = -0.0176\ 1.4281\ -30.8175\ 347.2487$

This defines the following polynomial:

$$y = -0.0176x^3 + 1.4281x^2 - 30.8175x + 347.2487$$

Left: original image. The vertical limits of the scanning process, performed by *hzs*, are indicated by crosses

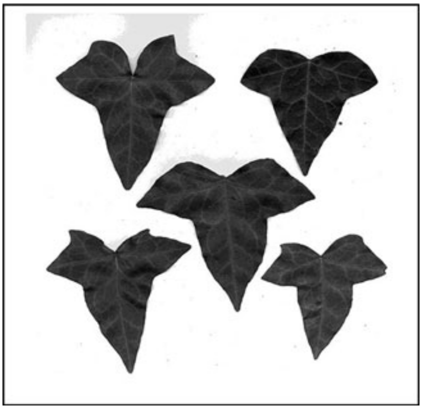
Right: pivotal points found by *hzs* (circles). The curve is a 3rd-order polynomial, which slightly under-fits this data. Notice that the Y axis is inverted



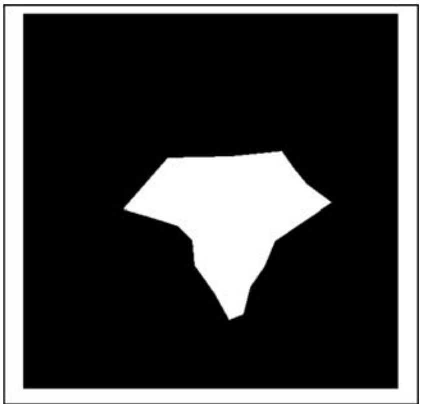
41.239 pgn

Format	*pgn*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey-scale or binary
Type	Drawing
Function	Draw a filled polygonal interactively, using the cursor
Switch images	Yes
Typical uses	Selecting specific bodies or regions of interest, to improve speed of processing. Selecting sub-images for use as morphology structuring elements of convolution kernels
Remarks	The user places the cursor at each of the nodes of the polygon in turn and then presses RETURN to finish. The result is a binary image, which could be used as a mask to isolate an object of special interest (e.g., the central leaf in the illustration below)
Illustration	
Input image	Ivy leaves
File number	92
Command	*pgn*

Left: original image



Right: polygonal region defined by the author using *pgn*. Use *mni* to use this as a mask to isolate the largest leaf

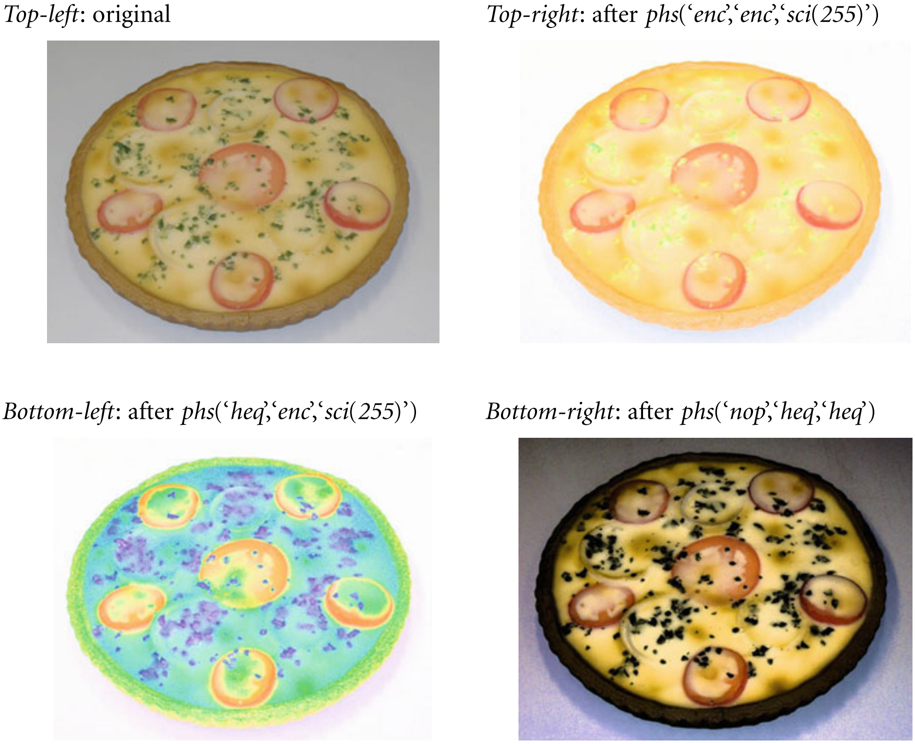


41.240 pgt

Format	$c = pgt(x, y)$	
Arguments	x	X-coordinate of the given point
	y	X-coordinate of the given point
Defaults	None	
Output values	c	Intensity at the given point
Image type	Grey or binary	
Type	Image measurement	
Switch	No	
Function	Find the intensity at a point given its XY-coordinates	
Typical uses	Understanding image structure	
Remarks	Also see *cur*, *fap*, *vpl*	

41.241 phs

Format	*phs*(*a*, *b*, *c*)	
Arguments	*a*	Processing sequence for the hue (H) channel
	b	Processing sequence for the saturation (H) channel
	c	Processing sequence for the intensity (I) channel
Defaults	*a*	‘*nop*’ (no operation)
	b	‘*sci*(*255*)’ (*set to maximum value*)
	c	‘*sci*(*255*)’ (*set to maximum value*)
Output values	None	
Image type	Colour	
Type	Colour image processing	
Function	Operation *a* is applied to the H channel Operation *b* is applied to the S channel Operation *c* is applied to the I channel	
Switch images	Yes	
Typical uses	Enhancing colour contrast to improve visibility or processing	
Remarks	Also see *pci*	
Illustration		
Input image	plastic replica of a pizza	
File number	219	
Command	*phs*(‘*enc*’,‘*enc*’,‘*sci*(*255*)’) *phs*(‘*heq*’,‘*enc*’,‘*sci*(*255*)’) *phs*(‘*nop*’,‘*heq*’,‘*heq*’)	



Top-left: original

Top-right: after *phs*(‘*enc*’,‘*enc*’,‘*sci*(*255*)’)

Bottom-left: after *phs*(‘*heq*’,‘*enc*’,‘*sci*(*255*)’)

Bottom-right: after *phs*(‘*nop*’,‘*heq*’,‘*heq*’)

41.242 pis

Format	*pis*(*a*, *b*, *c*)	
Arguments	*a*	Folder for input images
	b	Operation to be performed on those images
	c	Folder for output images
Defaults	*c*	QT_work_files
Output values	None	
Image type	Any	
Type	Processing image sequences	
Function	Perform operation *b* on all images in folder *a*, leaving the results as numbered images in folder *c*	
Switch images	Depends on the command sequence *b*. Normally, both images are overwritten	
Typical uses	Processing image sequences	
Remarks	Example: pis(qt_images_path, ‘enc,thr,bed’,qt_work_path)	

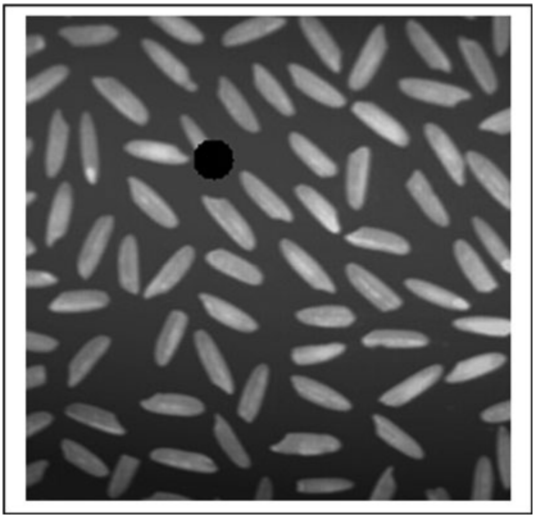
41.243 pki

Format	[*p*, *q*, *s*] = *pki*
Arguments	None
Defaults	Not applicable
Output values	*p* X-coordinate of the first point found with the peak intensity
	q Y-coordinate of the first point found with the peak intensity
	s Value of the peak intensity
Image type	Grey
Type	Image analysis
Switch	Yes
Function	Locate the point (*p*, *q*) with the peak intensity (*s*). If there is more than one such point, the coordinates and value of the left-top-most one are returned. The point (*p*, *q*) is plotted as a single white pixel in the current image, which is otherwise black
Typical uses	Analysis of Radon transform image. (See *rdn.*) Suppressing highlights due to glinting
Remarks	The point of maximum intensity and the area immediately around it (i.e., pixels, within a distance *r*) can be masked out by using the following command sequence: *wri*, [*a*, *b*, *c*] = *pki*; *zer*, *cir*(*a*, *b*, *r*), *blf*, *neg*, *rei*, *mni*

Illustration

Input image	Rice grains
File number	3
Commands	*wri*, [*a*, *b*, *c*] = *pki*; *zer*, *cir*(*a*, *b*, *10*), *blf*, *neg*, *rei*, *mni*

Below: point of peak intensity and the pixels surrounding pixels suppressed



41.244 plot3d

Format *plot3d*(*a*, *b*)

Arguments *a* Adjust the resolution of the plot along the X-axis (Large values reduce the resolution)

b Adjust the resolution of the plot along the Y-axis (Large values reduce the resolution)

Defaults *a* 1

b 1

Output values None

Image type Grey

Switch images No

Type Understanding image structure

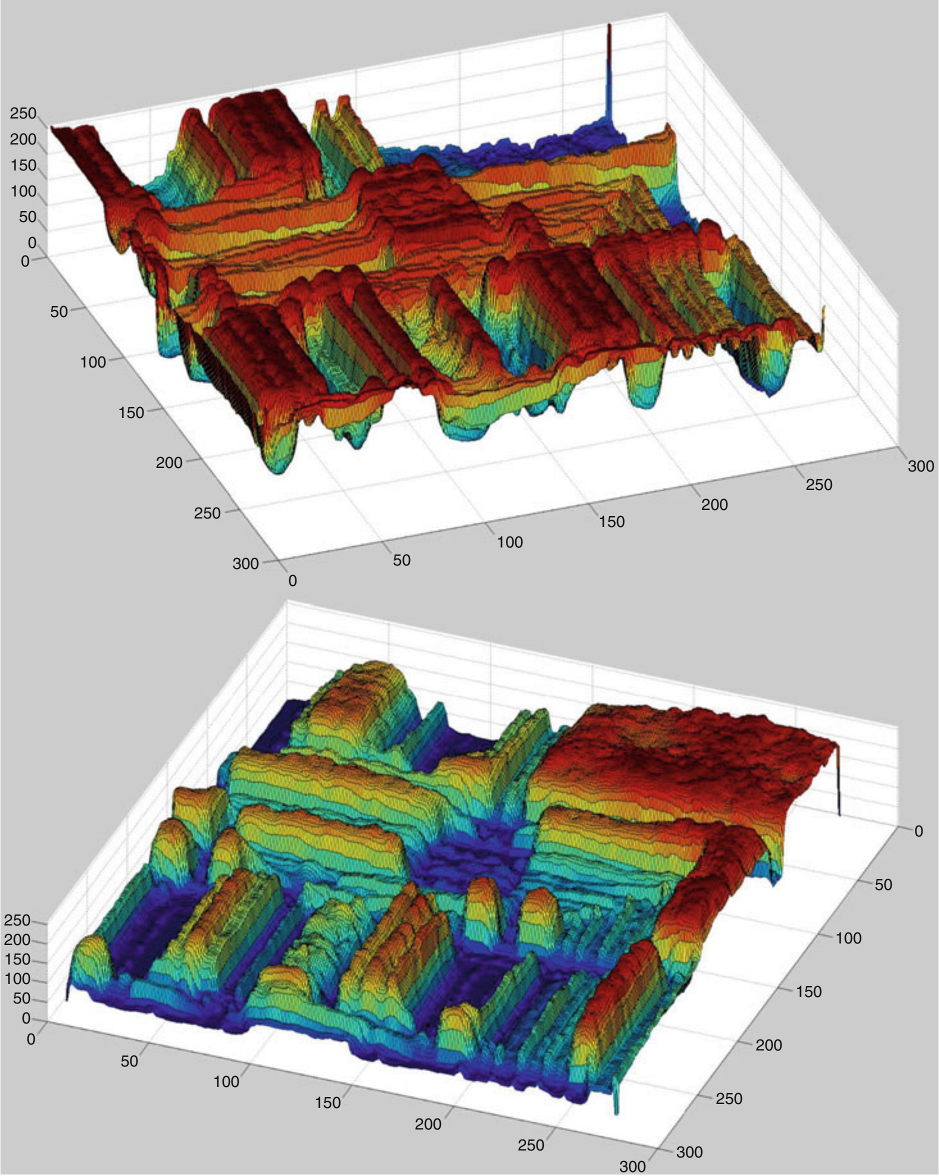
Function Display the current image as a 3-dimensional plot with a wire-mesh overlay and in pseudo-colour. The user can adjust the viewing point interactively with the mouse. (Click on the '*Rotate 3D*' icon first.) This creates the effect of flying over a wrinkled and coloured carpet, whose height is proportional to the image intensity. To exit, the user selects MATLAB's '*Rotate 3D*' icon and clicks on the image pane

Remarks It is often useful to apply image smoothing (*caf*, *raf*, or *mdf*) and/or enhancement (*enc*, *heq*, *sqr*, *sqt*, *nlg*, *alg*) first. Negation *(neg)* is also useful

Illustration

Input image	Circuit
File number	136

Top:	*rni(136), mdf(5), enc, plot3d(1, 1)*	The author selected the viewing point interactively
Bottom:	*rni(136), mdf(5), enc, neg, plot3d(1, 1)*	The author selected the viewing point interactively



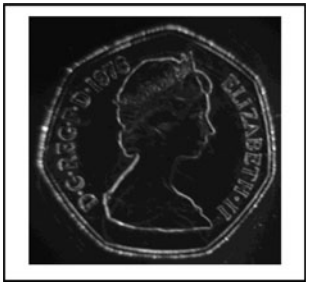
41.245 plt

Format	*plt*(*a*)	
Arguments	*a*	Height of sampling line for profile
Defaults	*a*	Half image height
Output values	None	
Image type	Grey	
Type	Measurement and anlysis	
Function	Plot the intensity profile along a defined row in the current image. The plot is drawn in a new figure	
Switch images	No	
Typical uses	*plt* is used principally as an aid to understanding the structure of an image and in guiding algorithm design	

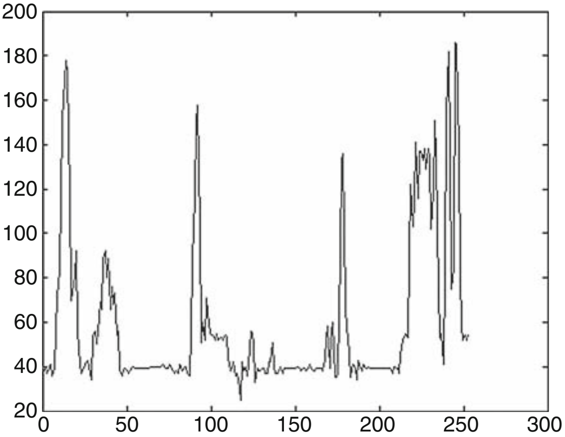
Illustration

Input image	Coin
File number	24
Command	*plt*

Left: input image



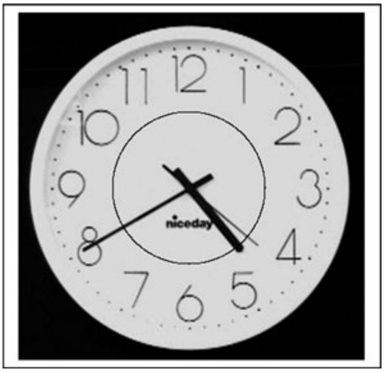
Right: intensity profile
Abscissa, horizontal position
Ordinate, intensity



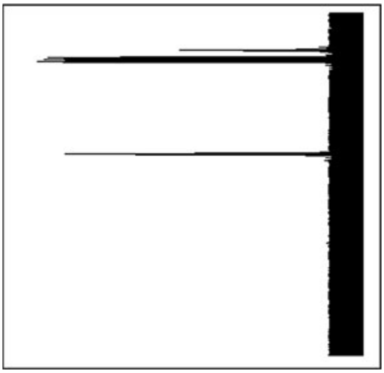
41.246 plv

Format	*plv*(*a*)
Arguments	a Vector to be plotted
Defaults	None
Output values	None
Image type	Grey
Type	Drawing
Function	Plot the given vector in the current image
Switch images	Yes
Typical uses	Used in conjunction with *lsc* or *scc*, *plv* is able to plot intensity profiles along a line or around a circular path
Remarks	*plt* and *ipl* plot intensity profiles in a new figure, whereas *plv* draws a graph in the current image. As a result, the output of *plv* can be processed like any other binary image. Also see *plt*, *lsc* and *scc*
Illustration	
Input image	Clock
File number	148
Command	*a* = *scc*(*288*, *247*, *85*); *plv*(*a*)

Left: input image For the purposes of illustration, the sampling circle used by *scc* has been superimposed and the image has been cropped. Notice that this circle intersects the second-, hour- and minute-hands and that it traverses the image in a clockwise direction, beginning at the 3 o'clock position



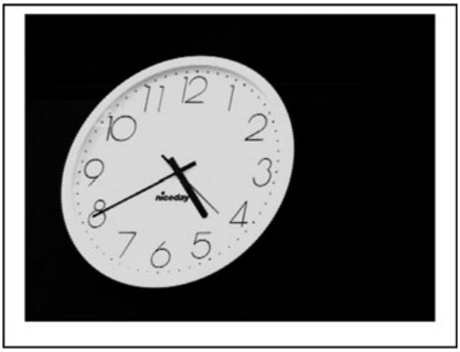
Right: Intensity plot. *Horizontal axis*: intensity. *Vertical axis*: angular position. Going from top to bottom, the three intensity 'peaks' correspond to the second-, hour- and minute-hands, respectively. Notice that this is an image and hence can be processed as normal using QT operators



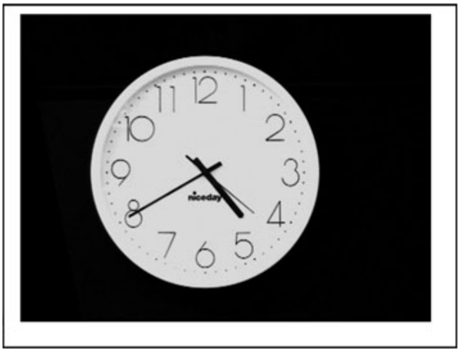
41.247 plw

Format	*plw*(*a*)
Arguments	*a* Warping parameter
Defaults	None
Output values	None
Image type	Grey scale or binary
Type	Image warping
Switch	Yes
Function	Parallelogram warping; the rows of the image are shifted sideways by an amount that is proportional to the vertical position
Switch images	Yes
Typical use	Correcting image distortion caused by viewing from an oblique angle
Illustration	
Input image	Clock, with parallelogram warping deliberately introduced (*plw*(*0.2*))
File number	148
Command	*plw*(−*0.2*)

Left: original



Right: after processing



41.248 pmf

Format *pmf(a, b, c, d)*

Arguments *a* *Start frame number*
b *End frame number*
c *Function to be applied*
d *URL of the AVI movie file (This must be RGB, non-compressed format)*

Default values *a* *1*
b *10*
c *neg*
d *QT_images/movie sample3.Avi*

Output values None

Output images The output images are saved in files
movie_frame1, movie_frame2, movie_frame2, etc.
in folder
/QT_image_sequences/

Image type Defined by the movie

Function Process a non-compressed AVI movie file with a given function

Switch images Not relevant as both the Current and Alternate images are destroyed

Typical uses Analysing AVI movies, or separating such movies into individual frames

Remarks The operator *pmf* is likely to be very slow as it processes many images. Examples of use

1. Convert to grey and negate each frame
   c = ‘*gry, neg*’
2. Apply edge detector (*sed*) to each colour channel
   x = ‘*sed, enc, neg*’, *c* = [‘*pci*(‘*char*(*39*), *x*, *char*(*39*),’)’]
3. Split the movie into separate frames for processing later
   c = ” (*empty string*)

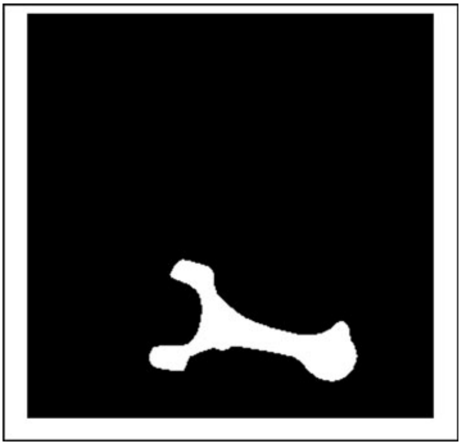
Use pis to process a set of images.

Use psf to process a series of images and then construct a movie file.

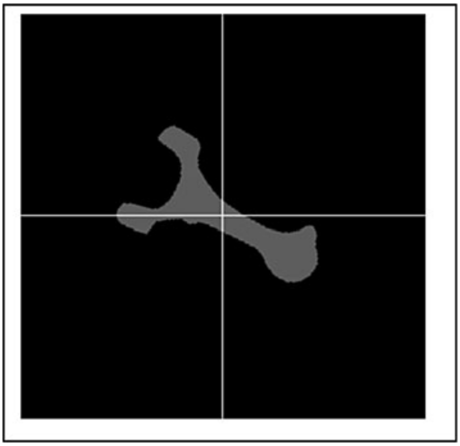
41.249 pon

Format	[*x*, *y*, *t*] = *pon*	
Arguments	None	
Output values	*x*	X-coordinate of the centroid
	y	Y-coordinate of the centroid
	t	Orientation
Image type	Binary, multiple blobs	
Type	Binary image transform	
Function	Find the position of the centroid of all white pixels (call this point A) and B, the white pixel furthest from A. Normalise the position, so that the centroid is at the centre of the image and then rotate it, so that the line AB is horizontal	
Switch images	Yes	
Typical uses	Analysing blob shape for a wide variety of applications in parts inspection and robot vision	
Remarks	*pon* is an alternative to *npo* and *npo_all*. Also see *rdc*	
Illustration		
Image	Four metal objects with one item selected (con-rod)	
Image generation	*rni*(46), *thr*, *big*	
Command	*pon*, *hin*, *dci* (The horizontal line through the centre of the image intersects the edge of the blob at the point that is furthest from the centre)	

Left: original



Right: after processing



41.250 pop

Format	*pop*
Arguments	None
Output values	None
Image type	Any
Type	Stack operator
Function	Pop the image stack. The top image on the stack is copied into the current image and is then deleted from the stack
Switch images	Yes
Remarks	Also see *push*, *ssk*, *rsk*, *csk*

41.251 pre

Format *[a, b] = pre*

Arguments None

Output values *a* X-coordinate of the point selected by the user

b Y-coordinate of the point selected by the user

Image type Any

Function The user delects a point, [*a*, *b*], with the cursor. This is then used to define the parameters for plotting the row and column intensity profiles

Switch images No

Typical uses The intensity plots are displayed as overlays on the current image, which is not altered. Any further processing deletes them. The alternate image also remains unaltered

Remarks Initial analysis of grey-scale images

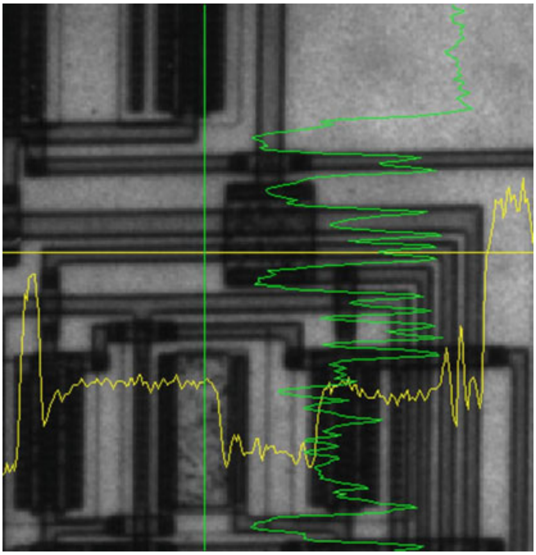
Also see *cur*, *plt*

Illustration

Input image Electronic circuit on ceramic substrate

File number 136

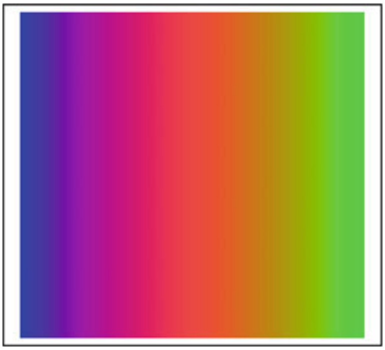
Command *prc* (The user selects a point to define which row and column profiles are to be plotted)



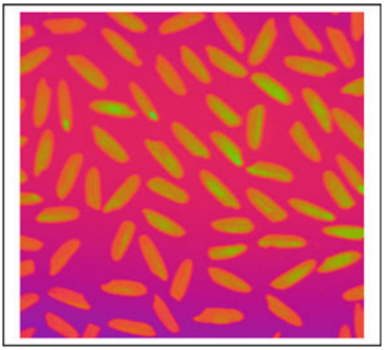
41.252 psc/rpc

Format	*psc* *rpc*	
Arguments	None	
Defaults	Not applicable	
Output values	None	
Image type	Grey scale	
Type	Image display	
Function	*psc*	Display the image using a pseudo-colour mapping based on gamma adjustment. The original grey-scale image is also displayed
	rpc	Display the image using a pseudo-colour mapping that is reversible (using the function *ity*). The original grey-scale image is also displayed
Switch images	Yes	
Typical uses	Improving user understanding of image structure	
Remarks	The human eye is more sensitive to changes in colour than intensity. Low-contrast intensity variations can often be seen more easily in a pseudo-colour image. The results of the pseudo-colour mapping can be processed in as any colour image. The function *rpc* produces a mapping that approximately preserves intensity. This means that the sequence [*rpc*, *ity*] produces a grey-scale image that is the same as the original	
Illustration		
Input image	Wedge generated by *wgx* Grains of rice (file number 3)	
Commands	*psc* *rpc*	

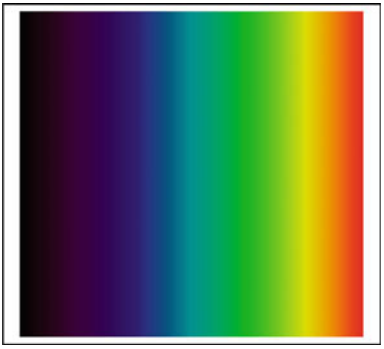
Top-left: *psc* applied to an intensity wedge (*wgx*)



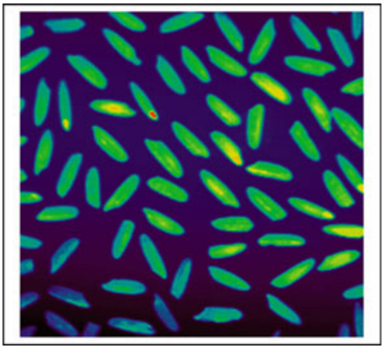
Top-right: *psc applied to the rice image*



Bottom-left: *rpc* applied to an intensity wedge (wgx)



Bottom-right: *rpc* applied to a the rice image



41.253 psf

Format	*psf* (*a*, *b*)
Arguments	*a*
Default	*a* = '*/QT_image_sequences/*'
Output values	None
Output movie	An AVI movie called '*movie_output.avi*' is stored in the folder '*QT_work_files*'
Image type	Defined by the input movie
Function	Process all of the images in folder *a* using function *b*
Switch images	Both Current and Alternate images are retained unchanged
Typical uses	Enhancing or annotating individual frames of a movie. For example, *psf* might be used to demonstrate how a moving object can be tracked
Remarks	This operators can be very slow as many images may have to be processed. For software to split MPEG files into individual frames visit *http://www.flydragonsoft.com/avi-decompressor.htm* Alternatively, use *pmf* with its second argument equal to the empty string (")

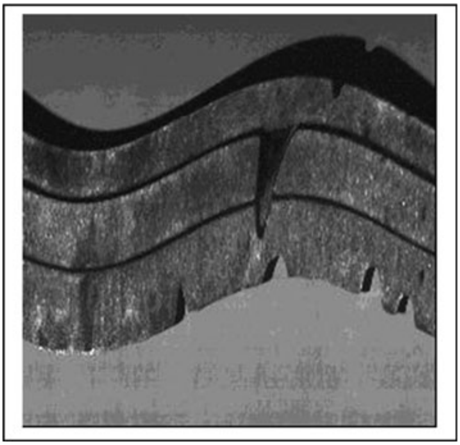
41.254 psh

Format	*psh*(*a*, *b*)
Arguments	*a* Horizontal shift *b* Vertical shift
Defaults	*b* 0
Output values	None
Image type	Grey scale or binary
Type	Affine
Switch	Yes
Function	Picture shift, without wrap-around
Definition	$C(i + a, j + b) \Leftarrow A(i, j)$
Switch images	Yes
Remarks	Those areas of the output image that are not covered by the shifted input picture are set to black. Also see *psw*

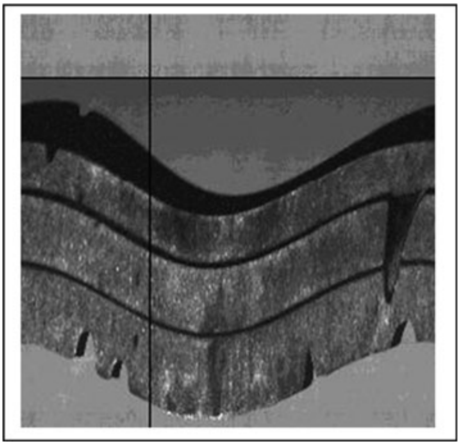
41.255 psw

Format	*psw*(*a*, *b*)
Arguments	*a* Horizontal shift
	b Vertical shift
Defaults	*b* 0
Output values	None
Image type	Grey scale or binary
Type	Affine
Switch	Yes
Function	Picture shift, with wrap-around
Switch images	Yes
Remarks	Also see *psh*
Illustration	
Input image	Line scan image of a circular component on a turn-table
File number	99
Command	*psh*(*80*, *40*)

Left: original



Right: after processing



41.256 ptc

Format *ptc*(*a*, *b*)

Arguments *a* X-coordinate for the pivotal point for the axis transformation

b Y-coordinate for the pivotal point for the axis transformation

Defaults *a* X-coordinate of the centre of the image

b Y-coordinate of the centre of the image

Output values None

Type Image warping

Switch Yes

Function Polar-to-Cartesian coordinate axis transformation

Switch images Yes

Typical uses Inspecting objects that have circular, spiral, or radial ('wheel spoke') features

Remarks Concentric circular features centred on the pivotal point (*a*, *b*) are mapped to parallel vertical lines, while radial lines are mapped to parallel horizontal lines. An Archimedean spiral (equation r = k θ) is mapped to an inclined straight line. Also see *ctp*

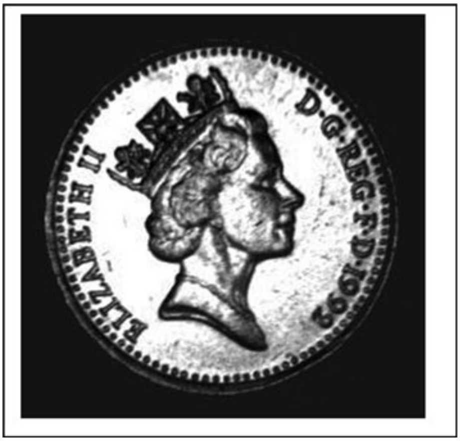
Illustration

Input image Coin

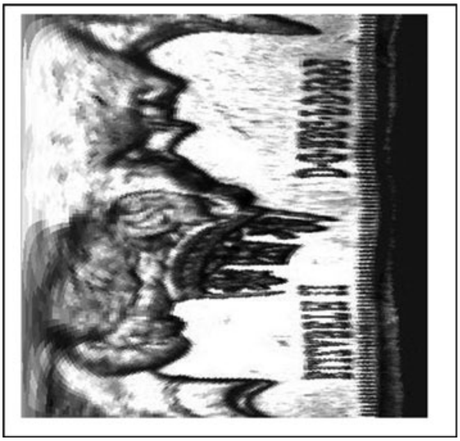
File number 23

Commands *ptc*

Below: original image



Right: processed image



41.257 pth

Format	*pth*(a)
Arguments	a Proportion of picture area ($0 \leq a \leq 1$)
Defaults	None
Output values	None
Image type	Grey-scale
Type	Threshold
Function	Threshold at that intensity level so that a proportion a of the pixels are set to white
Switch images	Yes
Typical uses	Analysing textured surfaces and other applications where the proportion of bright and dark pixels is known beforehand
Remarks	Function *ipp* provides automatic compensation for lighting variations. Also see *ipp*, *tmd*

41.258 push

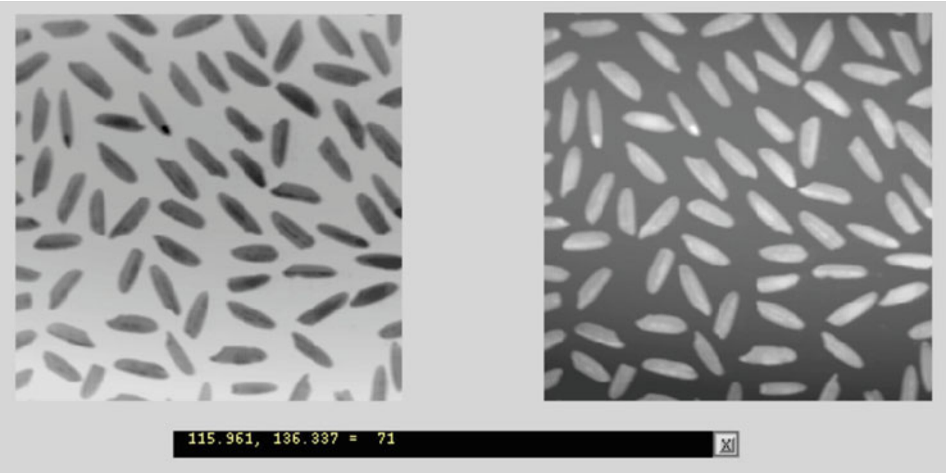
Format	*push*
Arguments	None
Output values	None
Image type	Any
Type	Stack operator
Function	Push the current image onto the image stack. The current and alternate images do not change
Switch images	No
Remarks	Also see *pop*, *ssk*, *rsk*, *csk*

41.259 pxv

Format	*pxv*(*a*)	
Arguments	a	Interactive display ON/OFF
Defaults	a	1 (display ON)
Output values	None	
Image type	Any	
Type	Miscellaneous	
Function	Interactive investigation of position and intensity	
Switch images	No	
Remarks	*pxv* (or *pxv*(*1*)) invokes the MATLAB function *impixelinfo*, which interactively displays information about image pixels in an image on the screen. This can be any image in Figure 1 or 2. Neither the Current nor Alternate image image is modified. Also see *cur*	

Illustration

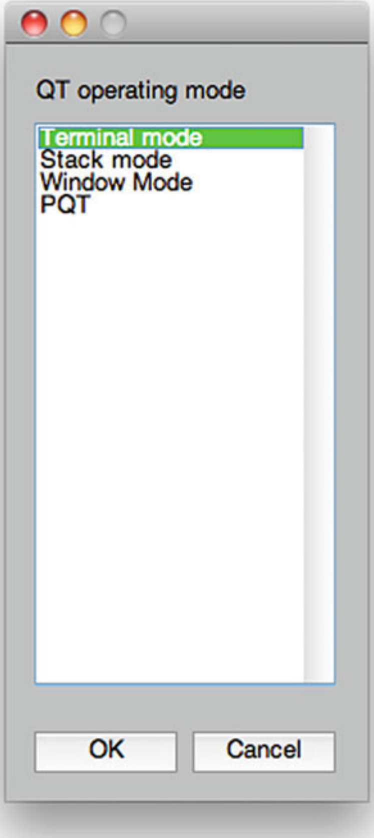
Screen dump of *Figure No. 1*. The current image is always displayed on the left and the alternate image on the right.



```
115.961, 136.337 =  71
```

41.260 qt

Format	*qt*
Arguments	None
Output values	None
Image type	Not relevant
Type	Not relevant
Function	The user is invited to select the operating mode via a pop-up menu
Switch images	No



QT operating mode

- Terminal mode
- Stack mode
- Window Mode
- PQT

41.261 qtp

Format	*qtp*(*a*)
Arguments	*a* Enable (a = 1) or disable (a = 0) functions that are
Default	*a* Flip the *enabled/disabled* state
Output values	None
Image type	Not relevant
Type	Information
Function	*qtp*(*0*) Disable new functions
	qtp(*1*) Enable new functions, previously downloaded using *qtu*
	qtp Flip the *enabled/disabled* state
Switch images	No

41.262 qts

Format	*qts*
Arguments	None
Output values	None
Image type	Any
Function	Operate in *Stack Mode*

Remarks

In *Stack Mode*, the user prompt is changed to

QT:

All standard QT commands (i.e., those available in *Terminal Mode* and listed by the *hlp* command) are executed as normal and the current image is then pushed onto the image stack

To exit *Stack Mode* and re-enter *Terminal Mode*, type any one of the following:

stop, *end*, *quit*, *exit*, *halt*

The image stack is implemented using a series of TIFF image files called

stack_image(*0*).*tif*, *stack_image*(*1*).*tif*, . . ., *stack_image*(*stack_size*).*tif*

(The stack size (variable *stack_size*) is initialised in *qtstart*.) These images are stored in folder *QT_work_file*s and together form what is called the *stack array*. The top of the stack is indicated by the global variable *stack_pointer* The file

stack_image(*stack_pointer*).*tif*

is therefore the top of the stack. When the current image is pushed onto the stack (command *push*), the following actions happen:

(i) The variable *stack_pointer* is incremented by 1, modulo *stack_size*

(ii) The current image is copied to file *stack_image*(*stack_pointer*).*tif*

No other files in the stack array are changed. When the stack is popped, the following actions result:

(i) The variable *stack_pointer* is decremented by 1, modulo *stack_size*

(ii) File *stack_image*(*stack_pointer*).*tif* is copied into the current image. Hence, it is usually possible to recover an image that was recently held at the top of the stack, if we simply decrement *stack_pointer* by, modulo *stack_size*. This is the basis of the command *uds*. (This facility is useful, if the user has been too enthusiastic in the use of the command *b*. See table below.) The best way to understand the stack operators is to enter Stack Mode (*qts*), then use *rsk*. This fills the stack with a random selection of standard QT images and displays part of the stack. Then, experiment with *pop*, *push*, *uds*, *rsi*, *f* and *b*.

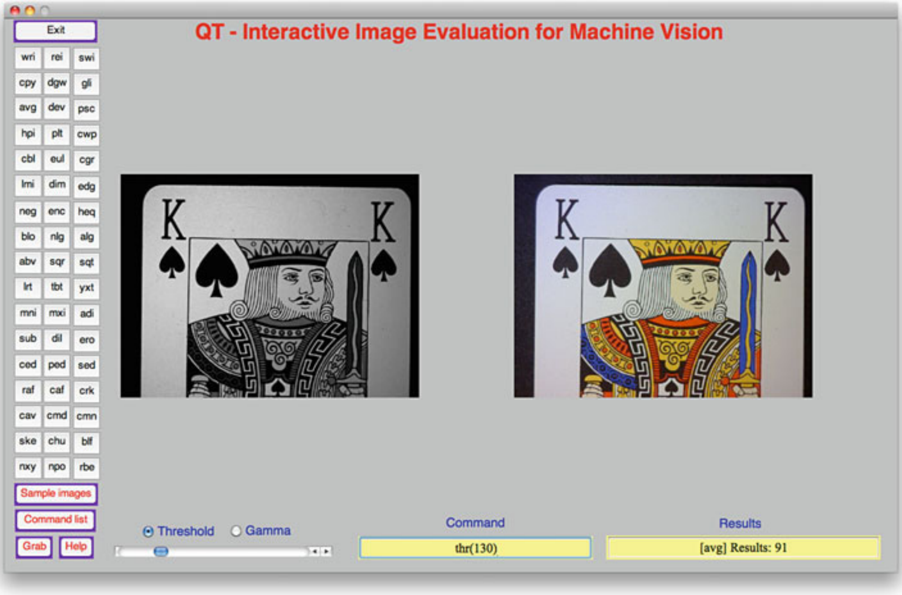
Secondary Commands, implemented by qts

These commands are valid only in *Stack Mode* (i.e., after typing *qts.*) The behaviour of some standard QT commands is slightly different in *Stack* and *Terminal Modes.* (Indicated by '∗')

Command	Function
end∗	Exit *Stack Mode*; return to *Terminal Mode*
exit	
stop	
quit∗	
halt	
qt(*l*)∗	Enter Window Mode
spon	Stack enabled
spof	Stack disabled
sdon	Stack display on
sdof	Stack display off
Null (*CR only*)	Interchange current and alternate images
pop	Pop the image stack
b	Rotate the stack array back one step
c	Grab an image
f	Rotate the stack array forward one step
h	Help: display command list
r	Read image from temporary file (See command 'w')
s	Read same standard QT image as the last time *rni* was used
t	Get image from the top of the stack but do not alter the stack
w	Write image to a temporary file (See command 'r')
z	Interchange current and alternate images. Stack is not changed
csk∗	Clear the stack. Fill it with images generated by a Gaussian noise source
dtx	Display text ON/OFF
ssk	Show part of the stack array
Other QT commands∗	Execute command as normal, then push current image onto the stack
Failed command	'WARNING: That command was not recognized – try again'

41.263 qtw

Format	*qtw*
Arguments	None
Output values	None
Image type	Not relevant
Type	System control
Function	Operate in Stack Mode
Switch images	No
Remarks	Provides a convenient frame-work facilitating rapid interactive image processing and is particularly helpful for training inexperienced users. Many popular functions can be run, simply by clicking on labelled buttons. A command-line interface and slider control of threshold and gamma correction are included



QT - Interactive Image Evaluation for Machine Vision

Command: thr(130)

Results: [avg] Results: 91

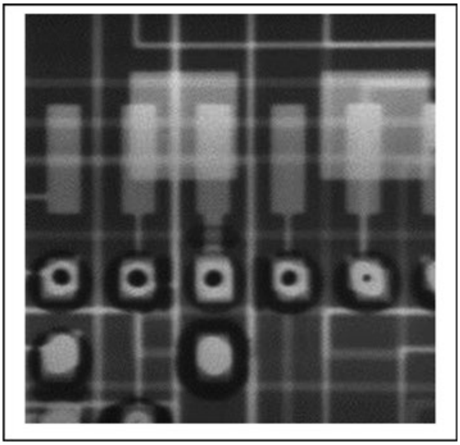
41.264 r

Format	$r(a)$
Function	Read an image from the image stack
Arguments	a
Defaults	0
Output values	None
Image type	Any
Type	User interface
Switch images	No
Function	Synonym for *rsi*
Remarks	This function is included simply to improve the effectiveness of the interactive dialogue. Alternatively, click on the appropriate thumbnail in Figure 2

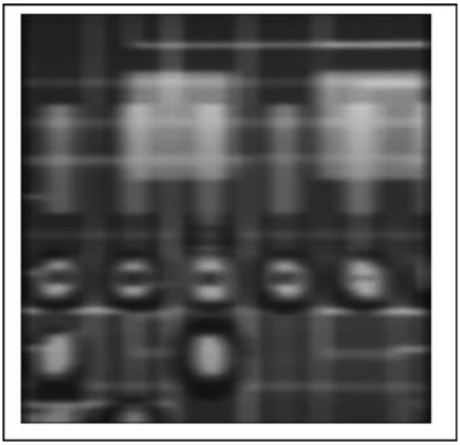
41.265 raf

Format	*raf(a, b)*
Arguments	*a* Filter kernel size, horizontal *b* Filter kernel size, vertical
Defaults	No arguments $a = 3$ $b = 3$ Single argument $b = a$
Output values	None
Image type	Grey
Type	Linear filter
Function	Local averaging within a rectangular window of size a × b pixels
Definition	For $a = b = 3$: $C(i, j) \Leftarrow [A(i-1, j-1) + A(i-1, j) + A(i-1, j+1) + A(i, j-1),+A(i, j) + A(a, j\ \ +1)+ A(i+1, j-1) + A(i+1, j) + A(i+1, j+1)]/9$
Switch images	Yes
Typical uses	Reducing the effects of noise Low-pass filtering an image, prior to subtracting the original, as part of a high-pass filter
Remarks	Both horizontal and vertical edges are blurred. The effect is most pronounced if *a* and/or *b* are large
Illustration	
Input image	Printed circuit board
File number	135
Command	*raf(15, 3)*
Remark	Vertical edges are blurred more than horizontal edges by this filter

Left: original



Right: after processing



41.266 rbe

Format *rbe*(*a*, *b*)

Arguments *a* If *a* = 0, remove blobs touching all 4 sides, otherwise remove blobs on 2 sides

b Connectivity (*b* = 4 or 8)

Defaults *a* 0

b 8

Output values None

Image type Binary

Type Binary image transform

Function Remove *b*-connected blobs (*b* = 4 or 8) that touch the edge of the current image

Definition If *a* = 0, remove all blobs that touch any of the 4 sides of the image

Otherwise, remove all blobs that touch either the left- or top-side of the image

In both cases, a blob can be defined in terms of 4- or 8-connectivity

Switch images Yes

Typical uses Analysing population density, size and shape of granular objects, such as seeds

Remarks To understand the importance of this function, imagine that the camera is viewing a small part of a larger field of uniformly scattered particles that do not touch or overlap (The image of rice grains below is one such example.) Some of the particles are only visible in part. Removing those blobs that touch the edge of the image, improves the accuracy of blob statistics as estimates of the characteristics of the overall population of physical objects. This remark applies to measurements such as area, size, eccentricity, solidity: functions *aeb*, *bpa*, *cab*, *cxa*, *eab*, *eqd*, *ext*, *oab* and *sly*.

In order to measure particle density accurately, *rbe*(*1*) is useful, since it eliminates those blobs that touch only two sides of the image (left or top)

Illustration

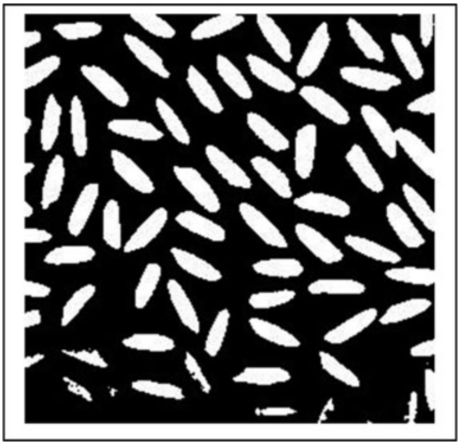
Input image Grains of rice, after thresholding

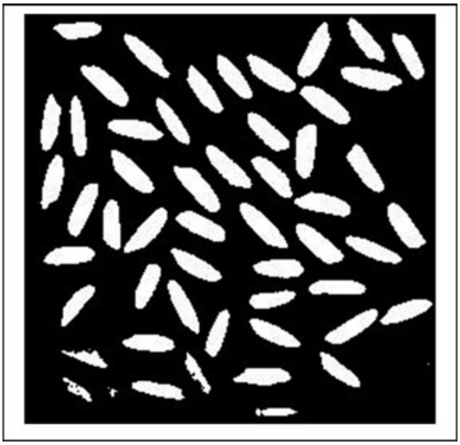
Image generation *rni*(*3*), *enc*, *thr*

Command Removing blobs from all four sides: *rbe* or *rbe*(*0*, *8*)

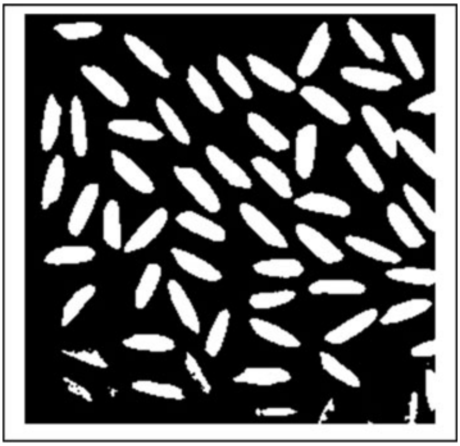
Removing blobs from only 2 sides: *rbe*(*1*) or *rbe*(*1*, *8*)

Top-left: original image *Top-right*: after *rbe*





Bottom: after *rbe*(*1*)



41.267 rbi

Format	*rbi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Input/output
Function	Restore the current and alternate images from files placed on the disc by *sbi*
Switch images	No
Typical uses	Switching to a new application study temporarily without losing image data from the previous one
Remarks	The current and alternate image files can conveniently be stored on disc using *wbi*

41.268 rcf

Format *rcf*(*a*)

Arguments *a* Weight vector, 9 elements

Defaults None

Output values None

Image type Grey

Type Non-linear filter

Function Rank convolution filter, operating on a 3∗3 window

Description Similar to *con*, except that the intensities are sorted in rank order before weighting and adding

Definition Consider the point (i, j). The nine intensity values within its 3 × 3 neighbourhood are found and then sorted in rank order. These are then multiplied by the weights defined by the rescaled input vector *a* and are then summed. (Rescaling and the addition of the constant *k2* are performed so that the computed intensity values are normalised to lie within the range [0, 255].) Edge effects are removed by masking around the border of the image

Switch images Yes

Typical uses Edge detection. Noise reduction

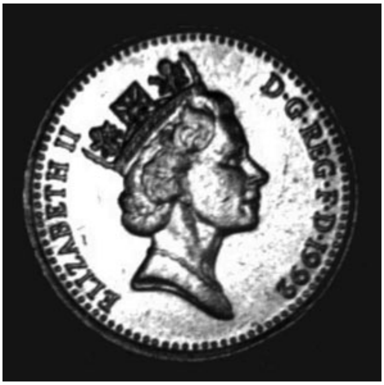
Remarks A range of operations similar to those performed by other QT functions can be achieved by *rcf*:

Weight matrix	Operation	Approximate QT equivalent
[1, 0, 0, 0, 0, 0, 0, 0, −1]	Edge detector	*lnb, wri, swi, snb, rei, sub*
[3, 2, 1, 0, 0, 0, −1, −2, −3]	Edge detector	No simple command sequence
[0,−1,−2,−1, 0, 1, 2, 1, 0]	Edge detector	No simple command sequence
[0, 0, 0, 0, 1, 0, 0, 0, 0]	Median filter	*mdf*(3)
[0, 0, 1, 2, 3, 2, 1, 0, 0]	Attenuate noise	*mdf*
[−1, 0, 0, 0, 3, 0, 0, 0, −1]	Sharpen	*shp*
[1, 2, 3, 4, 5, 4, 3, 2, 1]	Hybrid: low pass filter and median filter	No simple command sequence
[−1, 0, 0, 0, 2, 0, 0, 0, −1]	Approx. to second derivative	*lpc*

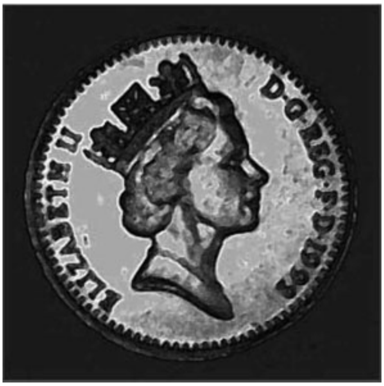
Illustration

Input image	Coin
File number	23

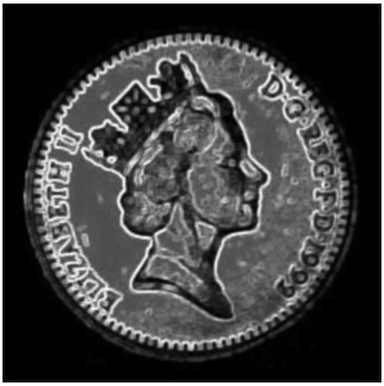
Top-left: original



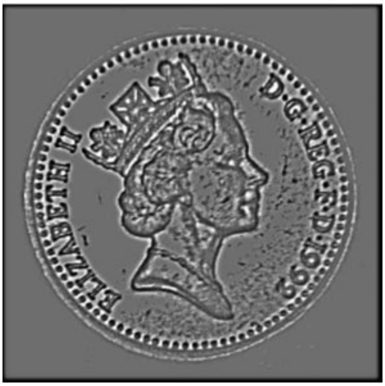
Top-right: after *rcf*([*1, 0, 0, 0, 3, 0, 0, 0, −1*]), *enc*



Bottom-left: after *rcf*([*0,−1,−2,−1, 0, 1, 2, 1, 0*]), *enc*



Bottom-right: high-pass filter; *rcf*([*1, 2, 3, 4, 5, 4, 3, 2, 1*]) applied 5 times then subtract original and enhance contrast (*enc*)



41.269 rci

Format	*rci*(*a*)
Arguments	*a* File number
Defaults	None
Output values	None
Image type	Colour image file
Type	Input/output
Function	Read a colour image file, defined by its number; do not convert it to grey-scale format
Remarks	This command is used to read one of the standard colour numbered images, held in a folder called QT_images. This folder must be located on MATLAB's search path. Also see *rni*

41.270 rdc

Format $[p, q] = rdc$

Arguments None

Output values p Vector of radial distance values, measured from the centroid
q Vector of circumferential distances, estimated from the chain code

Image type Binary

Type Image coding

Function Select the biggest blob and fill any lakes. Then, perform a raster scan, to find the top-left white pixel. Starting at this point, trace the outer edge. For each pixel on the edge, measure:
(a) The distance from the centroid of the blob (array p)
(b) The distance around the circumference. This distance is estimated from the chain code by counting 1 for each even-numbered chain-code element and √2 for each odd-numbered element.

Switch images No

Typical uses Determining the orientation of objects that do not have strong limb-like features and are not obviously elongated.

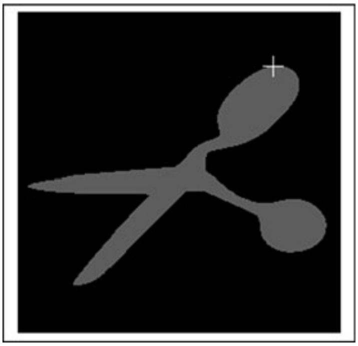
Remarks This function provides a periodic, single-valued representation of an edge contour. The output vectors p and q describe one cycle. Vector p measures distances from the centroid at a series of non-uniformly spaced points. Their positions around the edge of the blob is described by the output vector q. Hence, direct comparison of two p vectors is not possible and interpolation must be used first, to obtain homogenous sampling. To match two binary objects and compare the orientation of one to the other, we can use cross-correlation, after the sampling intervals have been homogenised. This is useful for shapes that have no obvious 'long axis', or possess distinctive features such as sharp corners, elongated limbs, well-defined and easily identifiable concavities, etc.

Illustration

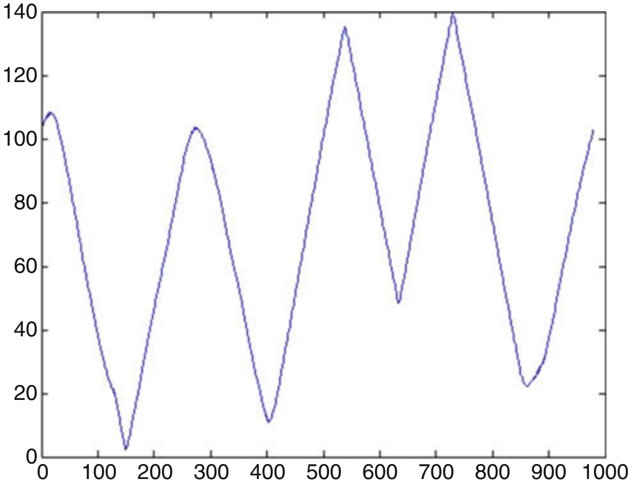
Image generation *rni(49), thr, blf*

Plotting: Linear: $[a, b] = rdc$; $plot(b, a)$
Polar: $[a, b] = rdc$; $b = 2*pi*b/max(b)$, $polar(b, a)$

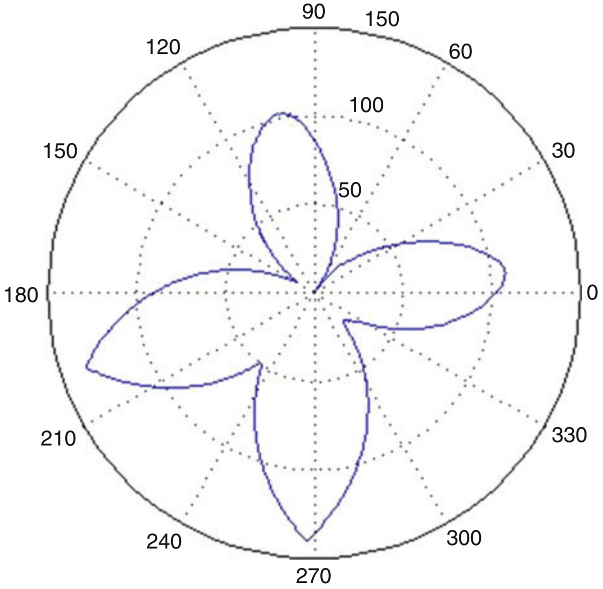
Top: original (The white cross indicates the starting position for the edge follower)



Centre: linear plot (Abscissa: circumferential distance. Ordinate: radial distance)



Bottom: polar plot (Angle: circumferential distance. Radius: radial distance)



41.271 rdf

Format *rdf*(*a*, *b*, *c*)

Arguments *a* Width of the filter window

b Height of the filter window

c Rank order of the two intensity values to be subtracted

Defaults Two arguments *(a, c)* supplied: The filter window is a square of size *a* × *a* pixels; *rdf*(*a*, *c*) has the same effect as *rdf*(*a*, *a*, *c*)

Output values None

Image type Grey

Type Monadic

Function The intensity values within each rectangular neighbourhood of size a × b are placed in rank order. The *c*th largest and *c*th smallest values are then subtracted and the resulting intensity scale expanded to improve contrast (using *enc*)

Switch images Yes

Typical uses Edge detection in images where there are no step-like intensity transitions

Remarks When an edge detector is needed for an image with no sharp edges, *rdf* produces better results than operators that always a 3 × 3 window. Notice that *rdf*(*3*, *1*) and *edd*(*2*) produce similar results. Also see *rkf*

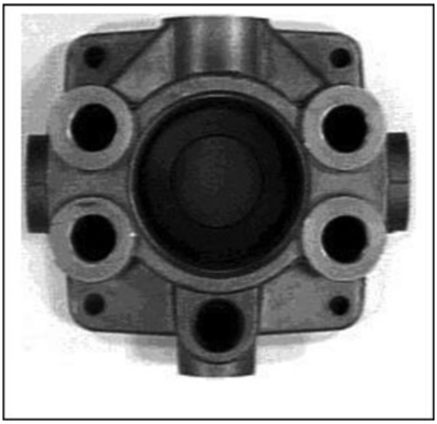
Illustration

Input image Hydraulics manifold

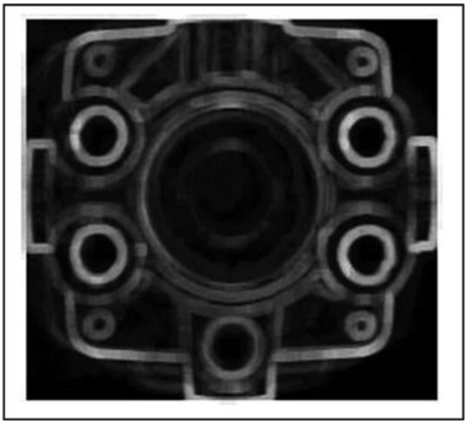
File number 37

Command *rdf*(*7*, *7*, *3*)

Left: original

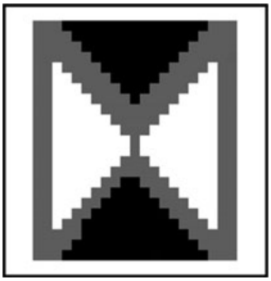


Right: after processing



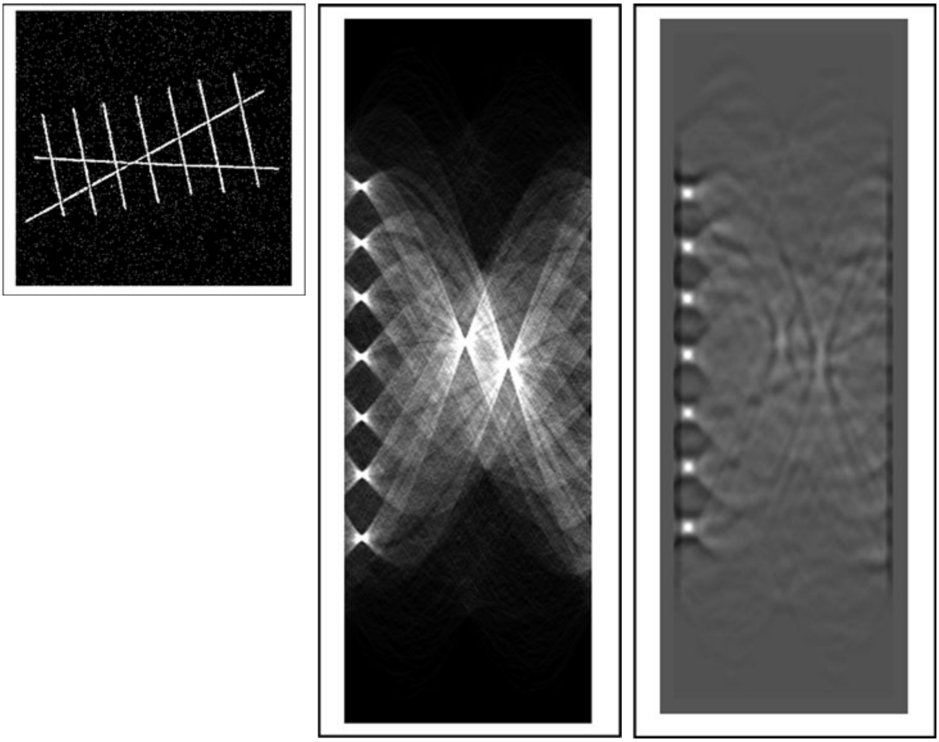
41.272 rdn

Format	*rdn*
Arguments	None
Defaults	None
Output values	None
Image type	Grey scale or binary
Type	Global transform
Switch	Yes
Function	Radon transform
Switch images	Yes
Typical use	Detecting linear streaks in noisy images
Remarks	The Radon transform produces an image (RT) that bears no obvious resemblance to the original; the [X, Y]-coordinates of bright spots in the RT image indicate the orientation and position of lines in the original, respectively. Also see *irt* and *slf*. The X-shaped spots can be detected by applying an appropriate convolution mask to the RT image: *Key*: Black: −1 Grey 0 White +1



Illustration

Input image	Lines, with preprocessing: *crk*(*3*), *enc*, *thr*, *spn*(*0.05*)
File number	158
Command	*rdn*, *wri*, *rni*(*161*), *y* = *round*((*double*(*x*)−*127*)/*127*); *rei*, *con*(*y*)



Left: original *Centre*: after *rdn* *Right*: after *con*(*y*)

41.273 rea

Format	*rea*(*a*)
Arguments	*a* File path name
Defaults	None
Output values	None
Image type	Defined by file that is being read
Type	Input/output
Function	Read an image. If *a* specifies a file containing a colour image, it is converted to grey scale. The image may be stored in a variety of formats, including BMP, JPEG, GIF, PNG and TIFF (Consult the MatLab documentation for *imread*)
Remarks	This function is not so easy to use as *rei* but it is much more versatile. Also see *rni*

41.274 red

See *sed*. (*red* is equivalent to *sed*(*2*))

41.275 rei

Format	$d = rei(a, b)$	
Arguments	*a*	File name/number
	b	0, read image previously saved in TIFF file, or 1, read image previously saved in JPEG file
Defaults	*a*	0
	b	0, read image previously saved in TIFF file
Output values	*d*	File path
Image type	Defined by file that is being read	
Type	Input/output	
Function	Read an image saved previously, in either TIFF (if $b = 0$) or JPEG format ($b = 1$), using *wri*	
Remarks	This function simply build the path name (See *wri*) and then calls *rea*. Also see *rni*	

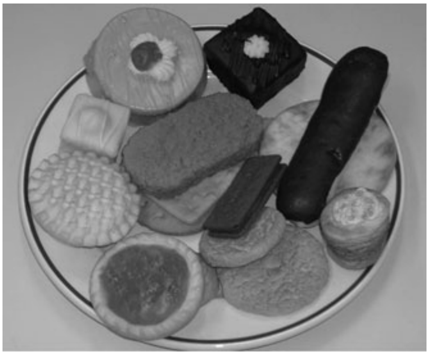
41.276 rev

Format	*function rev*
Arguments	None
Output values	None
Image type	Grey (Colour images can also be processed using pci)
Function	Bit reversal. For each intensity value, the bit order is reversed, so that the Most Significant BIT (MSB) becomes the Least Significant Bit (LSB) and the LSB becomes the MSB
Switch images	Yes
Typical uses	Obscuring the content of an image
Remarks	The function is exactly reversible; *rev*, *rev* reproduces the input image with no loss of information. An observer may be able to discern some gross structure in the output image but small features are not visible. To operate on a colour image, use *pci*(‘*rev*’)

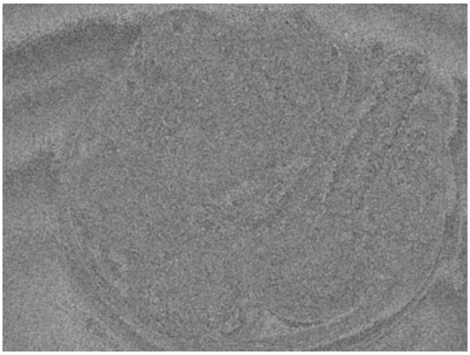
Illustration

Input image	Cakes and biscuits (Actually, these are plastic replica food products)
File number	225
Commands	*rni*(*225*), *rev* (Grey-scale image) *rci*(*225*), *pci*('*rev*') (Colour image)

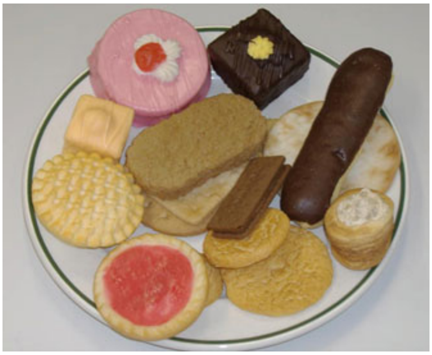
Top-left: original image (grey scale)



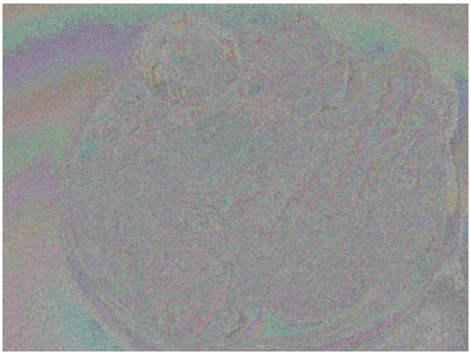
Top-right: after applying *rev*



Bottom-left: original image (colour)



Bottom-right: after applying *pci*('*rev*')



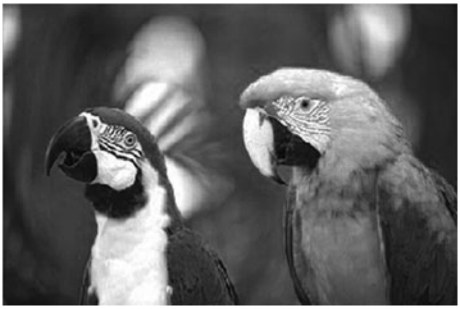
41.277 rgb

Format	*rgb*(*a*)	
Arguments	*a*	Select one of the *R*, *G*, *B* channels
Defaults	*a*	0 (Display *R*, *G* and *B* components separately. Do not alter the current image)
Output values	None	
Image type	Colour	
Type	Image display and channel separation	
Function	$a = 0$:	Separate and display the *R*, *G and B* channels. Do not alter the current image
	$a = 1$:	Set the current image to be equal to the *R*-channel of the colour image
	$a = 2$:	Set the current image to be equal to the *G*-channel
	$a = 3$:	Set the current image to be equal to the *B*-channel
Switch images	$a = 0$,	No
	$a \neq 0$,	Yes
Typical uses	Simplifying colour processing, reduce the problem one involving only grey-scale image processing	
Remarks	*rgb*(*0*) displays the 4 images in Figure 4 which is automatically scaled to fill the screen. Figure 4 closes when the user clicks on it. Also see *hsi*	

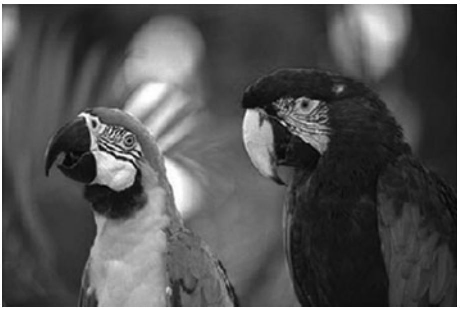
Illustration

Input image	Birds
File number	144
Command	*rgb*

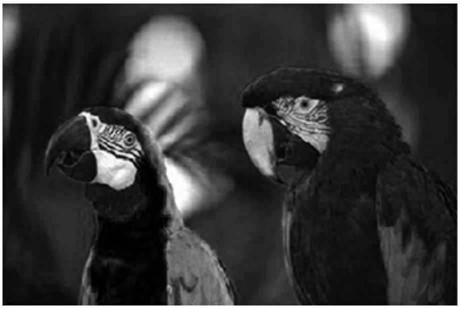
Top-left: *R*-channel



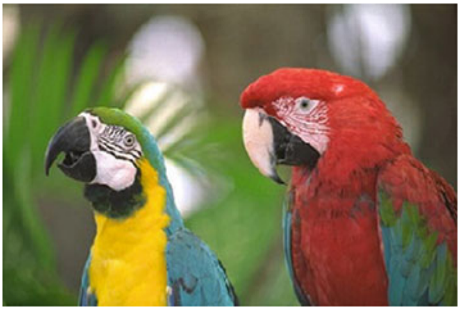
Top-right: *G*-channel



Bottom-left: *B*-channel



Bottom-right: original colour image



41.278 rgb_to_xyz/xyz_to_rgb

Format	$[X, Z] = rgb\_to\_xyz(R, G, B)$	
	$[R, G, B] = xyz\_to\_rgb(X, Z)$	
Arguments	R, G, B	R, G, B colour coordinates
	X, Y, Z	X, Y, Z colour coordinates
Defaults	None	
Output values	*X, Y, Z*	XYZ colour coordinates
	R, G, B	RGB colour coordinates
Image type	Not applicable	
Type	Colour processing	
Function	Convert colour coordinates RGB to/from XYZ	
Switch images	No	
Illustration		
Input image	plug	
File number	112	
Command	*thr*(*115*)	

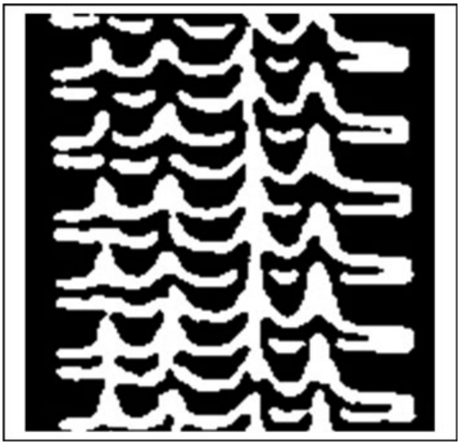
41.279 rim

Format	*rim*(*a*)	
Arguments	*a*	File name/number
Defaults	*a*	0 (zero)
Output values	None	
Type	Input/output	
Switch images	Yes	
Function	Read an image from the QT_images folder. The image may be nominated by a string, or using a numeric argument. The image may be coded in JPEG (file extension *jpg*) or TIFF (file extension *tif* or *tiff*) format	
Remarks	Also see *rea*, *rni*, *rci*, *gwi* and *wri*	

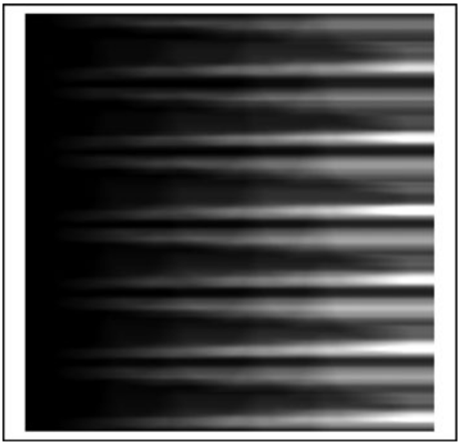
41.280 rin/cin

Formats	*rin* *cin*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Global
Function	Row/column integrate
Definition	rox: $C(i, j) \Leftarrow (C(i-1, j) + A(i, j))/N$, where $C(1, j) = A(1, j)$ (N is the image width) cox: $C(i, j) \Leftarrow (C(i, j-1) + A(i, j))/N$, where $C(i, 1) = A(i, 1)$ (N is the image width)
Switch images	Yes
Typical uses	Detecting linear horizontal/vertical features. The illustration below shows how *rin* and *cin* may be used to locate the 'feathering' on a certain type of cake decoration
Remarks	Also see *rdn*
Illustration	
Input image	Cake decoration pattern
File number	54 (cropped)
Command	*rin/cin*

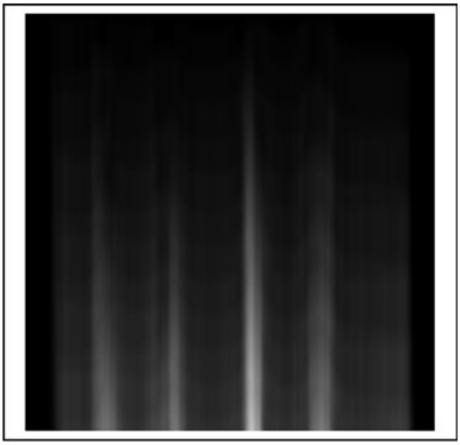
Top-left: original



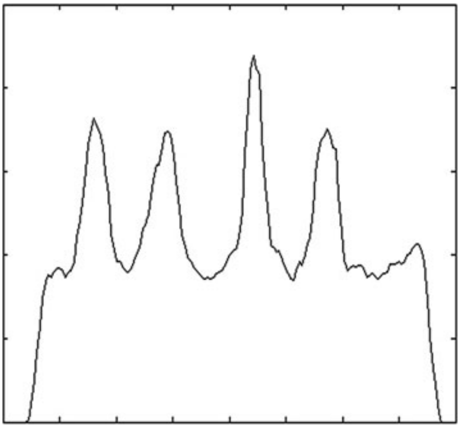
Top-right: *rin*



Bottom-left: *cin*



Bottom-right: intensity profile: *cin*, *yxt*, *csh*, *yxt*, *plt*



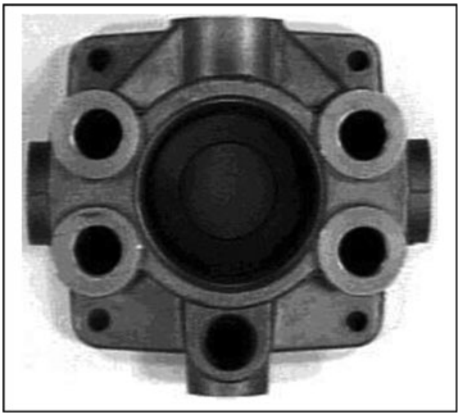
41.281 rkf

Format	*rkf*(*a*, *b*, *c*)	
Arguments	*a*	Width of the filter window
	b	Height of the filter window
	c	Rank order of the intensity value to be selected
Defaults	Two arguments *(a, c)* supplied: The filter window is a square of size *a* × *a* pixels	
Output values	None	
Image type	Grey	
Type	Monadic	
Function	The intensity values within each rectangular neighbourhood of size a × b are placed in rank order. The *c* th largest is then selected as the value for the pixel at the centre of that window	
Switch images	Yes	
Typical uses	Noise reduction	
Remarks	*rkf* is able to emulate *mdf*, *lnb*, *snb*, *dil and ero* and is less sensitive to noise than these other operators. Also see *nrf*, *mdf* and *rdf*	

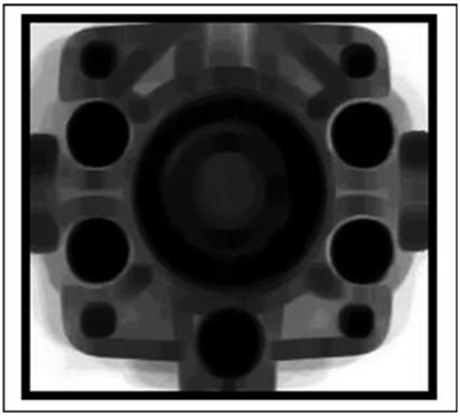
Illustration

Input image	Hydraulics manifold
File number	37
Command	*rkf*(*11*, *11*, *7*)

Left: original



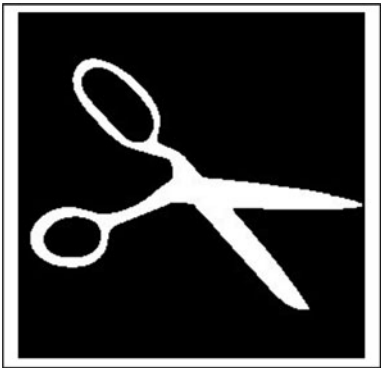
Right: after processing



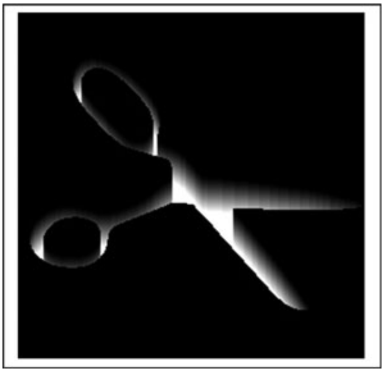
41.282 rlc/rlr

Format	*rlc* *rlr*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Switch	Yes
Function	Run-length code along the columns/rows
Switch images	Yes
Typical uses	Blob-shape analysis
Illustration	
Input image	Scissors
File number	48
Command	*rlc/rlr*

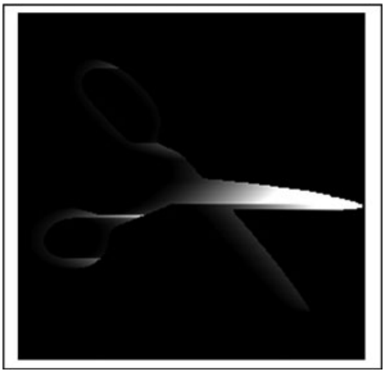
Top-left: original



Top-right: *rlc*



Bottom: *rlr*



41.283 rlr

See rlc.

41.284 rmn

See *rmx*.

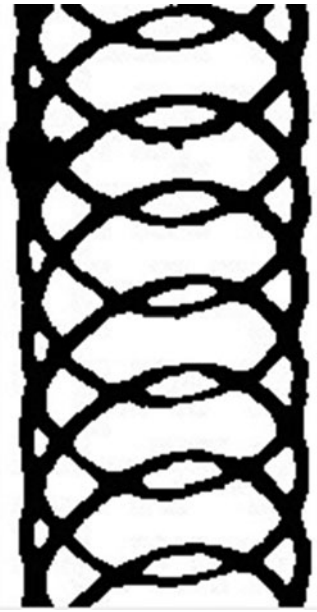
41.285 rmx/rmn

Format	*rmx* *rmn*
Arguments	None
Output values	None
Image type	Grey-scale
Type	Grey-scale image analysis
Function	Find the regional maxima/minima of the intensity function
Switch images	Yes
Typical uses	Analysing textured surfaces and images of granular material
Remarks	*rmx* can be used to analyse binary images, by applying *rmx* to the output of a suitable operator, such as the grass-fire transform (*gft*). *gft*, *rmx* provides an approximation to reversing the watershed function (*wsh*)

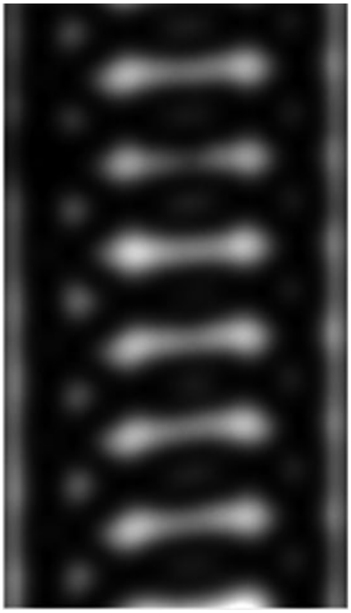
Illustration

Input image	Cake decoration pattern
File number	55
Commands	*rni*(*55*), *thr*, *neg*, *thn*, *neg*, *gft*, *enc*, *caf*(*3*), *rmx*, *shk*, *crs*(*3*), *rni*(*55*), *mxi*

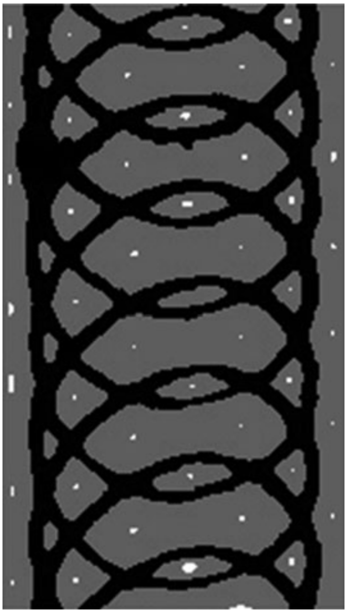
Top-left: original image



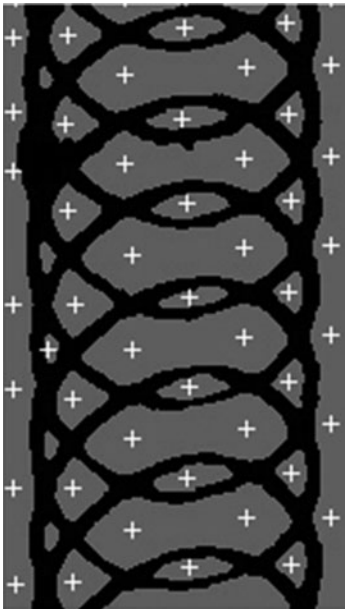
Top-right: after *gft*



Bottom-left: after *rmx*



Bottom-right: after mxi



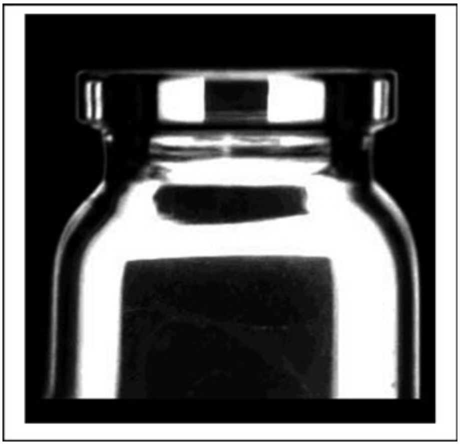
41.286 rni

Format	*rni*(*a*)
Arguments	*a* File number
Defaults	None
Output values	*None*
Image type	Colour or grey scale image file can be read. Colour images are converted to grey
Type	Input/output
Function	Read one of QT's standard images, defined by its number and stored locally in a folder called QT_images (This must be on MATLAB's search path)
Remarks	This function reads JPEG and TIFF images, which may be colour or monochrome. Also see *rci*, *rea*, *rei*, *img*, *gwi*

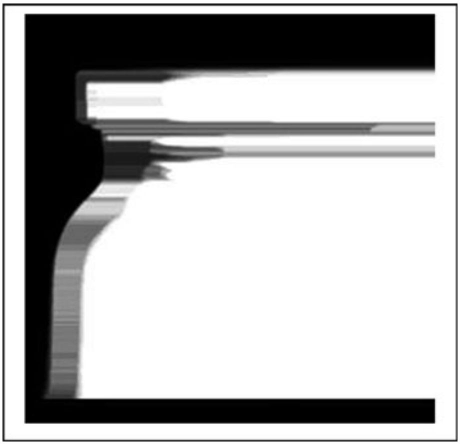
41.287 rox/cox

Formats	*rox* *cox*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Global
Function	Row/column maximum
Definition	rox: $C(i, j) \Leftarrow MAX(C(i-1, j), A(i, j))$, where $C(1, j) = A(1, j)$ cox: $C(i, j) \Leftarrow MAX(C(i, j-1), A(i, j))$, where $C(i, 1) = A(i, 1)$
Switch images	Yes
Typical uses	Analysing silhouettes of convex and nearly convex objects, such as bottles and coins; use *rox*, *wri*, *swi*, *lrt*, *rox*, *lrt*, *rei*, *mni* to 'fill in' the dark centre of the vial. (See illustration below.) This can lead to a significant reduction in the amount of processing required later
Remarks	The function *cox* is defined here by inter-changing the image axes (*yxt*) and applying *rox*. It is, of course, possible to define *cox* directly, in a similar manner to *rox*. These functions may be regarded as creating shadows of binary objects, with the "illumination" originating at the left (*rox*), or top (*cox*). Also see *rin*/*cin*
Illustration	
Input image	Glass vial
File number	32
Command	*rox/cox*

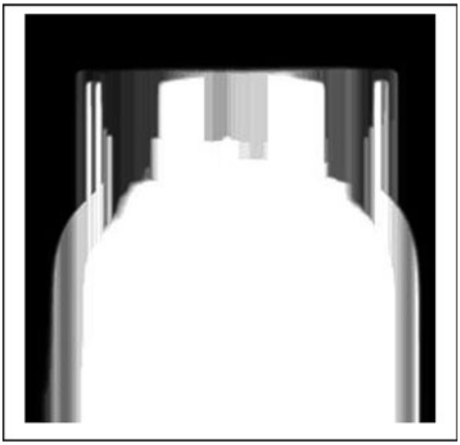
Top-left: original



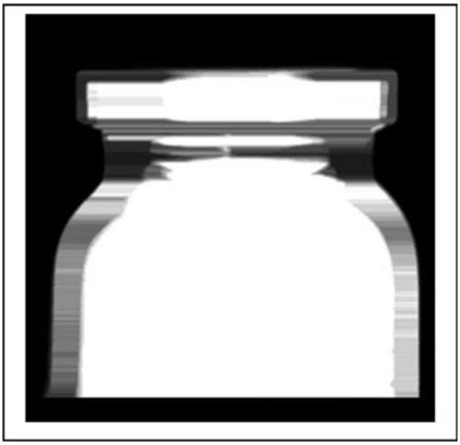
Top-right: *rox*



Bottom-left: *cox*



Bottom-right: after *rox*, *wri*, *swi*, *lrt*, *rox*, *lrt*, *rei*, *mni*



41.288 rsb

See *csh*

41.289 rsf

Format	*rsf*
Arguments	None
Output values	None
Image type	Grey
Type	Image warping
Function	Automatically resize and position the image display windows (Figure 1 and Figure 2) to fit onto the computer screen
Switch images	No
Remarks	The position and size of the Command Window should be adjusted manually

41.290 rsi/wis/interactive reading and writing of images

Format *rsi*(*a*)
wis(*a*)

Arguments *a* Integer in the range [−1, 7]

Defaults *a* 0

Output values None

Image type Any

Type Read/write images

Function *rsi* Read an image from the image stack
wis Write the current image into the image stack

Switch images *rsi* Yes
wis No

Typical uses Storing and retrieving intermediate processing results during an interactive session

Remarks *rsi* and *wis* are used in the same way as *rei* and *wri*, providing random access to nine images stored on disc. The operators *pop* and *push* are disabled. The image stack is used only to provide the visual display, thereby eliminating the need for the user to remember where images are stored. Operators *r* and *w* have the same function as *rsi* and *wis*, respectively. The user can also read/write images by clicking on the appropriate thumbnail while holding the CONTROL key down. The following table summarises these functions. Also see *rni*, *rti*, *rsk* and *ssk*

Writing	Reading	Comments
wri(a)	rei(a)	*Argument a* can be numeric or alpha-numeric string.
wis(a) or w(a)	rsi(a) or r(a)	*a* is numeric Image stack display is updated (*wis* only)
CNTRL/CLICK	CLICK	Interactive writing/reading images Convenient and fast for the user

Screen shot, showing the image stack display (Figure 2) current and alternate images (Figure 1, *left* and *right* respectively) and the command window (right-hand-side).

>> chu
>> adi
>> lnb
>> sub
>> neg
>> thr(200)
>> swi
>> thr(140)
>> |
```

41.291 rsk

Format	*rsk*
Arguments	None
Output values	None
Image type	Any
Type	Stack operator
Function	Fill the image stack with randomly chosen images, selected from those held in the folder QT_images
Switch images	No
Remarks	The main function of this operator is help the user demonstrate how the stack works. To do this, switch to Stack Mode (*qts*), or use *ssk* (stay in Terminal Mode), then observe the stack display (Figure 2), as images are popped (*pop*) and pushed (*push*) onto the stack. Also see *csk*

41.292 rsz

Format	*rsz*(*a*, *b*)	
Arguments	*a*	Width of the output image
	b	Height of the output image
Defaults	No arguments:	$a = b = 512$
	One argument:	$b = a$
Output values	None	
Image type	Any	
Type	Image geometry	
Switch	Yes	
Function	Adjust the size/aspect ratio of the image	
Switch images	Yes	
Typical uses	Adjusting the size or aspect ratio of an image to make subsequent processing faster, or more convenient	
Remarks	The output image can be larger or smaller than the original, along either axis	

Illustration

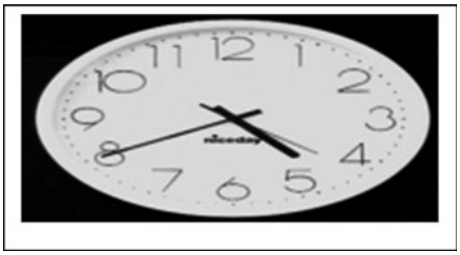
Input image Clock, cropped manually

File number 148

Command *rsz*(*200*, *100*)

Top-left: original

Top-right: after processing



41.293 rti

Format *rti*
Arguments None
Output values None
Image type Any
Type Image display
Function Display the (9) most popular QT test images in the image stack
Switch images No

Typical screen display. *rti* loads images into the stack (9 thumbnails at the bottom). An image can be loaded into the current image, simply by clicking on the appropriate thumbnail.

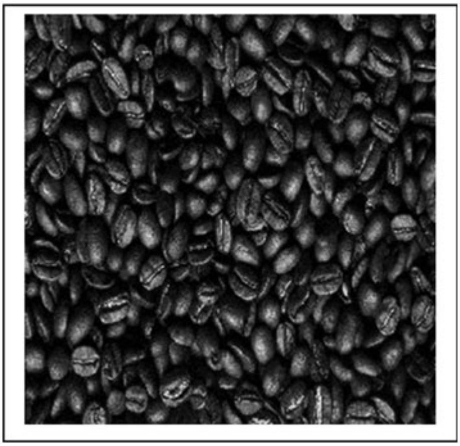
41.294 rxm

Format	*rxm*(*l*, *u*)	
Arguments	*l*	Lower limit
	u	Upper limit
Defaults	*l*	3
	u	5
Output values	None	
Image type	Grey scale	
Type	Image filter	
Function	Relaxed median filter	
Switch images	Yes	
Typical uses	Reducing the effects of camera noise and eliminating fine texture	
Reference	A. Ben Hamza et al, '*Removing Noise and Preserving Details with Relaxed Median Filters*', Journal of Mathematical Imaging and Vision, 11, 161–177, 1999	
Remarks	*rxm* provides a better filter for reducing the effects of impulse noise than does the standard median filter (*mdf*)	

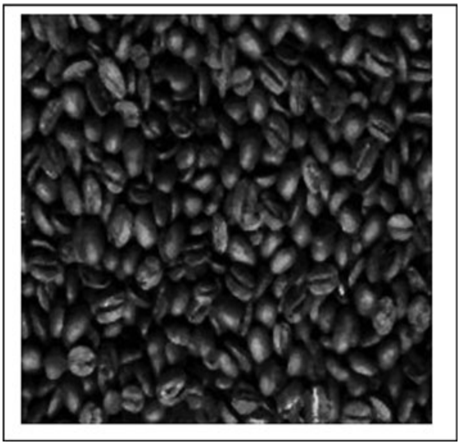
Illustration

Input image	Coffee beans
File number	4
Command	*rxm*(*5*, *11*)

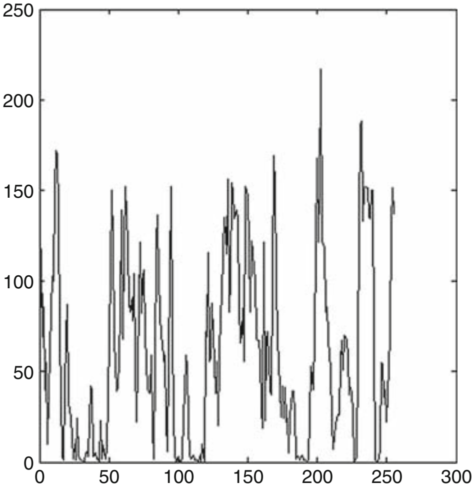
Top-left: original image



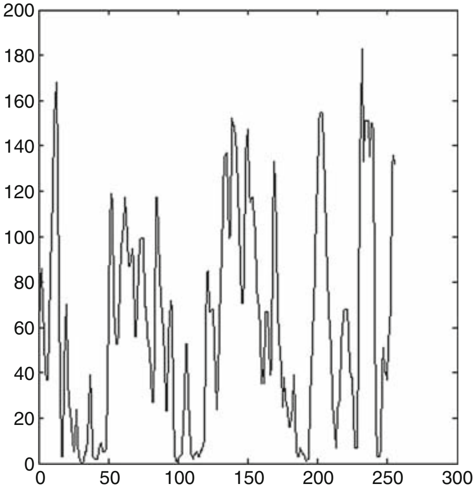
Top-right: after processing



Bottom-left: intensity profile for the original image



Bottom-right: intensity profile after *rmx*(*5*, *11*)



41.295 sai

Format	*a* = *sai*
Arguments	None
Defaults	Not applicable
Output values	*a* Sum of all intensities
Image type	grey scale
Type	Image measurement
Switch	No
Function	Sum the intensities of all pixels
Typical uses	Camera set-up in variable lighting conditions
Remarks	The result from *sai* is the product of that from *avg* (average intensity) times the number of pixels

41.296 sat

See *hsi*

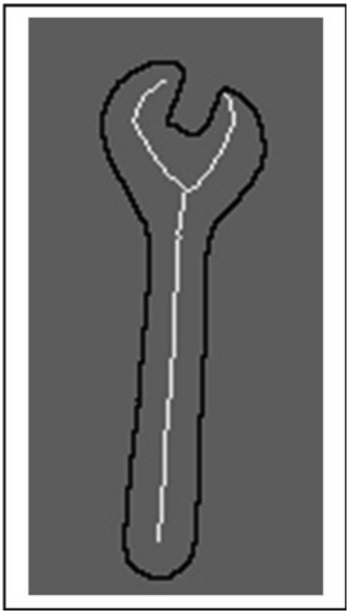
41.297 say

Format	*say*(*a*)
Arguments	*See below*
Defaults	*See below* ‘*You did not tell me what to say*’
Output values	None
Image type	Not relevant
Type	User interface support
Function	Converts a given string (argument *a*) to speech. A verbal warning is given if no string is specified
Switch images	No. Neither image is altered
Typical uses	Verbal feedback provides a good way to follow the execution of a cyclic QT program

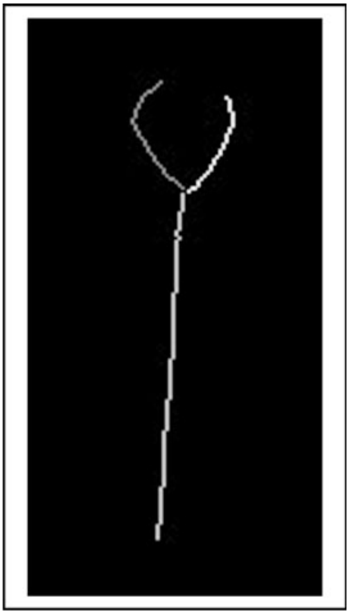
41.298 sbc

Format	*sbc*(*a*)
Arguments	*a* Pixel count
Defaults	*a* 1
Output values	None
Image type	Binary
Type	Blob transform
Switch	Yes
Function	Retain white pixels that have exactly *a* 8-neighbours
Typical uses	Shape analysis
Remarks	*sbc* (or *sbc*(*0*)) finds limb ends in ‘match-stick’ figures (equivalent to *jnt*); *sbc*(*2*) isolates individual limbs (illustrated below); *sbc*(*3*) finds joints (equivalent to *jnt*)
Illustration	
Input images	Four metal parts (file number 46), processed to isolate the spanner (wrench)
Image generation	*crp* (interactive selection of cropping rectangle), *tbt*, *thn*
Commands	*sbc*(*2*), *ndo*, *enc* The last two commands show the results more clearly

Left: binary: original image



Top-right: after processing



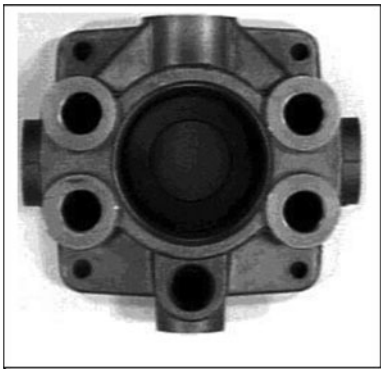
41.299 sbi

Format	*sbi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Input/output
Function	Save both current and alternate images on disc
Switch images	No
Typical uses	Switching to a new application study temporarily without losing image data from the previous one
Remarks	The current and alternate image files can be restored using *rbi*

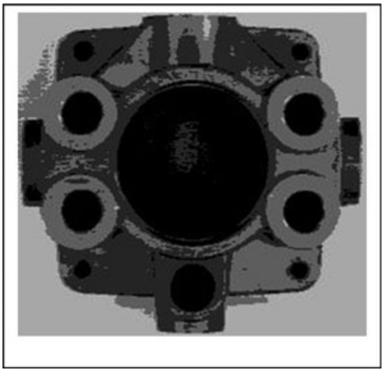
41.300 sca

Format	*sca*(*a*)
Arguments	*a* Number of bits to be retained ($1 \leq a \leq 8$)
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Posterising; reducing the number of bits in the representation of the intensity for each pixel
Definition	Set the (8-*a*) least-significant bits to zero
Switch images	Yes
Typical uses	Plotting intensity contours Reducing the amount of information to be stored
Remarks	Also see *bcl*, *bcp*
Illustration	
Input image	Hydraulics component
File number	37
Command	*sca*(*2*)

Left: original



Right: after processing



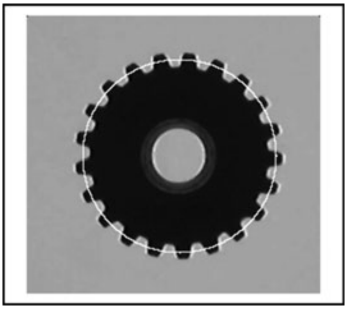
41.301 scc

Format	z = scc(x, y, r)	
Arguments	*x*	X-coordinate of the centre of the scanning circle
	y	Y-coordinate of the centre of the scanning circle
	r	Radius of the scanning circle
Defaults	*None*	
Output values	*z*	Vector containing 360 intensity values
Image type	Grey	
Type	Image analysis	
Switch	No	
Function	Circle-scan; sample the intensities uniformly around the circle centred on (*x*, *y*) and of radius *r*	
Typical uses	Reducing processing time, by converting a 2D image into 1D vector. Determining periodicity in known directions	
Remarks	The intensity is sampled at 1° intervals. Hence the output vector (*z*) has 360 elements. These elements are equal to −1, if the sample point is outside the image	

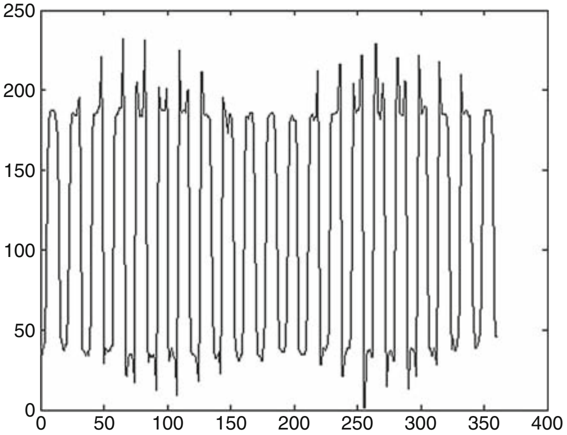
Illustration

Input image	Gear with median filtering to reduce noise effects
File number	171
Command	rni(171), *mdf*, *x* = *scc*(*129*, *119*, *81*), *figure*(*2*), *plot*(*x*), *figure*(*1*), *cir*(*129*, *119*, *81*, *255*)

Left: original with scan circle superimposed by *cir* (The circle parameters were defined manually)



Right: after *plot*(*z*) Horizontal axis, scan angle. Vertical axis, intensity



41.302 sci

Format	*sci*(*a*)
Arguments	*a* New intensity value
Defaults	*a* 0 (black)
Output values	None
Image type	Binary
Type	Drawing
Switch	Yes
Function	Set all pixels to a given intensity value (*a*). C(i, j) ⇐ a
Switch images	Yes
Typical uses	*sci* and *zer* are both used extensively in a wide variety of situations
Remarks	*zer* is equivalent to *sci*(*0*)

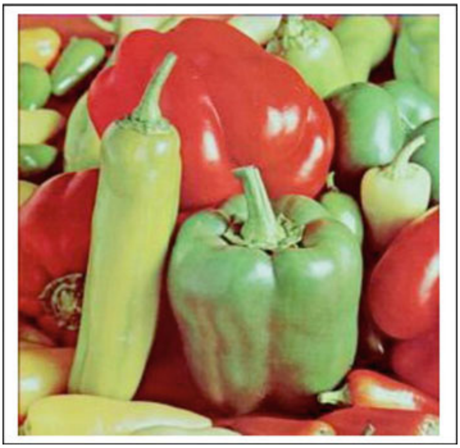
41.303 scp

Format	*scp*
Arguments	None
Output values	None
Image type	Colour
Type	Analysing colour images
Function	The user is invited to define a polygonal mask region within a colour image. Then, QT extracts the RGB values for all pixels within that region and plots them in 3D space
Switch images	Yes
Typical uses	Analysing colour images, particularly when building colour recognition systems
Remarks	See *shs* and *pcf*. The user can ‘fly around’ the cloud of points in the RGB scattergram, to obtain a variety of views and thereby gain an improved understanding of the structure of the cluster(s)

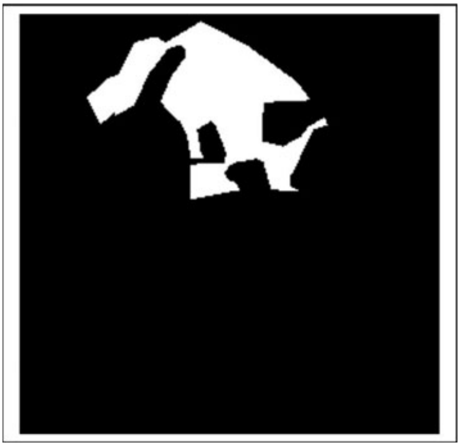
Illustration

Input image	peppers
File number	73
Command	*scp*

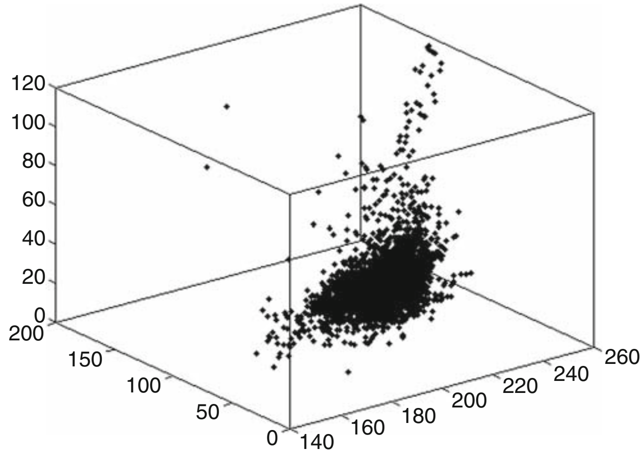
Left: *original*



Right: *polygonal mask drawn by the author*



Bottom: scattergram of RGB values found within the polygonal mask region



41.304 scr/usc

Format *scr*(*p*)
usc(*p*)

Arguments *p* New image size(after normalising to produce a square image)

Defaults 512

Output values None

Image type Grey scale

Type Image scrambling

Function *scr*: Scramble the input image by following the Hilbert curve
usc: Reverse the scrambling performed by *scr*

Switch images Yes but the picture displayed in the Alternate Image is reformatted to be square and of size $2^{\mathrm{m}} \times 2^{\mathrm{m}}$, where m is an integer and is equal to $\lceil log_2(p) \rceil$

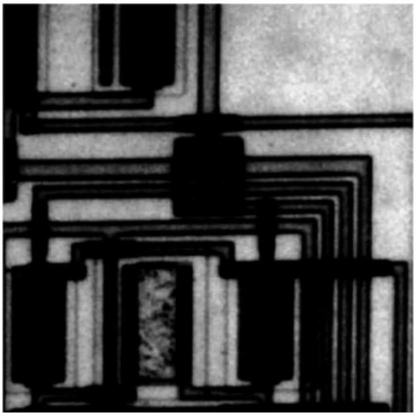
Remarks Also see *rev* and *hbt*. It is also possible to scramble the image using *usc* and then reverse it with *scr*. Notice that [*scr*, *rev*] is reversible, using [*rev*, *usc*]. Further scrambling options can be obtained using *lrt*, *tbt* and *yxt*. For example, the scrambling produced by [*scr*, *scr*, *yxt*, *lrt*, *scr*] can be reversed using [*usc*, *lrt*, *yxt*, *usc*, *usc*] and vice versa. Although not very secure, these coding methods will confuse casual observers. To encode a colour image, using a grey-scale operator, *scramble*, apply *pci(‘scramble’)*

Illustration

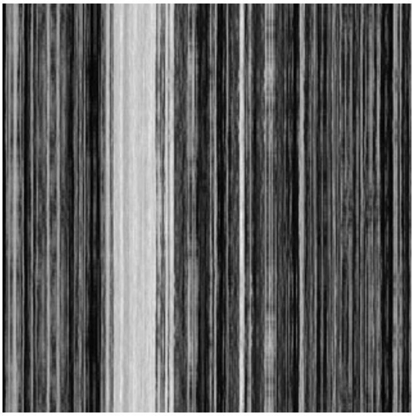
Input image Thick film circuit

File 136

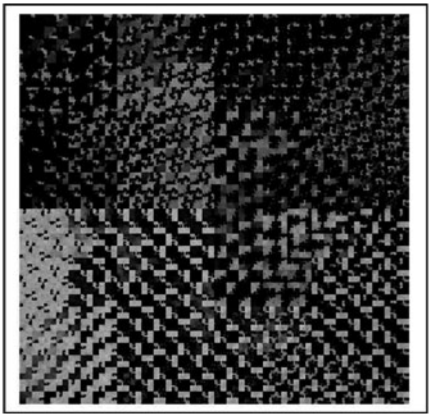
Top-left: original image



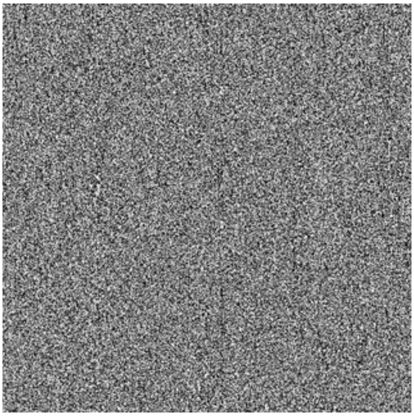
Top-right: after applying *scr*



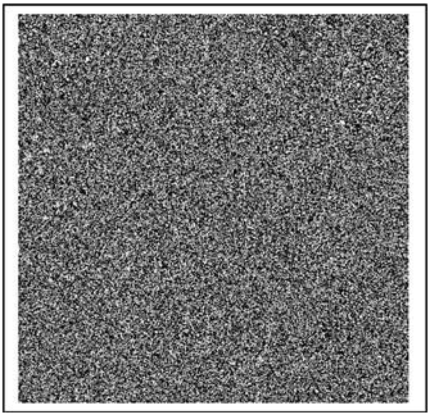
Centre-left: after applying *usc*



Centre-right: after applying *scr*, *rev*



Bottom-left: after *usc*, *rev*



41.305 scv

Format *scv*(*x*, *y*, *r*, *g*, *b*)

Arguments *x* *X*-address of the pixel to be accessed

y *Y*-address of the pixel to be accessed

r *R*-channel value

g *G*-channel value

b *B*-channel value

Defaults None

Output values None

Image type Any

Type Accessing individual pixels

Function Set the RGB values at point [*r*, *g*, *b*] in the current image to [*r*, *g*, *b*].

Switch images Yes

Typical uses Annotating images; placing points at critical features for display purposes. Testing image processing operators

Remarks Use *scv*, rather than accessing individual pixels of the current image directly, since it follows the QT convention that the x-address precedes the y-address. It also avoids the need to define the current image as *global* via the Command Window. Also see *ccv* and *siv*

41.306 sdm

Format $d = sdm(a, b, c)$

Arguments a Maximum X-shift

b Maximum Y-shift

c Incremental shift in the x and y directions

Defaults None

Output values d Grey-level spatial dependency matrix (SDM)

Image type Grey-scale image analysis

Type Global transform

Function Calculate the grey-level spatial dependency matrix (SDM). Steps:

(i) Let $S = \{[mc, nc] \mid 0 \leq mc < \mathrm{a}, 0 \leq nc < b\}$ (N.B. m and n are integers)

(ii) Choose an element $[X, Y]$ from S

(iii) Shift the image by an amount $[X, Y]$

(iv) Cross-correlate the shifted image with the original. The correlation score is held in $d(m, n)$

(v) Repeat steps (ii) – (iv) for all members of set S

Switch images Yes

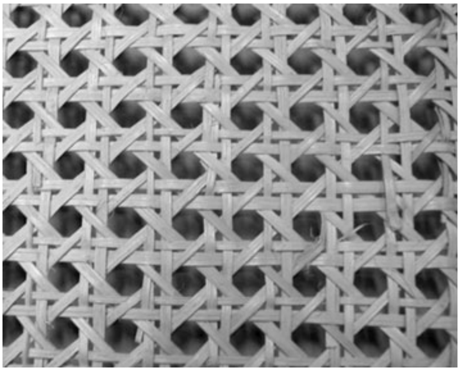
Typical use Describing texture and other images containing nearly periodic structures

Remarks In the illustration below, the periodic structure of the lattice is evident from the extended SDM. However, it is normal to calculate the SDM with image shifts that are smaller than the period. The SDM may be presented to a pattern classifier to obtain a decision about the nature/identity of the texture

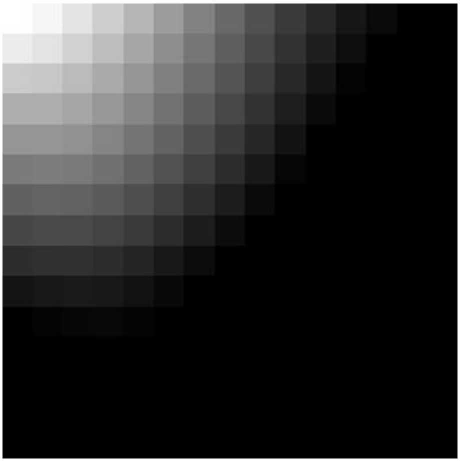
Illustration

Input image	Woven lattice of split cane
File number	239
Commands	*x* = *sdm*(*50*, *50*, *2*); *y* = *uint8*(*255∗x*) (This represents the SDM as an image)

Top: original image



Bottom-left: SDM represented as an image array



Bottom-right: Extended SDM (sampled) shows the periodic nature of the image

41.307 seb

Format [*x*, *y*, *z*] = *seb*(*s*)

Arguments *s* Scaling factor

Defaults *s* Chosen automatically, to maximise use of intensity scale

Output values *x* Vector containing the X-coordinates of edge pixels

y Vector containing the Y-coordinates of edge pixels

z Vector containing the chain code value for each edge pixel (See *fcc*)

Image type Binary

Type Blob transform

Function Shade the outer edge of a blob according to the distance travelled around its circumference. The starting point is the top-left-most, non-black pixel. The edge follower travels in a clock-wise direction. The edges of any lakes are ignored

Switch images Yes

Typical uses Analysing blob shape, by relating points of high curvature (corners detected using *cnr* or *hcd*) to circumferential position

Remarks A single blob can be processed using *seb*. If any other blobs are present, the result is an error. Other blobs and any lakes must analysed separately. Also see *fcc*

Illustration

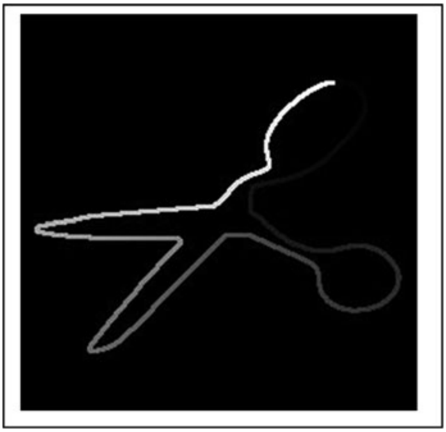
Input image Scissors

File number 49

Command *seb*, *lnb* (*ln*b broadens the edge contour, making it easier to see)

Left: original

Right: after processing



41.308 sed

Format	*sed*(*a*)	
Arguments	*a*	Function selector ($0 \leq a \leq 4$)
Defaults	*a*	0
Output values	None	
Image type	Grey	
Type	Edge detector	
Function	Sobel and similar edge detectors	

Definitions

sed(*0*)

$$C(i, j) = [\ |A(i-1, j-1) + 2A(a, j-1) + A(i+1, j-1) - A(i-1, j+1) + 2A(i, j+1) + A(i+1, j+1)| + |A(i-1, j-1) + 2A(a-1, j) + A(i-1, j+1) - A(i+1, j-1) + 2A(i+1, j) + A(i+1, j+1)|\ ]/6$$

sed(*1*)

$$C(i, j) = [\ |\ A(i-1, j-1) + A(a, j-1) + A(i+1, j-1) - A(i-1, j+1) + A(i, j+1) + A(i+1, j+1)\ | + |A(i-1, j-1) + A(a-1, j) + A(i-1, j+1) - A(i+1, j-1) + A(i+1, j) + A(i+1, j+1)\ |\ ]/4$$

sed(*2*)

$$C(i, j) = [\ |\ A(i-1, j-1) - A(i+1, j+1)\ | + |\ A(i-1, j+1) - A(i+1, j-1)\ |\ ]/2$$

sed(*3*)

$$C(i, j) = [\ |\ A(a, j-1) - A(i, j+1)\ | + |\ A(a-1, j) - A(i+1, j)\ |\ ]/2$$

sed(*4*)

$$C(i, j) = [\ |\ A(a, j-1) - A(i, j+1)| + |\ A(a-1, j) - A(i+1, j)| + |A(i-1, j-1) - A(i+1, j+1)\ | + |\ A(i-1, j+1) - A(i+1, j-1)\ |\ ]/4$$

Switch images Yes

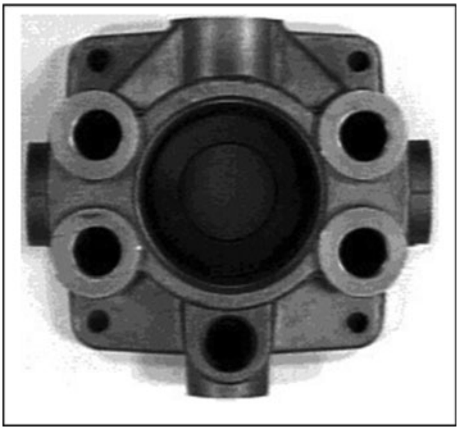
Typical uses Highlighting edges (i.e., regions of large intensity gradient)

Remarks There are many similar operators that differ slightly in their definition and performance. Others can be constructed using different weights for the *con* operator. Notice that line *47* (*adi*) could replaced by *mxi*, to define another set of edge detectors

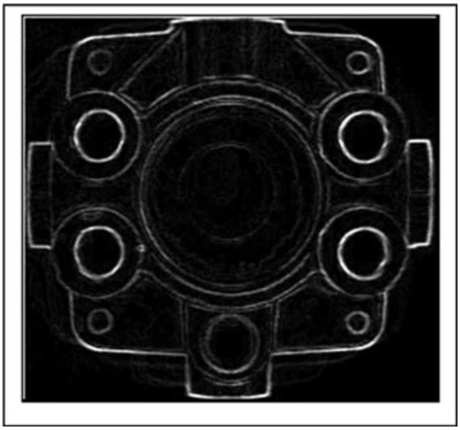
Illustration

Input image	Hydraulics component
File number	37
Command	*sed*(*0*), *enc*

Left: original



Right: after processing



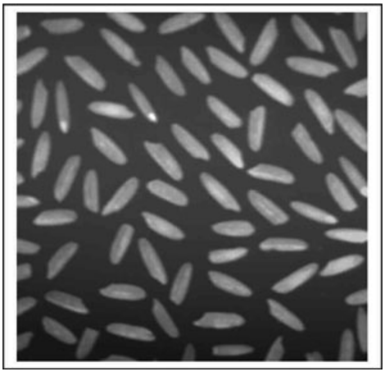
41.309 seg/rbk

Format	c = *seg*(*a*, *b*) *rbk*(*a*)	
Arguments	*a*	Size of structuring element for opening operation
	b	Increment/decrement for thresholding ($-1 \leq b \leq 1$) (*seg* only)
Defaults	*a*	15
	b	0 (seg only)
Output values	c	Threshold parameter (seg only)
Image type	Grey	
Type	Monadic	
Function	(i) Apply opening with a disc-like structuring element of size a (ii) Subtract the original image (iii) Enhance contrast (iv) Threshold using Otsu's method for calculating the threshold parameter (*seg* only)	
Switch images	Yes	
Typical uses	*seg* is used for image segmentation (i.e., isolating an objects of known size from the background	
Remarks	*seg* is far more reliable than *thr* for objects of known size. *rbk* is similar to *seg* but does not include thresholding	

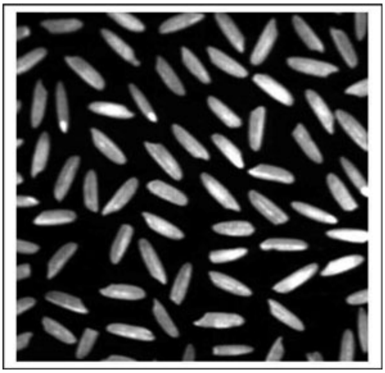
Illustration

Input image	Rice grains
File number	3
Command	*seg*(*15*, *0*) *and rbk*(*15*)

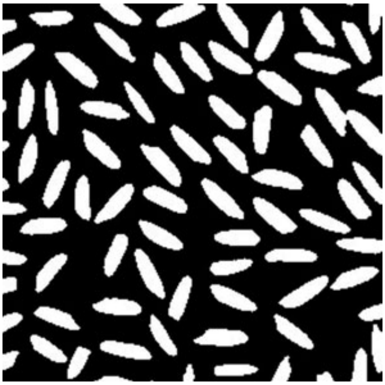
Top-left: original



Top-right: after *rbk*(*15*)



Bottom-left: after *seg*(*15*, *0*)



41.310 shk

Format *shk*

Arguments None

Defaults Not applicable

Output values None

Image type Binary

Type Blob transform

Switch Yes

Function Shrink each blob to a single white pixel. If it has *N* lakes ('holes'), the blob is reduced to a match-stick figure with *N* loops

Typical uses Inspecting granular materials. Inspecting sheet materials with textured surfaces or randomly distributed spots (e.g., certain floor coverings)

Remarks *shk* preserves the Euler number. We can reduce all blobs to a single point using *blf*, *shk*. If the blob contains no lakes, the point produced by *shk* lies within that blob. However, this is not guaranteed if we fill the lakes. Hence, applying *shk* to a circular ring (O), generates a point within the lake, rather than the white area.

Illustration

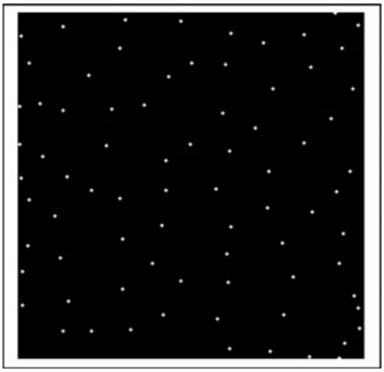
Input images Binary image derived from rice grains (image file 4)
Scissors (image file 164)

Image generation Rice grains: *rni*(*4*), *enc*, *thr*, *dil*, *ero*
Scissors: *thr* (needed to avoid artifacts due to JPEG coding)

Commands Rice grains: *shk*, *dil* (*dil* was included simply to make the spots visible)
Scissors: *shk*

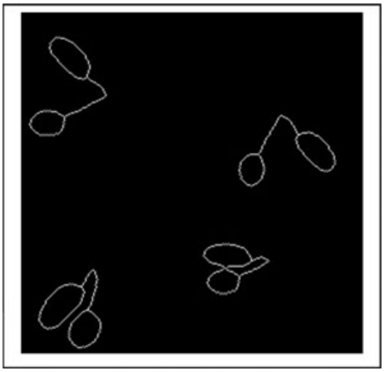
Left: binary rice grains image

Top-right: binary rice grains after *shk*, *dil*



Bottom-left: scissors image

Bottom-right: scissors image after *shk*



41.311 shp

See *con*

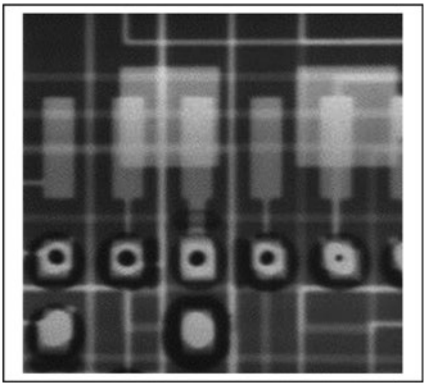
41.312 shr

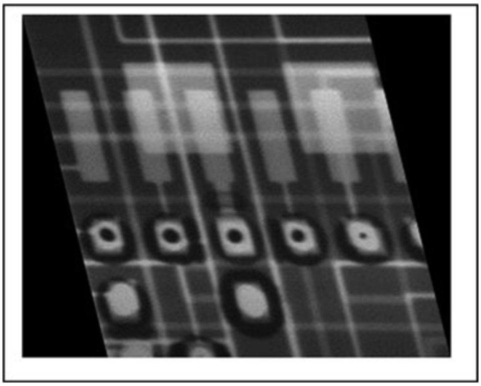
Format	*shr*(*a*)
Arguments	*a* Warping factor ($0 \leq a \leq 1.0$)
Defaults	None
Output values	None
Image type	Grey
Type	Image warping
Function	A shear transformation is applied to the image. An upright rectangle is mapped into a parallelogram
Switch images	Yes
Typical uses	Correcting image distortion due to motion during scanning
Remarks	Notice that the image becomes larger (wider) as a result of applying this operator. A command sequence of the form *shr*(*a*); $b = -a$; *filter-2-dimensional*; *shr*(*b*) performs filtering along two non-orthogonal axes

Illustration

Input image	Printed circuit board
File number	135
Command	*shr*(*0.25*)

Left: original (size: 256∗256) *Right*: after processing (size: 256∗320)

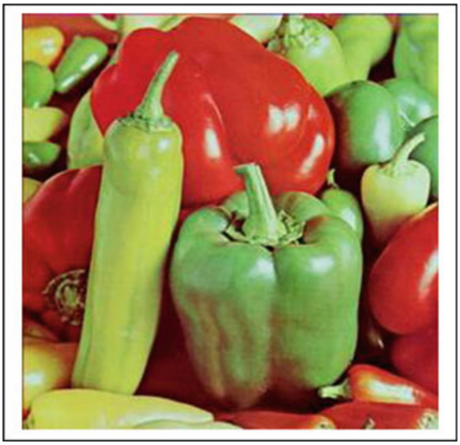




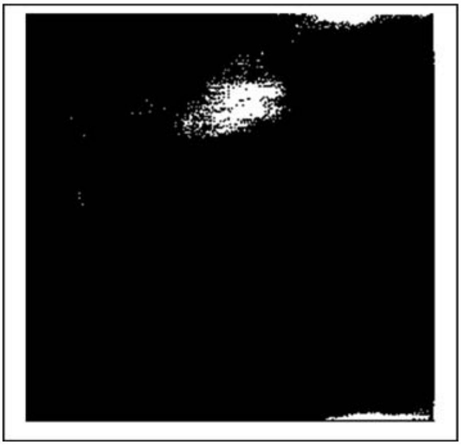
41.313 shs

Format	*shs*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Colour
Type	Colour image processing
Switch	Yes
Function	Plot the scattergram of hue (vertical axis) versus saturation (horizontal axis)
Typical uses	Analysis of clustering of colour measurements. Data reduction of images containing blocks of nearly constant, highly saturated colours, prior to applying a programmable colour filter (*pcf*)
Remarks	Also see *pcf*
Illustration	
Input image	Peppers
File number	73

Top-left: original colour image.

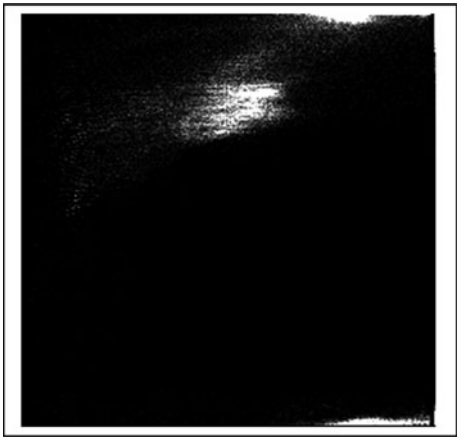


Top-right: after *shs*

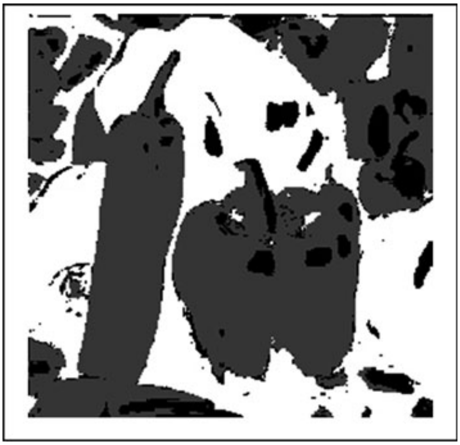


Centre-left: after *shs, enc, thr*

Centre-right: after *shs, enc, thr, kgr(25), dil(15), ndo, enc, hil(170,255,255), dil(8))*.
This is the alternate image forming the colour look-up table used by *pcf* in the example below.



Bottom-left: output of *pcf*

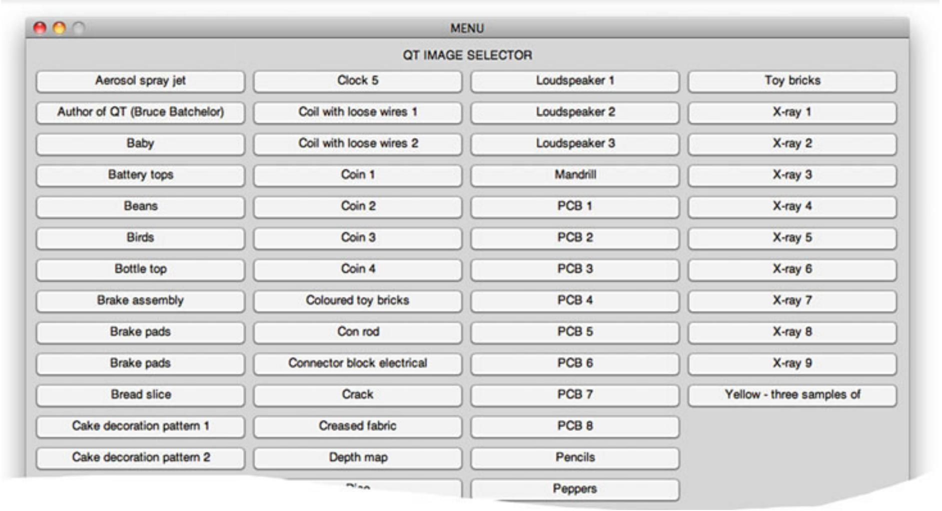


41.314 sia

Format	*sia*(*a*)	
Arguments	*a*	Name of the folder where the new images are to be found
Default value	*a*	The string QT_images
Output values	None	
Image type	Binary, grey or colour	
Type	QT maintenance/extension	
Function	Save all image files in the named folder (*a*) to the Image Archive: QT_images The new image files are in TIFF format	
Switch images	No	
Typical uses	Extending the Image Archive quickly by adding a new batch of image files	
Remarks	Also see *aia*	

41.315 sim

Format	*sim*
Arguments	None
Output values	None
Type	User aid
Switch images	No
Function	Display a menu showing the names of popular images. The user clicks on one of these, which is then read into the Current Image and displayed in Figure 1. The most recent image captured from the camera using *frz*
Remarks	Also see *did*



41.316 sir

Format	*sir*(*x*, *y*, *w*, *h*, *z*)	
Arguments	*x*	X-coordinate of top-left corner of the rectangle
	y	Y-coordinate of top-left corner of the rectangle
	w	Width of the rectangle
	h	Height of the rectangle
	z	Intensity value for pixels within the rectangle
Defaults	*z*	0
Output values	None	
Type	Drawing	
Switch images	Yes	
Function	Set all pixels within the specified rectangle to intensity *z*	
Remarks	Also see *rea*, *rni*, *rci*, *gwi* and *wri*	

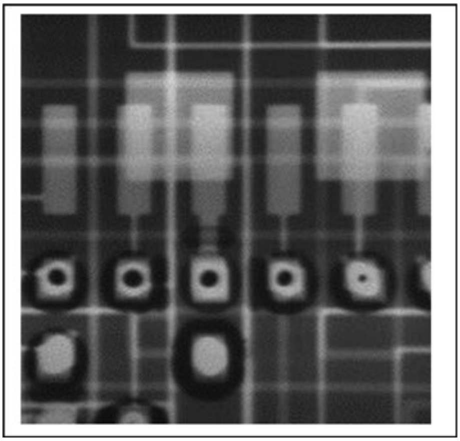
41.317 sit

Format	*sit*
Arguments	None
Defaults	None
Output values	None
Image type	Grey scale
Type	Monadic
Function	Apply a sigmoid intensity mapping function
Switch images	Yes
Typical uses	Enhance image contrast for display of further processing
Remarks	The central part of the intensity scale is stretched; the ends are compressed. *sit* can be used in conjunction with other monadic functions (e.g., *enc*, *heq*, *sqr*, *sqt*, *din*, *neg*, *alg*, *nlg*), to produce other useful mapping operators

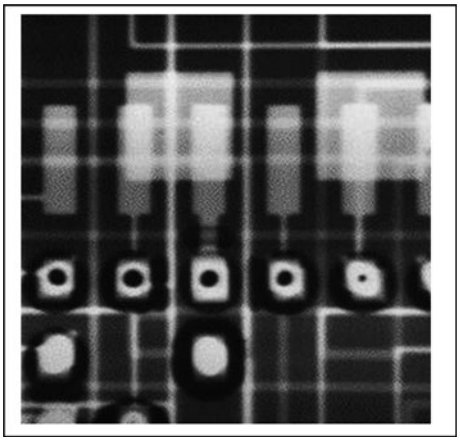
Illustration

Input image	X-ray, PCB
File number	135
Command	*sit*

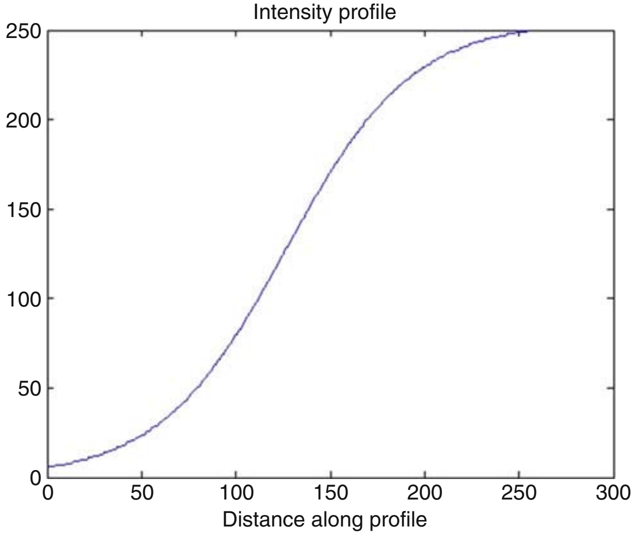
Left: Original image



Top-right: *after processing*



Bottom: Intensity mapping function for *sit*



41.318 siv

Format	d = *siv*(*a*, *b*, *c*)		
Arguments	*a*	X-address of the pixel to be accessed	
	b	Y-address of the pixel to be accessed	
	c	New intensity value	
Defaults	None		
Output values	*d*	0	Inputs *[a, b]* within range
	d	1	Inputs *[a, b]* out of range
Image type	Any		
Type	Accessing individual pixels		
Function	Set the intensity at point [*a*, *b*] in the current image to level *c*		
Switch images	Yes		
Typical uses	Annotating images; placing points at critical features for display purposes. Testing image processing operators		
Remarks	Use *siv*, rather than accessing individual pixels of the current image directly, since it follows the QT convention that the x-address precedes the y-address. It also avoids the need to define the current image as *global* via the Command Window		

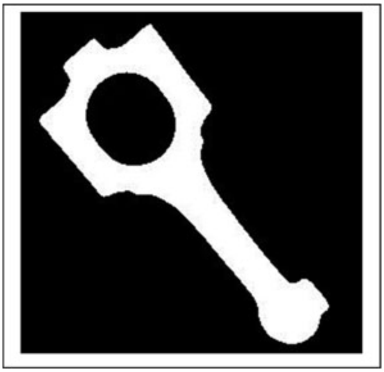
41.319 ske

Format	*ske*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Binary
Type	Blob transform
Function	Skeleton of a single blob in a binary image
Switch images	Yes
Typical uses	Blob shape analysis
Remarks	The skeleton is a connected figure that approximates the medial axis; each point in the skeleton is equidistant from at least two edge points

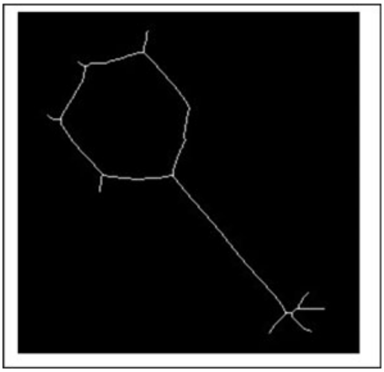
Illustration

Input image	Con-rod
File number	47
Command	*thr*, *ske* (N.B. *thr* avoids the artifacts created by storing a binary image in JPEG format)

Left: original



Right: after processing



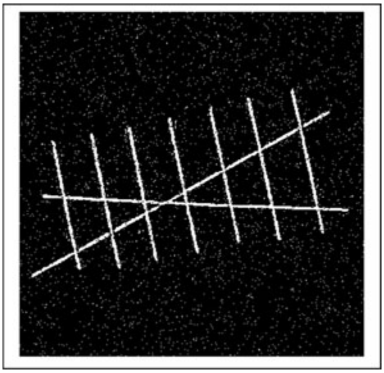
41.320 slf

Format	a = *slf*
Arguments	None
Defaults	None
Output values	*a* Orientation of strongest linear feature
Image type	Binary
Type	Global transform
Switch	Yes
Function	Strongest linear feature
Definition	The Radon transform (*rdn*) is computed first. The resulting image (RT) is then processed to find the brightest spot. Its X-coordinate indicates the orientation of the strongest linear feature in the input image. The input image is then rotated so that the strongest linear feature is vertical
Switch images	Yes
Typical use	Detecting linear streaks in noisy images
Remarks	It is a simple matter to identify other lines that are nearly parallel to the strongest linear features; apply *cin*, *rsb*, If there are other lines parallel to the strongest linear feature, these will appear as bright streaks in the output image (Also see *rdn* and *irt*)

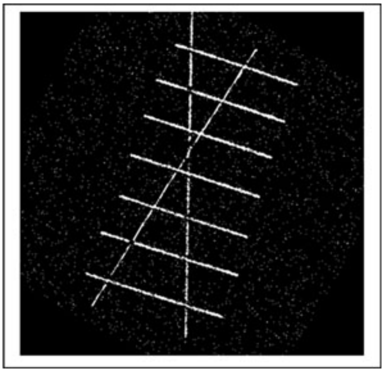
Illustration

Input image	Lines, with pre-processing to create a noisy binary image: *crk*(*3*), *enc*, *thr*, *spn*(*0.05*)
File number	160
Commands	*a* = *slf*; *cin*, *rsb*, *tur*(−*a*), *enc*, *thr*(*255*), *big*, *thn*

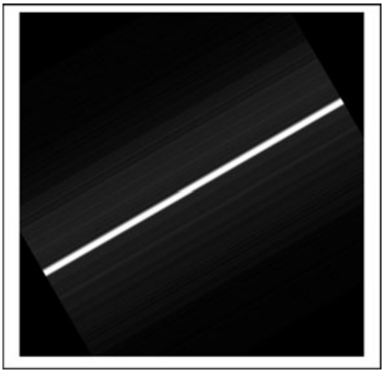
Left: original



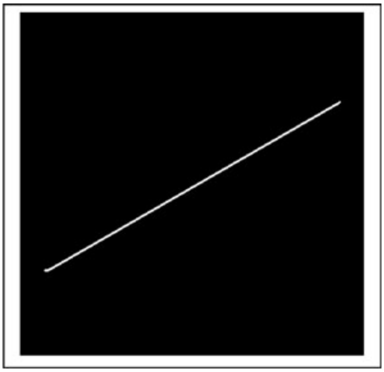
Right: immediately after *slf*



Bottom-left: just after *tur*(−*a*)



Bottom-right: final result, after *thn*



41.321 sly

See *bpa*.

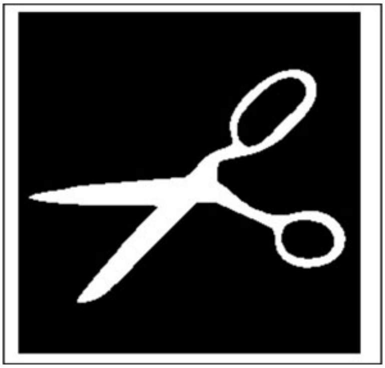
41.322 sme

Format	*sme*(*u*)
Arguments	*u* Separation parameter for edge-follower 'bugs'
Defaults	*u* 10
Output values	None
Image type	Binary image, single blob, no lakes
Type	Binary image analysis
Switch	Yes
Function	Smooth the edge of the blob
Switch images	Yes
Typical uses	Noise reduction, prior to analysing blob geometry
Remarks	Convex and concave corners can be detected separately, by subtracting the output from the original image

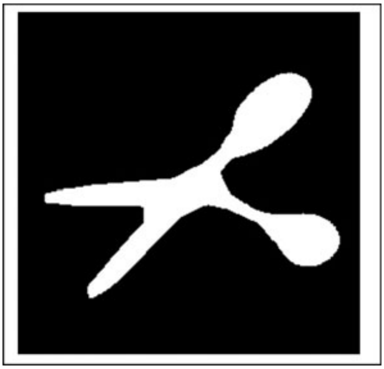
Illustration

Input image	*rni*(*49*), *thr*, *blf*
Commands	(i) *sme* (ii) *sme*, *rei*('*original*'), *sub*, *neg*

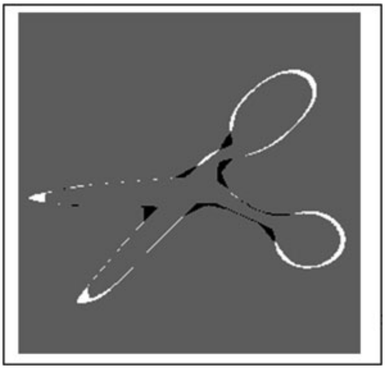
Left: original image



Top-right: *sme*



Bottom-left: *sme*, *rei*('*original*'), *sub*, *neg*



41.323 snb

Format	*snb*(*a*)	
Arguments	*a*	Size of processing window
Defaults	*a*	3
Output values	None	
Image type	Grey scale or binary	
Type	Non-linear filter	
Switch	Yes	
Function	Smallest (i.e., darkest) neighbour in an *a* × *a* window	
Typical use	Noise reduction. Component of a number of other operators (e.g., *snb*, *sub* is a highly effective edge detector.)	
Remarks	*snb*(*a*) is equivalent to *ero*(*a*, *1*). Also see *lnb*	

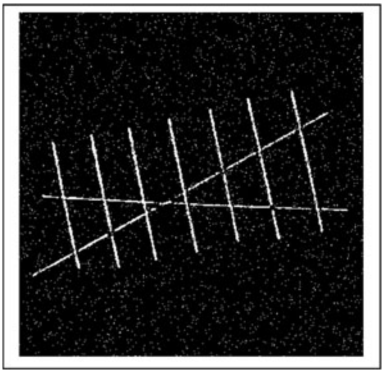
41.324 sob

Format	*[x, y] = sob*	
Arguments	None	
Output values	*x*	X-coordinate of the point defined by the user with the cursor
	y	Y-coordinate of the point defined by the user with the cursor
Image type	Binary	
Type	Miscellaneous	
Function	Select one 8-connected blob with the cursor	
Switch images	Yes	
Typical uses	Interactive selection of blobs in a complex image, prior to more detailed analysis	
Remarks	*cob* allows more than one blob to be selected; *sob* allows only one but does return the point defined by the user	

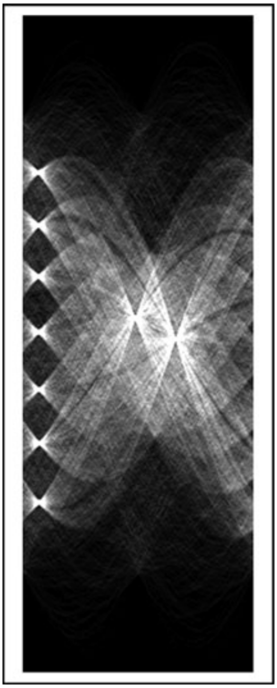
41.325 irt

Format	*irt*
Arguments	None
Defaults	None
Output values	None
Image type	Grey scale or binary
Type	Global transform
Switch	Yes
Function	Inverse Radon transform
Switch images	Yes
Typical use	Isolating individual linear streaks in noisy images
Remarks	Normally, *irt* is used in conjunction with *rdn* (Radon transform). The example shown below illustrates how a group of nearly vertical, parallel lines can be identified. The Radon transform image (RT) is first weighted by multiplying it by the intensity wedge (*wgx*, *neg*). The contrast is then adjusted by applying *sqr*. (This reduces the number of 'noise' points in the final image.) Finally, *irt* is applied. Also see *rdn*
Illustration	
Input image	Lines
File number	158
Command	*rdn*, *wri*, *wgx*, *neg*, *rei*, *mul*, *sqr*, *irt*

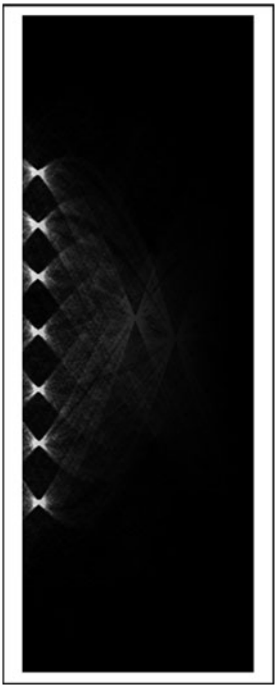
Top-left: *original*



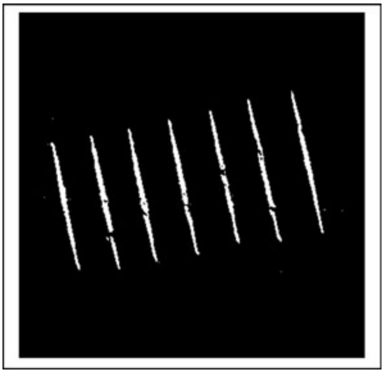
Centre: just after *rdn*



Bottom-left:just before *irt*



Bottom-right: after *irt*



41.326 spi

Format *spi*(*A*, *B*, *T*)

Arguments *A* Background process (QT command sequence)

B Interjected process (QT command sequence)

T Timer interval (seconds)

Defaults None

Output values None

Type Process control

Function Imagine process *A* is running. This might contain an infinite repeating loop

Every *T* seconds, *A* is suspended and process *B* is executed

When *B* terminates, *A* is restored and continues running, as if nothing had happened

Typical uses Occasional inspection by stealing time from an on-going process that can tolerate an occasional loss of a processing cycle. For example, *A* may be a nearly continuous product-inspection process and *B* a safety check that need only be performed once every few seconds, or even minutes

Stopping To stop both background and interjected processes, perform the following operations:

(i) Click in MATLAB's Command Window

(ii) Press CNTRL/C to terminate the background process (*A*)

(iii) Enter *q* (lower case *Q*) and press RETURN, to terminate the interjected process (B)

If step (iii) is not performed, the timer will still fire periodically and cause the interjected process to operate during keyboard interaction: very confusing!

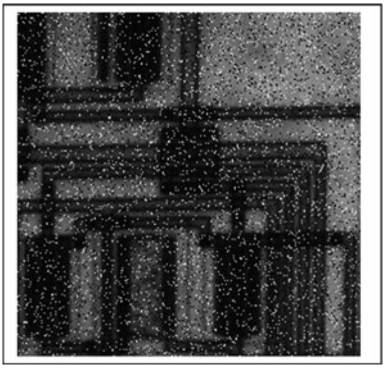
Remarks Normally, the execution time for process *B* is less than *T* seconds. It is important that processes *A* and *B* use separate disc image files, otherwise they will interfere with one another

Example of use *spi*([‘*n* = *round*(*100∗rand*(*1*, *1*));*rni*(*n*); *avg*; *psc*’], [‘*grb*(*6*); *gli*;, *psc*’], *10*)

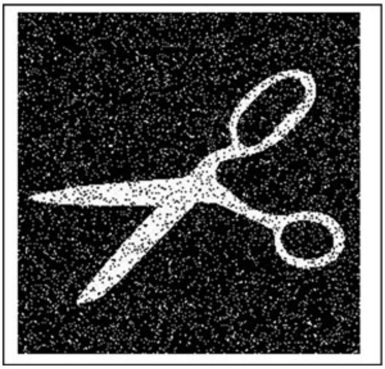
41.327 spn

Format	*spn*(*a*)
Arguments	*a* Proportion of the pixels that are changed ($0 \leq a \leq 1$)
Defaults	*a* 0.02. (1% of the pixels are set to black and 1% are set to white)
Output values	None
Image type	Grey scale or binary
Type	Drawing and image generation
Switch	Yes
Function	Add 'salt-and-pepper' noise to an image
Definition	A proportion *a*/2 of the pixels in the current image are selected at random and are set to black. A similar proportion are randomly selected and set to white
Switch images	Yes
Typical uses	Testing image filtering functions
Remarks	Also see *gsn*
Illustration	
Input images	Circuit (grey-scale) and scissors (binary)
File numbers	136 and 49
Commands	*spn*(*0.1*) for the grey-scale image (circuit, 136) *spn*(*0.2*) for the binary image (scissors, 49)

Left: processing a grey-scale image



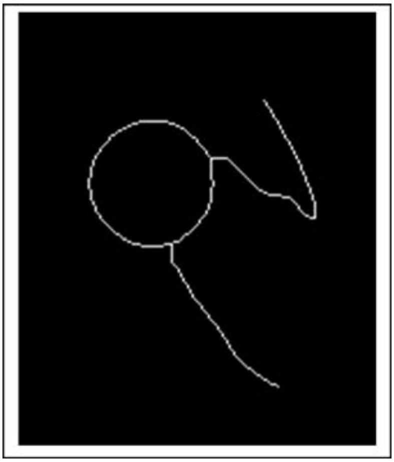
Right: processing a binary image (49)



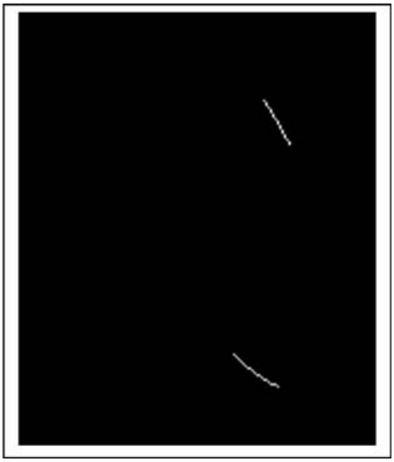
41.328 spr

Format	*spr*(*a*)
Arguments	*a* Number of end points to be removed
Defaults	*a* 1
Output values	None
Image type	Binary
Type	Morphology
Function	Remove all white pixels that have only one white 8-neighbour. (These are the end points of skeleton figures created by *ske* or *thn*). This is repeated recursively *a* times
Switch images	Yes
Typical uses	Part of a routine for analysing binary images arising in robot vision applications, for example grasping the ends of flying leads (e.g., images no. 18 and 19). First, the image is processed to create a skeleton and then *spr* is applied. The resulting short line-features are then analysed (using *lmb*), to find their ends. Then, the position coordinates and orientation of each wire end can be calculated. These values are then sent to a robot, enabling it to grasp the ends of the wires (one at a time)
Remarks	Also see *ske*, *thn*, *lmb*
Illustration	
Input images	Skeletons derived from images 19 (coil with flying leads) and 46 (silhouettes of four metal components)
Command	*spr(20) and spr(15)*

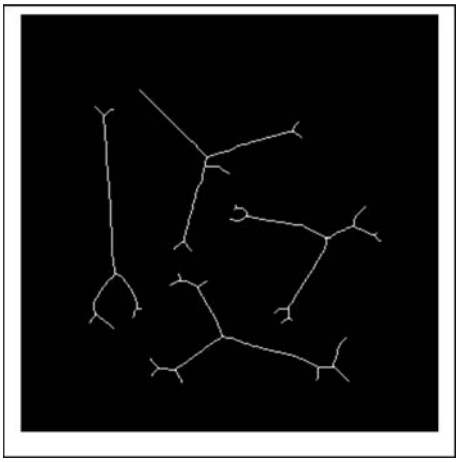
Top-left: skeleton derived from image no. 19



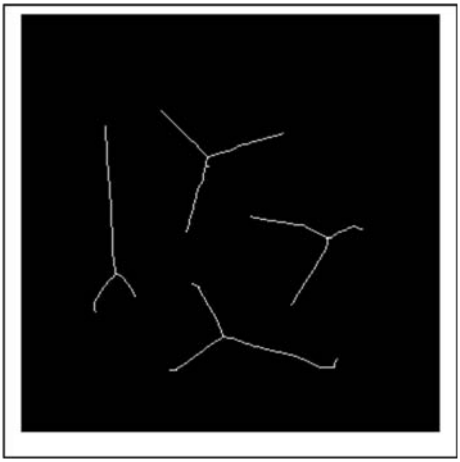
Top-right: after *spr*(*20*), exr



Bottom-left: skeleton derived from image no. 46



Bottom-right: after *spr*(*15*)



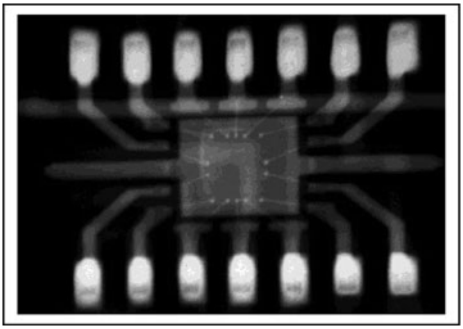
41.329 sqi

Format	*sqi*(*a*)	
Arguments	*a*	Intensity value for the padding area to be added to the image
Defaults	a	0 (zero)
Output values	None	
Image type	Grey-scale or Binary	
Type	Image shaping	
Function	Pad the image to make it square. The new rectangular padding area is added to the right/below the original image, depending on its aspect ratio	
Switch images	Yes	
Typical uses	Certain QT operators/sequences require a square image to work properly (e.g., *tur* and *yxt*, *adi*)	
Remarks	Also see *pad*	

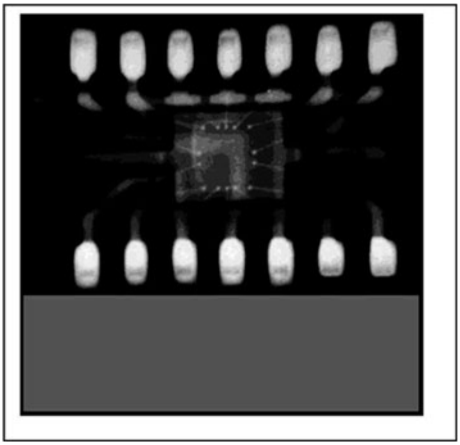
Illustration

Input image	Integrated circuit x-ray
File number	113
Command	*sqi(128)*

Left: original image



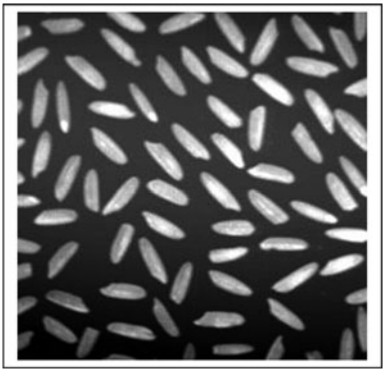
Right: after processing



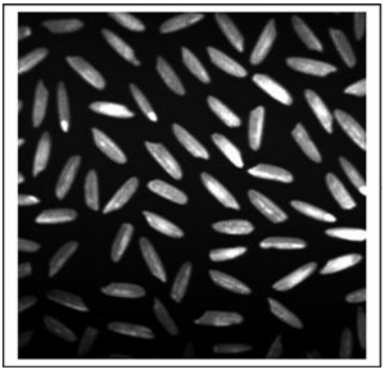
41.330 sqr

Format	*sqr*
Arguments	None
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Square of intensities in the current image
Definition	$C \Leftarrow A^2/255$
Switch images	Yes
Typical uses	Used to improve contrast in bright regions of the image
Remarks	Also see *alg*, *nlg and sqt*
Illustration	
Input image	Rice grains after contrast enhancement (*enc*)
File number	3
Command	*sqr*

Left: original



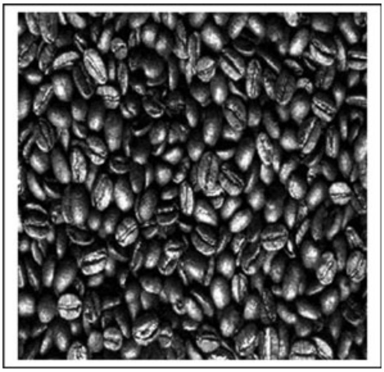
Right: after processing



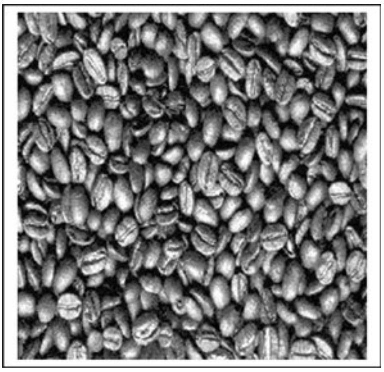
41.331 sqt

Format	*sqt*
Arguments	None
Defaults	None
Output values	None
Image type	Grey
Type	Monadic
Function	Square root of intensities in the current image
Definition	$C \Leftarrow \surd(255 * A)$
Switch images	Yes
Typical uses	Used to improve contrast in dark regions of the image
Remarks	Also see *alg*, *nlg* and *sqr*
Illustration	
Input image	Coffee beans after contrast enhancement (*enc*)
File number	4
Command	*sqt*

Left: original



Right: after processing



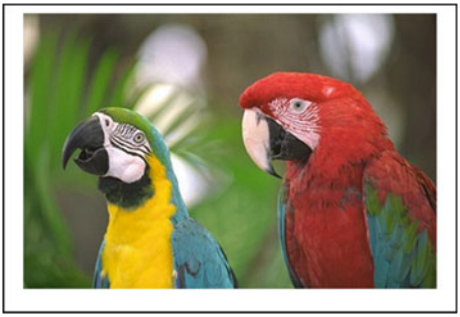
41.332 srgb

Format	*srgb*(*a*, *b*)
Arguments	*a* Colour channel (plotted along the horizontal axis) *b* Colour channel (plotted along the vertical axis)
Defaults	Not applicable
Output values	None
Image type	Colour
Type	Colour image analysis
Switch	Yes
Function	2-dimensional colour scattergram
Switch images	Yes
Typical uses	Analysing the structure of a colour image
Remarks	The scattergram is displayed in the current image with 256 × 256 pixels. The input parameters define the colour channels to be plotted, according to the following scheme: 1. *R*-channel ('red') 2. *G*-channel ('green') 3. *B-channel* ('blue') This function is most useful if there are strong clustering of colours; *srgb* works particularly well with 'block colours' (printing terminology, refers to colours that are discrete that do not blend with one another)

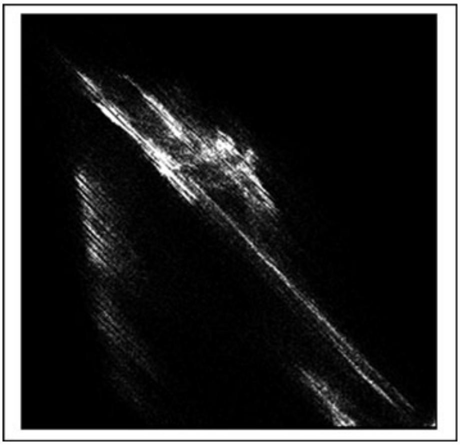
Illustration

Input image	Birds
File number	144
Commands	*srgb*(*1*, *2*)/*srgb*(*2*, *3*)/*srgb*(*3*, *2*)

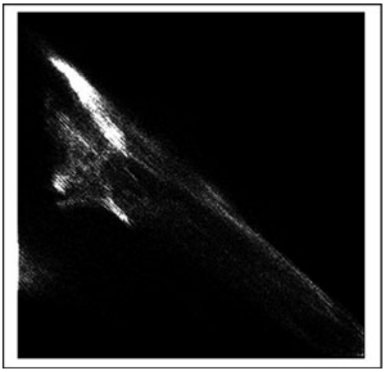
Top-left: original colour image



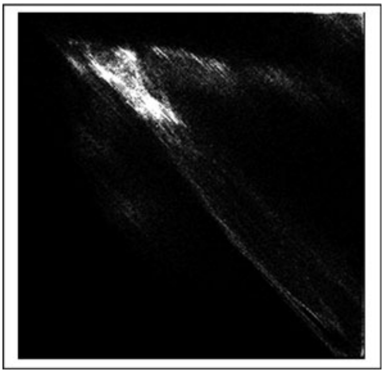
Right: *srgb*(*1*, *2*) Horizontal axis: *R*-channel Vertical axis: *G*-channel



Bottom-left: *srgb*(*2*, *3*) Horizontal axis: *G*-channel Vertical axis: *B*-channel



Bottom-right: *srgb*(*3*, *1*) Horizontal axis: *B*-channel Vertical axis: *R*-channel



41.333 ssk

Format	*ssk*
Arguments	None
Output values	None
Image type	Any
Type	Stack operator
Function	Part of the image stack is displayed in Figure 2. The top image on the stack is labelled *0*. Other images are labelled *1*, *2*, *3*, ... The previous image at the top of the stack is labelled ‘−*1*’. (It is possible to recover this image as the stack is actually implemented as a circular data structure)
Switch images	No
Remarks	Also see *push*, *pop*, *rsk*, *csk*

41.334 startup

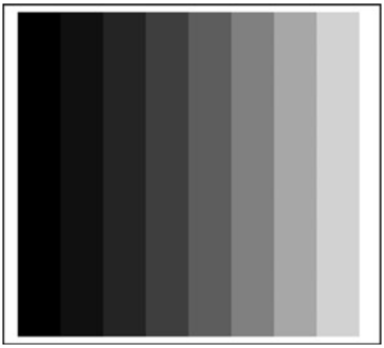
Format	*startup*	
Arguments	None	
Output values	None	
Image type	Not relevant	
Type	Not relevant	
Function	*startup*	Automatically initialises QT. May be run manually at other times
	qtstart	Manually initialises QT in versions that do not have automatic initialisation
Switch images	No	
Remarks	MATLAB automatically runs the M-file *startup.m* immediately after loading. QT uses this feature for initialisation, before any user input is accepted. The global variable *qt_control_vector*(*1*) controls the display of results in functions such as *avg*, *cgr*, *cwp*, *cbl*, *gli*, etc. The stand-alone version of QT allows the display of results from these functions, while the web version does not (To do so, would create a very messy display)	

41.335 stp

Format	*stp*(*a*)	
Arguments	*a*	Determines the number of steps ($1 \leq a \leq 8$. See *sca*)
Defaults	*a*	3
Output values	None	
Type	Drawing and image generation	
Switch	Yes	
Function	Draw a series of intensity steps; intensity varies across the image	
Switch images	Yes	
Typical uses	Testing prototype image processing functions. Generating other test patterns	
Remarks	This function is particularly useful for setting up a display monitor, so that the contrast is subjectively uniform over whole image	

Illustration

Command *stp*(*3*)



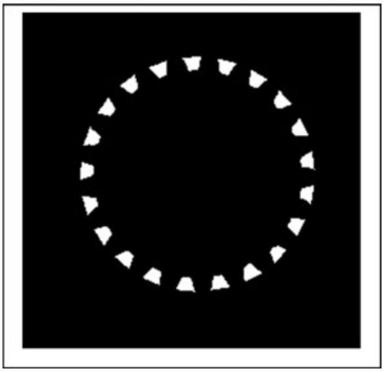
41.336 str

Format	*str*
Arguments	*None*
Output values	*None*
Image type	Binary
Type	Binary image analysis
Function	Draw a straight line from the overall centroid (i.e., considering all blobs) and the centroid of each individual blob
Switch images	Yes
Remarks	*str* is used in *chu_all* to connect disjoint blobs together so that *chu* can be applied to find the convex hull of the whole assembly. In addition, *str*, *mxi*, *nxy* can be used as an approximate way to implement *nxy_all*. Similarly for *npo*

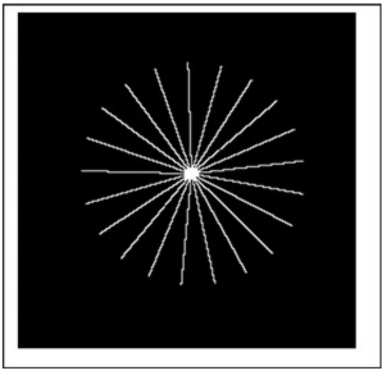
Illustration

Input generation	*rni*(*171*), *enc*, *thr*, *neg*, *big*, *blf*, *chu*, *exr*, *ero*
Command	*str*

Left: original



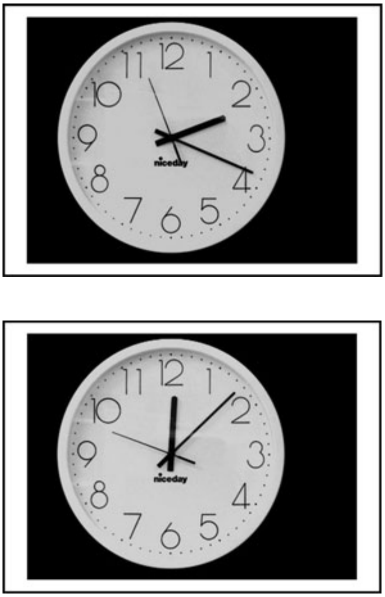
Right: after processing



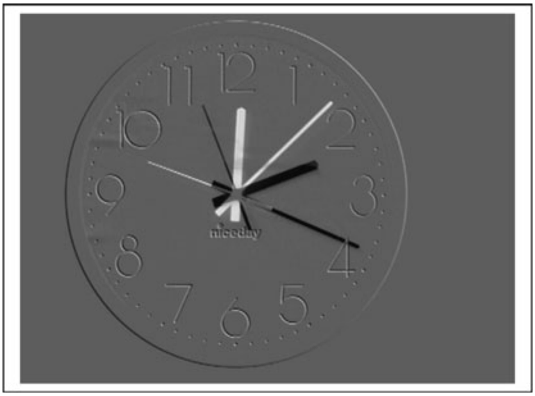
41.337 sub

Format	*sub*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey
Type	Dyadic
Function	Subtract the intensities in the current and alternate images
Definition	C ⇐ (255 + A − B)/2
Switch images	Yes
Typical uses	High-pass filtering; subtracting the filtered (blurred) and original images Finding differences between two images derived from the same camera, under identical lighting conditions
Remarks	*sub* is a component of numerous algorithms
Illustration	
Input image	Clock 1 and Clock 2
File number	142 and 143
Command	*sub*

Left: two originals



Right: after processing



41.338 swi

Format	*swi*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Miscellaneous
Function	Interchange the current and alternate images

41.339 tbt

Format	*tbt*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale or binary
Type	Affine transform
Switch	Yes
Function	Invert the vertical axis
Definition	$C(i, j) \Leftarrow A(i, h + 1 - j)$, where h is the picture height
Switch images	Yes

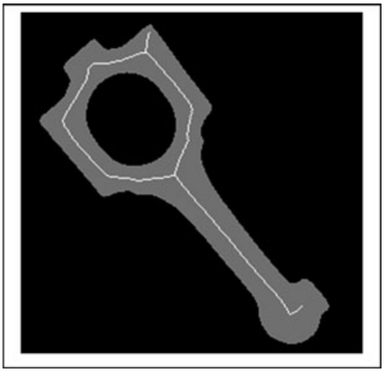
41.340 tha – thh

Formats	*tha*(*a*) *thb*(*a*, *b*, *c*) *thc*(*a*) *thd*(*a*) *the* *thf* *thg* *thh*
Arguments	See below
Defaults	See below
Output values	None
Image type	Grey
Type	Monadic
Function	Threshold at some level derived by analysing the image. Functions *tha*, *thb*, *thc* and *thd* require additional parameters (e.g., offset or bias values), supplied by the user
Definition	See below
Switch images	Yes
Typical uses	Image segmentation (i.e., isolating an object silhouette from its background)
Remarks	This family of operators all use the function *thr*, calculating the threshold parameter automatically or semi-automatically. Commands *tha*(*0.5*) *and thb* provide useful ways to make thresholding insensitive to lighting variations, when processing images obtained by back-lighting. Alphabetic naming of these functions was adopted, since it is difficult to define their functions exactly in a few words. See program listings for more details.

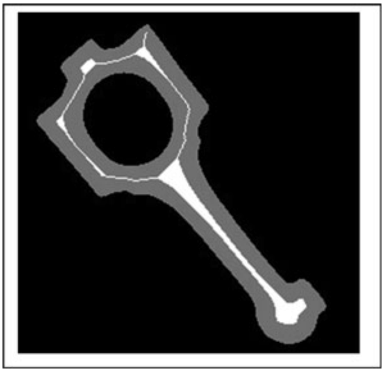
41.341 thn

Format	*thn*(*a*)
Arguments	*a* Number of times the thinning operation is applied
Defaults	Indefinitely large
Output values	None
Image type	Binary
Type	Blob transform
Function	*thn(a)* thins each blob in a binary image *thn* generates a match-stick figure (‘skeleton’)
Switch images	Yes
Typical uses	Blob shape analysis
Remarks	*thn* creates a match-stick figure that is usually cleaner (i.e., has fewer small spurs) than *ske*. *thn* creates a skeleton for each blob in the image, whereas *ske* draws only one. *thn*(*a*) may produce partially thinned blobs
Illustration	
Input image	Con-rod
File number	47
Command	*Left*: *thn*, *adi* *Right*: *thn*(*10*), *adi*

Left: after *thn*, *adi*



Right: after *thn*(*10*), *adi*



41.342 thr

Format *thr*(*a*, *b*)

Arguments *a* Lower intensity threshold limit

b Upper intensity threshold limit

Defaults *a* 128

b 255

Output values None

Image type Grey

Type Monadic

Function Threshold the input image. All pixels whose intensities lie within the range *[a, b]* are mapped to white (255). All other are set to black (0)

Switch images Yes

Typical uses Image segmentation (i.e., isolating an object silhouette from its background). Reducing data content in an image, to make subsequent analysis easier

Remarks To novice users, thresholding is an obvious function to use in many applications. However, it is sensitive to lighting variations and will not produce reliable image segmentation in any but the simplest applications. For this reason, *thr* is almost always used in conjunction with a suitable filter, edge detector, or an intensity-normalisation function, such as *enc* or *heq*

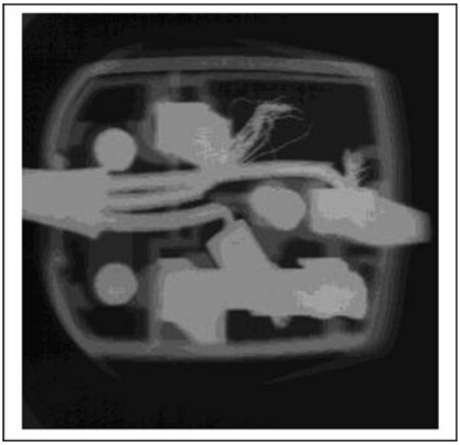
Illustration

Input image UK power plug

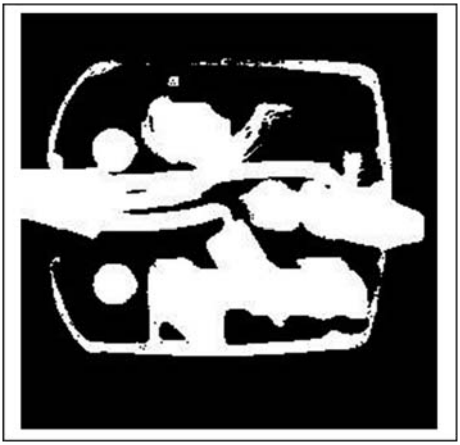
File number 112

Command *thr*(*115*)

Left: original



Right: after processing



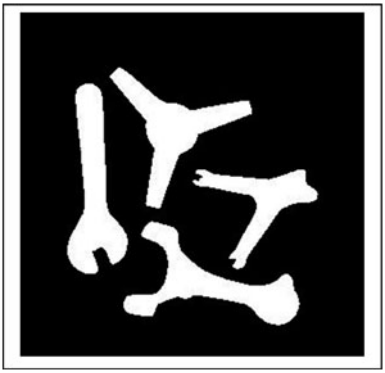
41.343 tim

Format	$b = tim(a)$
Arguments	*a* Function call
Defaults	None
Output values	*b* Execution time
Image type	Any
Type	Miscellaneous
Switch	Possible; depends on function specified by *a*
Function	Function timer
Definition	Time the execution of the specified function *a*. (Notice that the function to be timed is enclosed between single quotes, as shown in the example below)
Typical uses	Program analysis
Remarks	Example of use: *b = tim('maj(20)')* Output: *Execution time for function call 'maj(20)' was 498 ms*

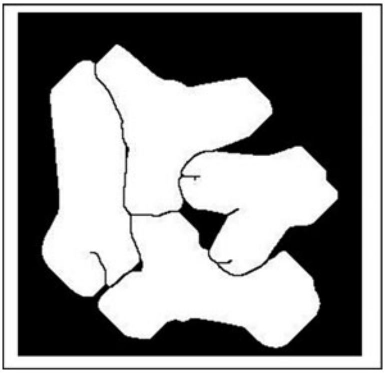
41.344 tkn

Format	*tkn*(*a*)
Arguments	*a* Number of times the (dilation) operation is repeated
Defaults	*a* 1
Output values	None
Image type	Binary
Type	Blob transform
Switch	Yes
Function	'Thicken' objects in a binary image; add pixels to the exterior, until doing so would result in previously unconnected objects being 8-connected
Switch images	Yes
Typical uses	Blob-shape analysis
Remarks	Unlike *dil*, this operation preserves the Euler number. Also see *gft* and *wsh*. Execution can take a long time for large values of *a* (Typically $a > 10$)
Illustration	
Input image	Four metal parts, after thresholding
File number	46
Command	*thr*, *tkn*(*20*) (Thresholding eliminates artifacts due to JPEG coding)

Top-left: original



Top-right: *after processing*



41.345 tlp/trp/rtp/rbp/brp/blp/lbp/ltp

Format [*x*, *y*] = *tlp*

Arguments None

Defaults Not applicable

Output values x X-coordinate of the top-left-most white point (*tlp*)

y Y-coordinate of the top-left-most white point (*tlp*)

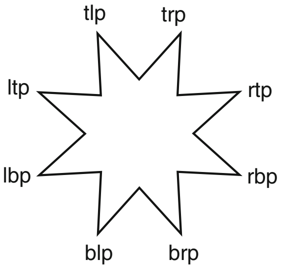
Image type Binary

Type Image analysis

Switch No

Function Use these functions to find the XY-coordinates of the other extremal points as follows:

tlp	Top-left
trp	Top-right
rtp	Right-top
rbp	Right-bottom
brp	Bottom-right
blp	Bottom-left
lbp	Left-bottom
ltp	Left-top



Typical uses Locating binary objects for further analysis

Remarks The other functions are defined in a similar way to *tlp*

41.346 tsk

Format	*tsk*(*a*)
Arguments	*a* Index number of the image to be read from the stack *a* 0 (Top of the stack)
Output values	None
Image type	Any
Type	Stack operator
Function	Read the file at position *a* in the image stack. If *a* is zero, the image at the top of the stack is read. If *a* is negative, an image that was recently located at the top of the stack is read. When an image is popped from the stack, it is not destroyed
Switch images	Yes
Remarks	The stack is implemented as a circular array of TIFF image files, labelled *stack_image*(*0*), *stack_image*(*1*), . . ., *stack_image*(*stack_size-1*) Image *stack_image*(*stack_pointer*) is at the top of the stack. When we perform *pop*, the top of the tack moves to *mod*((*stack_pointer* + *1*), *stack_size*) The image which had been at the top of the stack immediately before *pop* is now at position (*stack_pointer-1*). Assuming that not more than (*stack_size-k*) images have been pushed (using *push*) onto the stack, the previous *k* images can be accessed successfully by *tsk*. (There is no warning, to indicate whether or not this can be accomplished successfully) Also see *push*, *pop*, *rsi*

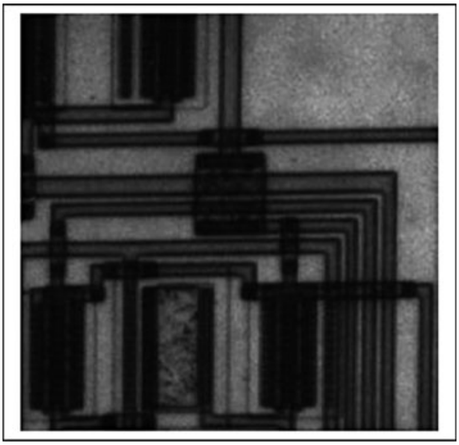
41.347 tur

Format	*tur*(*a*)	
Arguments	*a*	Angle of rotation (degrees)
	b	Control cropping/no cropping
Defaults	*b*	0 (no cropping)
Output values	None	
Image type	Grey scale or binary	
Type	Affine	
Switch	Yes	
Function	Rotate the image by a given amount, about the centre of the image	
Switch images	Yes	
Typical uses	Defining circularly symmetric filters	
Remarks	*tur*(*X*, *0*) *or tur*(*X*) keeps the image size constant; the corners are cropped. On the other hand, *tur*(*X*, *1*), rotates the image without cropping. This makes the output image larger. In both cases, bilinear interpolation is used to avoid producing ragged edges	

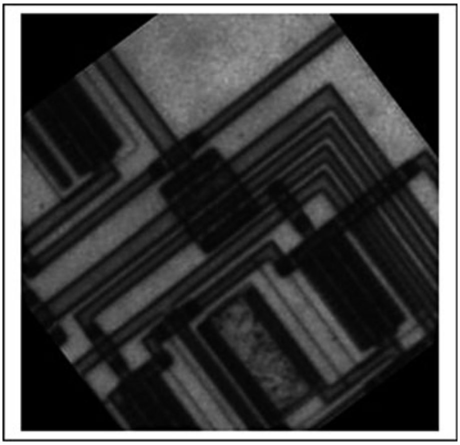
Illustration

Input image	Circuit
File number	136
Command	*tur*(*37*) *tur*(*37*, *1*)

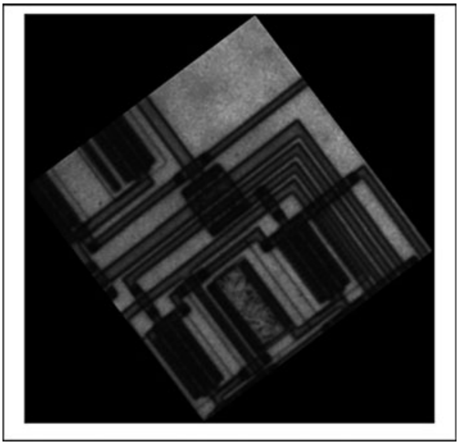
Top-left: original



Top-right: after *tur*(*37*). Image size is unchanged



Bottom-left: after *tur*(*37*, *1*) *I*mage size has increased

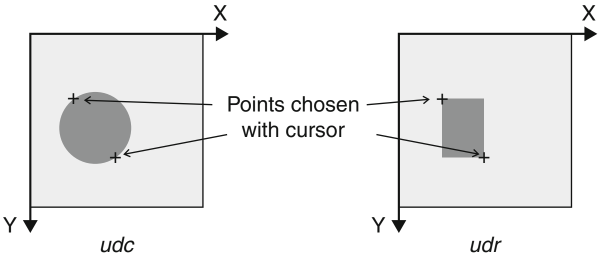


41.348 txt

Format	*txt*(*a*, *b*)	
Arguments	*a*	Text to be superimposed on the current image
	b	Colour of lettering
Output values	*a*	See below
	b	‘r’ (red lettering)
Image type	Any	
Type	Binary image analysis	
Function	Argument *a* not supplied: Superimpose *Current* and *Alternate* labels on the displayed images Argument *a* supplied: Superimpose text defined by *a* on the display of the current image (In neither case is the image changed)	
Switch images	Yes	
Typical uses	Teaching and demonstrations	
Remarks	The text disappears when the current image is modified and redisplayed	

41.349 udc/udr

Format	*udc*(*a*)	
Arguments	*a*	0, fill the circle/rectangle; otherwise draw an open circle/rectangle
Defaults	*a*	0
Output values	None	
Image type	Grey	
Type	Graphics	
Function	Draw the largest possible circle/rectangle intersecting two points specified by the user with the cursor. See drawing below	
Switch images	Yes	
Typical uses	Defining structuring elements for dilation/erosion	
Remarks	Also see *pgn*, *use* Figure – For both functions. two points, denoted by crosses, are selected by the user with the cursor. *udc* draws the circle whose diameter intersects those two points. *udr* draws that rectangle whose diagonally opposite vertices coincides with these points.	



41.350 uds

Format	*uds*(*a*)
Arguments	*a* Increment the image stack pointer
Output values	None
Image type	Any
Type	Stack operator
Function	In Stack Mode, or when watching the stack with *ssk* in Terminal mode, use *uds*(*a*) to read the *a*th stack image
Switch images	Yes
Remarks	The variable stack_pointer is incremented: $stack\_pointer = mod(stack\_pointer\text{-}a,\ stack\_size)$ This is equivalent to rotating the circular array of images forming the image stack. Also see *tsk*

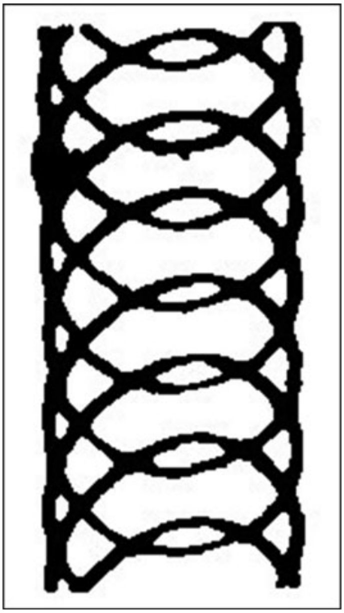
41.351 ult

Format	*ult*
Arguments	None
Output values	None
Image type	Binary
Type	Binary image transformation
Function	Ultimate erosion of the negative image
Switch images	Yes
Typical uses	Inspecting pre-defined patterns, by reducing them to a simpler form that is easier to analyse
Remarks	This generates a number of white spots, each one indicating a regional maximum of the Euclidean distance transform. Also see *rmx*, *gft*

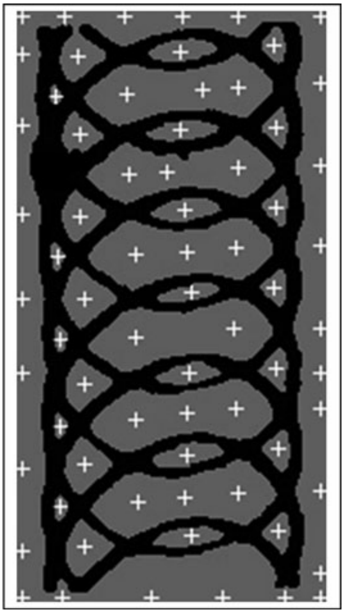
Illustration

Input image	Cake decoration pattern
File number	55
Command	*ult*

Left: original



Right: after processing



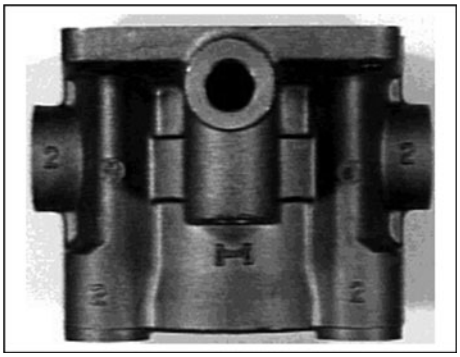
41.352 uns

Format	*uns*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Grey scale
Type	Convolution operator
Switch	Yes
Function	Unsharp mask; high-frequency accentuating filter
Definition	Linear convolution in a 3 × 3 window with the following weight matrix

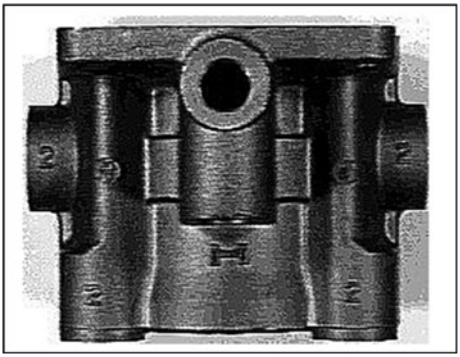
−0.1667	−0.6667	−0.1667
−0.6667	4.3333	−0.6667
−0.1667	−0.6667	−0.1667

Switch images	Yes
Typical uses	Enhancing low-contrast images for display
Remarks	
Illustration	
Input image	Hydraulics manifold
File number	38
Command	*uns*

Left: original

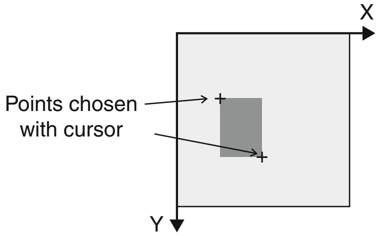


Top-right: after processing



41.353 use

Format	*use*(*a*)
Arguments	*a* Dilation control
Defaults	*a* 1
Output values	None
Image type	Two binary images: current image; alternate images
Type	Binary image analysis
Function	1. The user defines a structuring element (SE) window using the cursor (See diagram below) 2. The current image is then thinned (*thn*) and dilated *a* times 3. The contents of this window is then used to define the SE 4. Erode the current image using the SE just calculated (*gbe*)
Switch images	Yes
Typical uses	Designing/choosing SEs
Remarks	*use* is an interactive design tool for morphology; it is not intended for batch mode operation. Also see *jas*. The user defines the top-left and bottom-right vertices of the SE window.

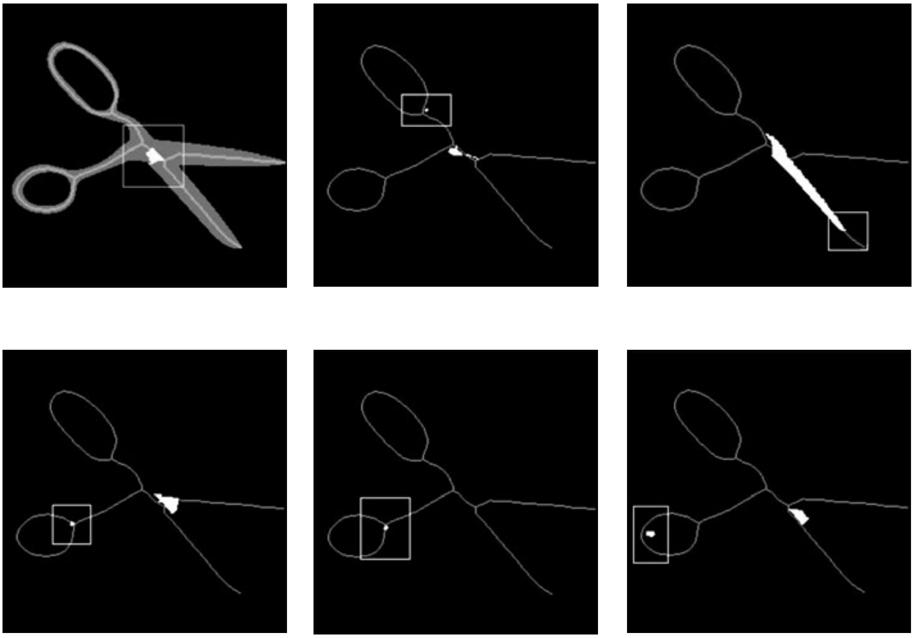


Illustrations

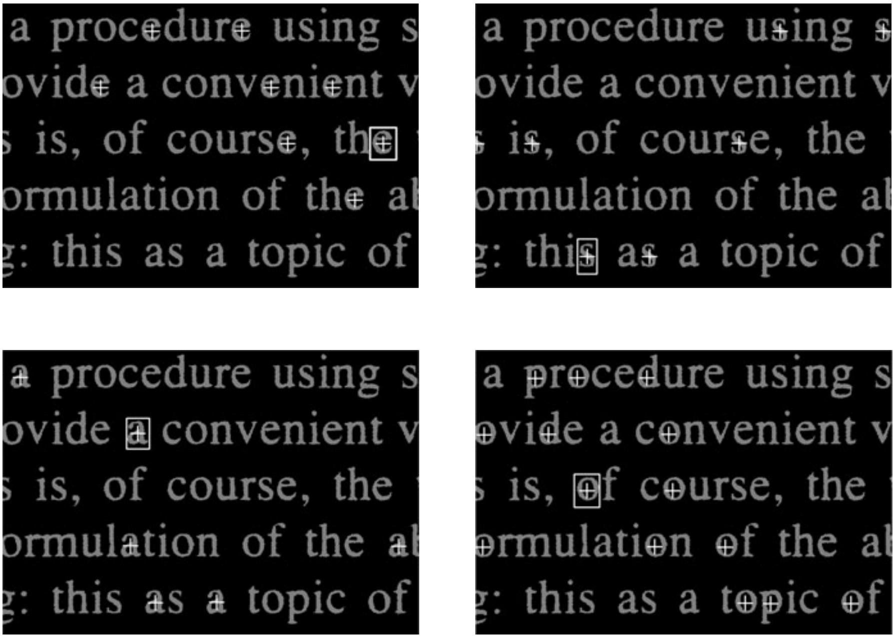
Example 1: *Scissors Images*

Input image	Scissors
File number	48
Command	*rni(48), a = use(1); neg, sqr, neg, rni(48), swi, adi, mxi*

Top left: The SE defined by the user consists of that part of the dilated skeleton lying within the white rectangle. Erosion of the original "scissors" image with this SE, produces a single blob in the area close to the hinge of the scissors. Processing: *rni(48), a = use(1); neg, sqr, neg, rni(48), swi, adi, mxi.*
Top centre: The SE is based on the Y-shaped feature at the base of the larger finger-hole. Erosion detects this and some points near the hinge; the SE is too small to be more specific.
Top-right: The SE is a close approximation to a diagonal line. Erosion with this SE detects most of one blade.
Bottom-left: Erosion with a small SE detects the Y-shaped feature and points in the hinge area.
Bottom-centre: Erosion with this larger SE detects the Y-shaped feature but not the hinge area.
Bottom-right: This small SE is based on the loop of the smaller finger-hole. Erosion with it incorrectly detects the 'V' formed by the blades.



Example 2: *Printed text*
Top-left: The SE is a dilated skeleton of the lower-case letter 'e'. Erosion with this SE correctly detects all other occurences of 'e' and nothing else.
Top-right: The SE is a dilated skeleton of the lower-case letter 's'. Erosion correctly detects all other occurences of 's' and nothing else.
Top-left: The SE is a dilated skeleton of the lower-case letter 'a'. Erosion correctly detects all other occurences of 'a' and nothing else.
Top-left: The SE is a dilated skeleton of the lower-case letter 'o'. Erosion correctly detects all other occurences of 'o' but erroneously detects 'p' and 'd' as well



41.354 vfs

Format *vfs*(*a*)

Arguments *a* Upper limit on spatial frequency, measured along the horizontal axis

Defaults None

Output values None

Type Drawing and image generation

Switch Yes

Function Generate a pattern with a sinusoidal intensity variation along each row. The spatial frequency varies linearly with vertical position in the image; low frequencies are generated near the top and high frequencies near the bottom

Switch images Yes

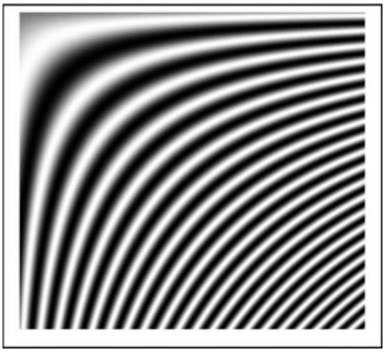
Typical uses Analysing the behaviour of 1-d (horizontal) filters

Remarks When a filter is applied to the image generated by *vfs*, the contrast varies according to the vertical position (i.e., spatial frequency). The contrast can be measured using a simple QT command sequence and a graph plotted of filter response versus frequency; the use of this function is illustrated below

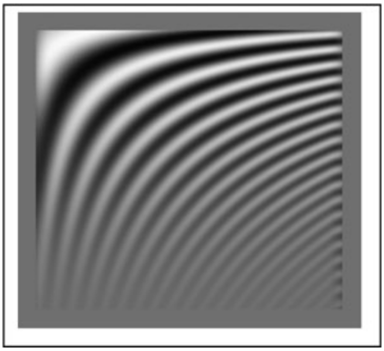
Illustration

Notes: The image generated by *vfs*(*20*) is shown below, together with the result of horizontal smoothing (i.e., *con*[*1, 1, 1, 1, 1, 1, 1, 1, 1, 1*; *1, 1, 1, 1, 1, 1, 1, 1, 1, 1*; *1, 1, 1, 1, 1, 1, 1, 1, 1, 1*]) applied three times. The row-minimum (I_{min}) and row-maximum (I_{max}) were then found for each row. A graph of ($I_{max} - I_{min}$) was then plotted against spatial frequency. (Graph labelled 'Filter response')

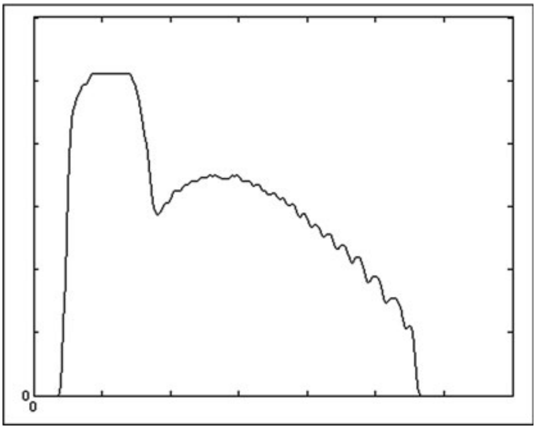
Left: vsf(20)



Right: after filtering



Filter response (Abscissa, Spatial frequency. Ordinate, Filter response, i.e., minimum-to-maximum difference in intensity along each row)



41.355 vgr

See *con*

41.356 vpl

Format	*vpl*(*x1*, *y1*, *x2*, *y2*, *v*)	
Arguments	*x1*	X-coordinate of the beginning of the line
	y1	Y-coordinate of the beginning of the line
	x2	X-coordinate of the end of the line
	y2	Y-coordinate of the end of the line
	v	Intensity of the line
Defaults	*v*	255
Output values	None	
Type	Drawing and image generation	
Switch	Yes	
Function	Draw a digital straight line of intensity *v*, beginning at [*x1*, *y1*] and ending at [*x2*, *y2*].	
Switch images	Yes	
Typical uses	Annotating images for publication	
Remarks	Either or both end points may lie outside the image;	

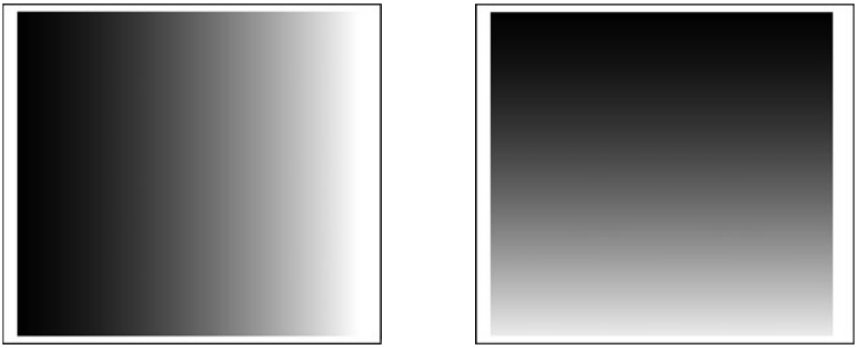
41.357 w/wis

Format	*w*(*a*)
Function	Copy the current image into the image stack
Arguments	*a*
Defaults	0
Output values	None
Image type	Any
Type	User interface
Switch images	No
Function	Synonym for *wis*
Remarks	Alternatively, CNTRL/click on the appropriate thumbnail in Figure 2

41.358 wgx/wgy

Format	*wgx*
Arguments	None
Defaults	Not applicable
Output values	None
Type	Drawing and image generation
Switch	Yes
Function	Draw an intensity wedge; intensity varies linearly with distance across the image
Definition	$c(i, j) \Leftarrow 255*i/I_w$ where I_w is the width of the image
Switch images	Yes
Typical uses	Plotting intensity profiles. Analysing depth maps. Run-length coding. Generating test patterns
Remarks	Use *wgx*, *sca*(*3*) to generate a series of (8) intensity steps. *wgy* is defined in a similar way and generates a wedge in which the intensity varies in the vertical direction

Illustration



Left: *wgx*

Right: *wgy*

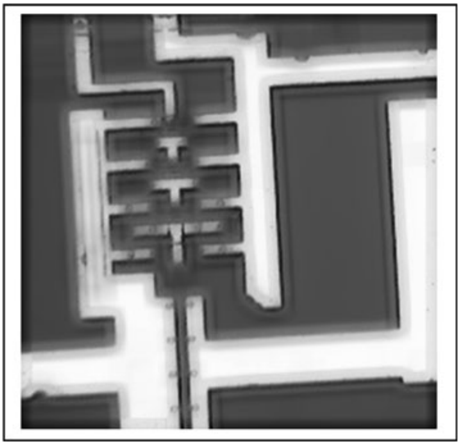
41.359 wnf

Format	*wnf*(*a*, *b*)	
Arguments	*a*	Width of the processing window
	b	Height of the processing window
Defaults	*No arguments*:	$a = b = 3$
	One argument:	$b = a$
Output values	None	
Image type	Grey scale	
Type	Linear filter	
Switch	Yes	
Function	Adaptive filter (Wiener filter), within a rectangle of size a × b pixels	
Typical uses	Defining circularly symmetric filters	
Remarks	The Wiener filter is a type of linear filter that adaptively tailors itself to the local image variance. Where the variance is large, it performs little smoothing and where the variance is small, the Wiener filter performs more smoothing. It often produces better results than fixed-kernel linear filtering (e.g., *raf*, *caf*), as it is more selective; it preserves edges and other high frequency parts of an image better, while reducing noise levels in areas of nearly constant intensity. The Wiener filter works best when the image is degraded with constant-power ('white') additive noise (e.g., Gaussian noise)	

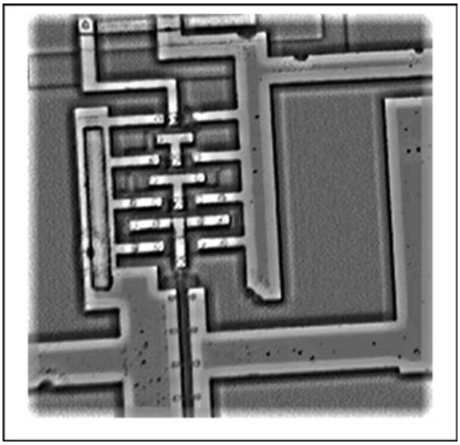
Illustration

Input image	Circuit
File number	257
Command	*wnf(15)*, *sub*, *enc*

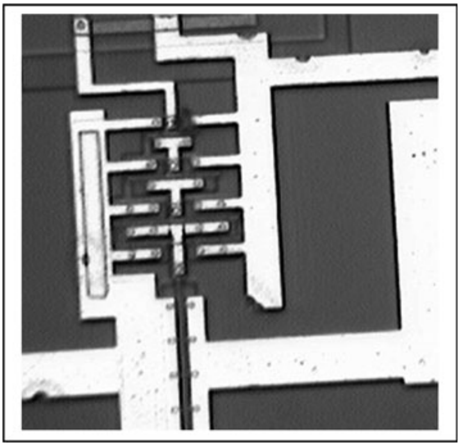
Top-left: original



Top-right: after *wnf(15)*



Bottom-left: after *wnf(15)*, *sub*, *enc* Image size has increased



41.360 wri

Format	*wri*(*a*, *b*)	
Arguments	*a*	File name/number
	b	0, save as TIFF file (loss-less, image can be reproduced exactly), or 1, save as JPEG file (compact image is degraded slightly)
Defaults	*a*	0
	b	0, save as TIFF file (loss-less, image can be reproduced exactly)
Output values	*d*	File path
Image type	Any	
Type	Input/output	
Function	Save the current image in TIFF format (if $b = 0$) or JPEG format ($b = 1$)	

Remarks: The file name (*a*) can be a number, or character string. An image saved in TIFF format can be read back again, using *rei*. Example:

Write: *wri*(*123*)   Read: *rei*(*123*)

The image is saved in a folder called *QT_work_files*, which must be located on MATLAB's search path. Sample commands:

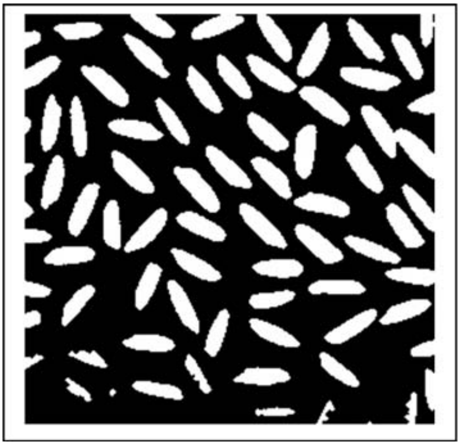
Command	Equivalent to	Image type
wri	wri(0, 0)	TIFF
wri(123)	wri(123, 0)	TIFF
wri(123, 1)	wri(123, 1)	JPEG
wri('im_file12')	wri('im_file12', 0)	TIFF

Also see *wsi* and *w*

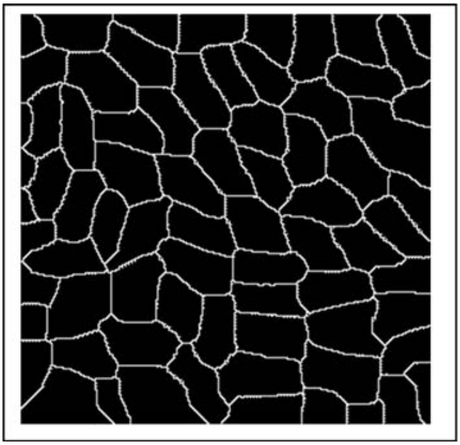
41.361 wsh

Format	*wsh*(*a*)
Arguments	*a* Connectivity (*a* = 4 or 8)
Defaults	*a* 8
Output values	None
Image type	Binary
Type	Blob transform
Switch	Yes
Function	Watershed function
Definition	The output of *wsh* is an image in which white pixels indicate points that are equidistant from the two (or more) nearest blobs
Switch images	Yes
Typical uses	Analysis of granular materials and webs that are sparsely populated with 'point' features
Remarks	The image resembles a honey-comb; each 'cell' consists of a 4- or 8-connected set of points each of which perceives the same blob in the input image as its nearest neighbour
Illustration	
Input image	Rice grains (file number 3) after thresholding and clean-up
Image generation	rni(3), enc, thr, ero, dil
Command	*wsh or wsh*(*8*)

Left: original



Top-right: after *wsh*



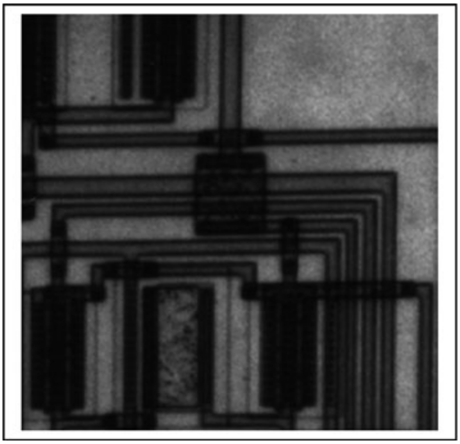
41.362 wsi

Format	*wsi*(a, b)	
Arguments	a	Multiplier for current image, before addition
	b	Multiplier for alternate image, before addition
Defaults	No arguments:	$a = b = 0.5$
	One argument:	$b = 1 - a$
Output values	None	
Image type	Grey scale or binary	
Type	Combining two images	
Switch	Yes	
Function	Linear weighted sum of the current and alternate images	
Definition	The current image is multiplied by a and the alternate image by b. These weighted images are then added together	
Typical uses	Defining new types of image filter, by adding outputs from standard filters together	
Remarks	In the illustration below, the output of *sed* (Sobel edge detector) is used to enhance the ‘crispness’ of an image	

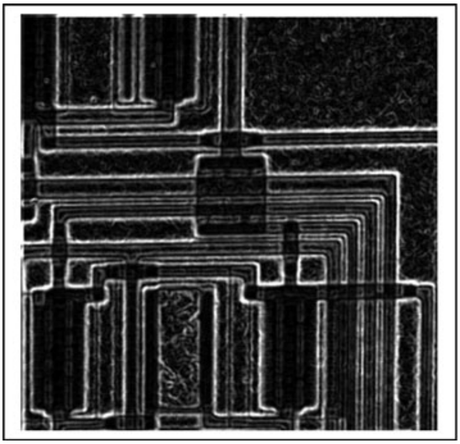
Illustration

Input image	Circuit
File number	136
Commands	*rni*(*136*), *sed*, *enc*, *rni*(*136*), *wsi*(*0.75*), *enc*

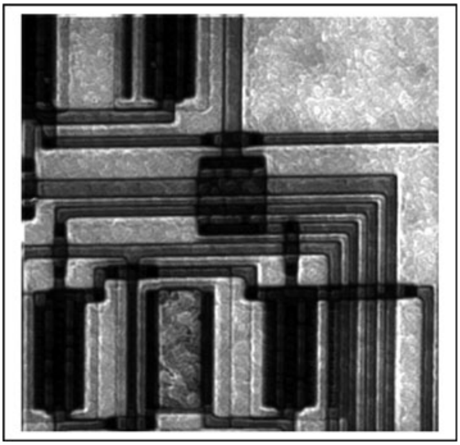
Left: original



Right: after *sed*, *enc*



Bottom-left: after processing



41.363 xyl

Format	[*xmin*, *xmax*, *ymin*, *ymax*] = *xyl*(*a*)	
Arguments	*a*	Function control
Defaults	*a*	0 (Do nothing, except calculate limit values)
Output values	*xmin*	Minimum X-coordinate
	xmax	Maximum X-coordinate
	ymin	Minimum Y-coordinate
	ymax	Maximum Y-coordinate
Image type	Binary	
Type	Measurement and anlysis	
Function	Calculate the minimum and maximum X and Y limits considering all white points. Three other functions are selected by the input parameter *a*:	
	a = 0 (default)	Do nothing else
	a = 1	Draw smallest enclosing rectangle
	a = 2	Crop at smallest enclosing rectangle
Switch images	No	
Typical uses	*bbx* and *mar* operate on a single blob, whereas *xyl* considers all white pixels. Also see *blp*/*brt*/. . .	

41.364 xyz

Format *b* = *xyz*(*a*)

Arguments *a* Text string

Default *a* Allowed

Output values *b* Text string

Image type Not relevant

Type Test m-function

Function Demonstrating/testing the update operator (*qtu*). *xyz* has no other useful function

Switch No

Remarks Updating of QT operators can be demonstrated thus:

1. Delete the file *xyz.m* from the folder *QT_new_mfunctions*
2. Enter *qtp*(*0*) (This ensures that all uploaded functions are ignored)
3. Run any one of the following, with or without the semi-colons.
   xyz; *q* = *xyz*; *q* = *xyz*('*My message*');
4. Enter *qtu*('*xyz*'). This down-loads Version 2 but does not run it. Check this, by inspecting the folder *QT_new_mfunctions* again
5. Repeat Step 3. Notice that this runs Version 1 of *xyz* again
6. Enter *qtp*(*1*). This enables the updated version to be run (in Step 9)
7. Repeat Step 3. This time, Version 2 of *xyz* runs

Notice that the user can switch between Versions 1 and 2 by repeatedly running *qtp*, *qtp*(*0*) or *qtp*(*1*)

41.365 yxt

Format *yxt*

Arguments None

Defaults Not applicable

Output values None

Image type Grey scale or binary

Type Affine

Switch Yes

Function Interchange the vertical and horizontal axes

Definition $C(j, i) \Leftarrow A(i, j)$

Switch images Yes

Remarks Non-square images will produce a result that cannot be combined with the original by using dyadic operators: *adi, sub, mni, mxi,* etc. Also see *bxy*

41.366 z

Format	*z*
Arguments	None
Defaults	Not applicable
Output values	None
Image type	Any
Type	Miscellaneous
Function	Interchange the current and alternate images
Remarks	A quick alternative to *swi* (The closest that MATLAB can approach *CNTRL/Z*)

41.367 zed

See *ced*

41.368 zer

See sci

Appendix A: Glossary

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

The following terms are defined in the context of Machine Vision, even though some have a wider range of use. Relevant terms relating to visual perception in humans and animals are also included but anatomical and physiological features of biological vision systems are not. Notice that British spelling is used.

2D. 2 dimensional.

2-dimensional (colour) scattergram. Derived by plotting one colour component against another, on a point-by-point basis, for a polychromatic image. E.g., we might plot the amount of red light against the amount of blue light.

2-dimensional array. (a) See Array-Scan Camera. (b) Digital image represented by a 2-dimensional matrix or array.

3D. 3-dimensional.

4-connected. In a binary image, pixels P and Q are 4-connected if P is a 4-neighbour of pixel Q, or P is a 4-neighbour of pixel R and R is 4-connected to Q. A blob is said to be 4-connected if all its members are 4-connected to each other.

4-neighbour. The 4-neighbours of a pixel (i, j) in a digital image are located at (i − 1, j), (i + 1, j), (i, j − 1) and (i, j + 1).

8-connected. In a binary image, pixels P and Q are 8-connected, if P is a 8-neighbour of pixel Q; or P is a 8-neighbour of pixel R and R is 8-connected to Q. A blob is said to be 8-connected if all its members are 8-connected to each other.

8-neighbour. The 8-neighbours of a pixel (i, j) in a digital image are located at (i − 1, j − 1), (i − 1, j), (i − 1, j + 1), (i, j − 1), (i, j + 1), (i + 1, j − 1) (i + 1, j) and (i + 1, j + 1).

A

Aberration. Failure of an optical lens to produce an exact point-to-point correspondence between the object and its resulting image. Types: chromatic, spherical, coma, astigmatism and distortion.

Absorption. Loss of radiant energy (e.g., light) as it passes through a transparent medium, such as glass, water, etc. Absorption is a function of wavelength, type of material and path length.

Accuracy. Performance parameter for a vision system that derives numeric value(s). (e.g., position/orientation of a specified feature) Not to be confused with Precision. (q.v.).

Achromatic (colour). A neutral colour such as black, white or grey (also see Chromatic).

Achromatic response function. (Also see Chromatic Response Function.)

Achromatopsia. (See Central Achromatopsia.)

Acousto-optic scanner. Type of scanning element in a flying spot scanner in which the scanning is performed by a laser beam directed through a piece of glass or clear crystal driven by a piezoelectric transducer. The glass behaves like a diffraction grating with a number of lines per mm proportional to the exciting frequency. By varying the exciting frequency a scanning action is produced.

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_42,

Active Illumination. Illuminating a scene with a light source that is co-ordinated with image acquisition. Examples: strobed flash tubes, steered structured light beams, Scanned LIDAR (q.v.) beams.

Additive mixture (of light). A mixture of light rays of various wavelengths, which reach the eye, creating an impression of colour that none of them alone might provide Ciné film, television and computer displays rely on light addition. (Also see Subtractive Mixture.)

Add-on lens. a simple lens that screws onto the front of a lens assembly and alters its Focal Length (q.v.) and Minimum Object Distance (q.v.). Also see Diopter, Extension Tube.

AGC. See Automatic Gain Control.

Algorithm. A sequence of well-defined computational steps, for solving a problem. Unlike an Heuristic (q.v.), an algorithm has a precisely known outcome, within a given input domain, although the term is often used informally, to include heuristics as well.

Aliasing. Phenomenon which gives rise to spurious results if an image is sampled at a spatial frequency below the Nyquist limit.

Ambient light. Light present in the optical environment of an imaging system that is generated from uncontrolled "external" sources, such as room lights, sun-light, light from nearby (human) operator's work-station, etc. Ambient light is unpredictable and highly variable. It therefore represents a major source of noise for a vision system.

Analogue (or analog). A smooth, continuous signal, voltage, current, or other physical value, representing a real number.

Analogue-to-Digital Converter (ADC). Device for converting an analogue signal into a series of discrete, digitally-encoded numbers (integers), for processing in electronic hardware or a computer.

Anamorphic mirror. Mirror that produces different magnifications along different directions in the image plane. Other distortion effects are also possible.

Angle of view. Angular width of the cone in 3D space within which objects are visible to a camera.

Angstrom. Unit of length: 10^{-10} m, 10^{-4} μm.

Anomaloscope. An instrument used for detecting anomalies of colour vision. The test subject adjusts the ratio of two monochromatic lights to form a match with a third monochromatic light.

Anomalous trichromacy. Abnormality in human vision in which there are three functioning cone types but one or more of them has abnormal spectral sensitivity. As normal, people with this condition require three primaries for colour matching but accept matches that normal subjects will not.

Aperture response. Cross-sectional sensitivity profile of a photosensitive element forming part of a solid-state array.

Aperture. Controls the amount of light passing through a lens. The F number scale (1.4, 2, 2.8, 4, 5.6, 8, 11, 16) for a standard photographic lens reduces the amount of light passing through the lens by half with each step increase in the scale.

Architecture. Organisation of the opto-electronic hardware of a vision system.

Array processor. Hardware accelerator for arithmetic calculations, using parallel processing (SIMD) techniques.

Array representation. Digital image representation in the form of a 2D array of pixels. Allows binary, monochrome (grey-scale) and colour images to be coded.

Array-scan camera. Imaging device in which photo-detectors are packed in a 2D array. Cameras used for broad-casting are invariably array-scan type.

Artifact. An artificially created structure (by accident or on purpose), form or shape, usually part of the background, used to assist in measurement or object location.

Artificial Intelligence. Subject of academic study devoted to providing computers with capability of performing functions normally attributed to human intelligence: learning, adapting, recognising, classifying, reasoning, self- correction and improvement.

Aspect ratio. Width:height ratio of a video image. (Broadcast standard is usually 4:3.)

Aspherical lens. Lens, or lens, assembly which has one, or more, non-spherical surfaces. Used principally to reduce spherical and other aberrations.

Assimilation. A perceptual phenomenon in which the colour of part of a scene is perceived as closer to the colour of the surround than it would if viewed in isolation. A thin coloured stripe between two black bars will look darker than it would between two white bars. (Also known as the *Von Bezold spreading effect.*)

Astigmatism. Optical aberration in which, instead of a point image being formed of a point object, two short line images are produced at right angles to each other.

Asynchronous camera. Video camera in which the scan starts on demand, rather than waiting for the end of the present frame period.

Auto iris lens. Lens whose aperture automatically adjusts itself to allow for variations in the ambient light.

Autocollimation. Procedure for collimating an optical instrument with objective and cross hairs in which the instrument is directed towards a plane mirror and the cross hairs and lens are adjusted so that the cross hairs coincide with their reflected image.

Autocorrelation function. Image correlated with itself shifted by various amounts. See Correlation.

Auto-focus. Facility in an imaging system allowing it to control the focus of the lens, to obtain the sharpest image on the detector.

Auto-iris lens. Lens with an electronically controlled iris. Maintains nearly constant mean light level when light conditions vary. Useful addition to AGC. (q.v.).

Automatic gain control. Function of a circuit (e.g., video amplifier) whose gain is automatically adjusted to allow for changes (in ambient light). In a video camera, the system gain is changes in an attempt to maintain a constant mean output level. Hence, as the input light level decreases, the gain increases, thereby maintaining a constant video level. Also see Auto-Iris Lens.

B

Back light compensation (BLC). Camera function used to avoid blooming and other effects of optical over-load.

Back-focal length. Distance from the rear surface of a lens to its focal plane.

Back-ground. That part of a scene behind the object to be inspected. Also used to describe the region surrounding a blob-like figure in a binary image.

Back-lighting (Back-illumination) Lighting arrangement for generating a high-contrast image of an object, by forming its silhouette.

Back-propagation. Training scheme for a neural network, by adjusting weights in the hidden and input layers.

Baffle. shield used to block light from entering/leaving an optical system.

Band-pass filter. Optical, electronic or image filter, which allows a narrow range of frequencies/wave-lengths to pass, blocking all others.

Bar code. Product/document/carton identification system that employs a series of machine-readable lines of varying widths of black and white. Usually read with a laser scanner.

Barrel distortion. Imperfection of an optical system in which a rectangle appears to bulge on all sides. Opposite of Pin-Cushion Distortion (q.v.).

Basic colour term. A word naming a basic colour category. (e.g., red, yellow, etc. but excluding terms such as “reddish-yellow”).

Bay. Imagine that a blob in a binary image is an island. A bay is an area of sea between headlands. One type of constituent part of the Convex Deficiency (q.v.) of the blob.

Beam expander. Optical system for increasing the width of a light beam.

Beam splitter. Partially silvered or aluminised mirror which splits an incident beam of light into a reflected beam and a perpendicular transmitted beam’. Other forms of beam splitter are also available.

Bezold-Brücke hue shift. A shift in the apparent colour of a long-wavelength stimulus towards yellow or blue as intensity increases. If a pair of long-wavelength lights differing only in intensity are compared, the brighter one will appear to be more yellow (less red) than the other. At short wavelengths, the higher intensity light will appear more blue (less green). There are three invariant points in the spectrum at which the colour appearance of monochromatic lights does not change with intensity. (See Invariant Hue.)

Binary hue. A hue that is perceptually mixed. E.g., orange appears to be a mixture of red and yellow. All binary hues are mixtures of two of the unique hues.

Binary image. Image in which each pixel can be represented by only the two binary digits 0 or 1, (i.e., black or white).

Birefringence. Phenomenon in certain naturally occurring materials, such as fluorspar, that has different refractive indices for light with horizontal and vertical polarisation.

Bit map. Representation of an image, graphics or characters by a 2D array of pixels arranged in rows and columns. In image processing, it is more common to refer to this an array representation.

Blanking. Interval during raster-scanning when the video signal is suppressed. (Originally introduced to allow frame/frame/field fly-back in CRT cameras.)

Blob analysis. Identification and measurement of distinct objects in an image, based on their geometric properties (e.g., area, perimeter, shape factor, length, number of holes).

Blob. 4- or 8-Connected (q.v.) blob-like shape in a binary image

Blooming. An effect by which a highly illuminated point on an image sensor spreads out to form a disc; caused by the high intensity of the incident beam saturating the image sensor at that point.

Borescope. Device for internal inspection of pipes, engines, gun barrels, etc. Used where access is difficult. It consists of a long narrow tube, containing a telescope optical system, with a number of relay lenses. Light is provided via the optical path, LEDs or fibre-optic bundles. A 45° mirror at the end allows inspection of tube walls. Also called endoscope.

Boundary. Curve delineating the boundary between two image regions, separated by intensity, colour or texture.

Brewster’s Angle. Angle of incidence for which a light wave polarised in the plane of incidence is totally transmitted at a dielectric boundary (about 67.4° for air-glass).

Brightness. That attribute of a visual sensation in which parts of a scene appear to emit more/less light than others. Often used synonymously with Intensity (q.v.). (Also see Luminance.)

Buried channel CCD. Type of CCD with a buried layer of doping material which together with the electrodes causes the charge packets to move below the surface; giving a high-charge transfer efficiency.

C

Calibration. Procedure for relating image- and world co-ordinates. Important for both metrology and robot control. May require use of specially made calibration targets, i.e., objects/charts with known dimensions.

Camera format. Length of the diagonal of a camera photo-detector array, or the diameter of a CRT camera. Standard sizes: 1″, 0.667″, 0.333 and 0.25″.

Candela. Unit of luminous intensity defined as 1/60th of the luminous intensity per cm^2 of a black body radiator at the temperature of freezing platinum.

Canny. Name of a type of Edge Detector. (q.v.).

Carbon dioxide (CO_2) laser. Powerful, continuous, IR laser that can emit several hundred watts at a wavelength of 10.6 μm. Used for welding and cutting.

Catadioptic. Mirror-lens assembly providing the function of a light-weight, long-focus (telephoto) lens. When the object-camera distance has to be large, a catadioptic system can be very effective, providing a brighter, clearer image than a multi-element lens assembly. However, the large working distance requires vibration-free mounting of the camera, to avoid image blur.

CCD. See Charge Coupled Device. Popular solid-state image sensor; the "work-horse" for the MV industry. Implemented with standard large scale integration technology. In a *Frame-transfer CCD*, the charge pattern, representing the entire image, is transferred from the sensing area to an on-chip storage buffer. From here it can then be sampled at random, to generate an RS170, CCIR, or a non-standard raster-scan video signal. The output from the camera is always one frame behind the image currently being captured.

CCPD. See Charge Coupled Photodiode Array.

Central achromatopsia. A defect of colour vision due to damage to the Visual Cortex (q.v.) or other parts of the brain. (The more common forms of colour defect are due to photoreceptor loss or abnormality.)

Centroid (properly *Geometric Centroid*). Standard method for defining blob positions in a digital image. The co-ordinates of the centroid of a blob-like object S are determined by calculating the centre of mass of a uniform laminate object with the same outline as S. In practice, the moments $M_{0,1}$ and $M_{1,0}$ are computed.

Chain code. Code used for describing a curve such as the periphery of an object. Each discrete point on the curve is represented by an integer from 0 to 7, representing the direction of the next point as an angle ranging from 0° to 315° in 45° steps. If the number of possible directions of travel is reduced to four (0°, 90°, 180° and 270°), the resulting sequence is called a Crack code.

Chalnicon. Type of vidicon with high resolution and sensitivity; not easily damaged by intense light.

Character. Single printed, typed or hand-written letter, digit, punctuation mark, mathematical or other symbol. Usually represented within a computer using one byte of storage.

Charge coupled device (CCD). Monolithic semiconductor device arranged as an array of elements such that the output from one element provides the stimulus for the next. Implemented with standard large scale integration technology. In a *Frame-transfer CCD*, the charge pattern, representing the entire image, is transferred from the sensing area to an on-chip storage buffer. From here it can then be sampled at random, to generate an RS170, CCIR, or a non-standard raster-scan video signal. The output from the camera is always one frame behind the image currently being captured. This is the most popular camera for the MV industry.

Charge coupled photodiode array (CCPD). Image sensor which combines the best properties of CCDs (low noise, high clock rate) and photodiode arrays (good spectral response, resistance to blooming), i.e., the image sensors are photodiodes but the scanning function follows the principles of operation of a CCD.

Charge injection device (CID). Charge transfer device used as an image sensor in which the image points are accessed by reference to their Cartesian co-ordinates. CIDs have low dark current but are relatively noisy. A CID array can be sub-scanned (i.e., a small ROI (q.v.) is sampled), addressed at random and read without destroying stored information. It is resistant to optical overload. Photo-detector sites are contiguous on the chip, providing the maximum area for capturing light.

Charge transfer efficiency. Efficiency with which charges are transferred between neighbouring locations in a CCD.

Chirality. Property of the shape of a blob. By "turning over" the shape, the chirality is reversed. Is used to determine Handedness. (q.v.).

Chirp scanner. Type of acousto-optic scanner excited by a "chirp" pulse, i.e., a pulse of linearly increasing frequency. The pulse, as it moves through the crystal, produces the effect of a travelling lens which performs the scan.

Chroma. Subjective measure of the amounts of pure chromatic colour present, irrespective of the amount of achromatic colour. For colours of the same hue and brightness, chroma and saturation are equivalent. Chroma increases with brightness, even if saturation is constant. Chroma is used in the Munsell Colour System (q.v.).

Chromatic. All colours other than the neutral colours (i.e., white, black, and pure grey) are chromatic. The word "colour" in ordinary language is often used to refer exclusively to chromatic colours. For example, we refer o to "coloured socks".

Chromatic aberration. An optical aberration in which the component colours in a point source of white light are brought to a focus at different points; caused by the variation of the refractive index of the glass with wavelength.

Chromatic response function. Perceived colour expressed as a function of the wavelength of a stimulus.

Chromaticity coordinates. Coordinates that specify position in a chromaticity diagram. (See CIE.) The chromaticity coordinates (x, y, z) are derived from the tristimulus values (X, Y, Z) by the formulae $x = X/X + Y + Z$, $y = Y/X + Y + Z$.

Chromaticity diagram. A diagram that represents the plane defined by the equation $X + Y + Z = 1$ in a Tristimulus Space (q.v.). Points in this plane represent variations in variations in the orientation of the vector [X, Y, Z] (hue and saturation) but not its length (intensity). (Also see CIE.)

Chromaticity. Denoted by a point in a chromaticity diagram. Chromaticity is often used as a convenient way to approximate hue and saturation, while ignoring brightness.

Chromophore. Light-absorbing part of a photo-pigment. In mammals and humans, the chromophore is a form of vitamin A, called *retinal.* The photo-pigment dissociates into two parts (opsin and chromophore) in response to the arrival of a photon of suitable energy, thereby evoking the visual response. The differences in spectral sensitivity among photo-pigments are due to variations in the structure of their opsins.

CID. See Charge Injection Device.

CIE (Commission Internationale de l'Eclairage). International body that recommends standards and procedures for quantifying lighting and colourimetry. *CIE Chromaticity Diagram.* Diagrammatic representation of the chromaticity co-ordinate system used to represent colours, by relating two of the normalised standard primary colours.

CIE illuminant C. Standard illuminant (i.e., idealised light source) that is an approximation to average daylight. Specified by its spectral power distribution.

CIE Standard Observer. A set of tri-stimulus values providing a standard and objective way of describing the colours of different light sources. While few people agree completely with the colour classification provided by the Standard Observer, it is close to what most people with normal colour vision regard as reasonable. More than one Standard Observer has been defined, to accommodate a variety of different viewing conditions.

Classification. Assignment of patterns/features/images/objects, etc. to one of two, or more, sets (classes) whose members are distinguished by some ill-defined notion of "similarity." A device for performing classification is called a *classifier* and is usually designed through self-adaptive learning.

Closing. Morphology operator useful for "filling holes" and smoothing edge boundaries in a binary image. Equivalent to *dilation* followed by Erosion. (q.v.).

C-mount. Standard threaded lens mounting for a video camera. A 1″ × 32 thread is employed. Distance from the shoulder of the lens to the image plane is 17.52 mm. A C-mount lens may be used on a CS-Mount (q.v.) camera, but a 5mm-adapter ring is required.

Coaxial illumination and viewing. Collimated front illumination, parallel to the camera's optical axis, produced by introducing a Beam Splitter (q.v.) in front of the camera.

Coherent fibre-optic bundle. Bundle of optical fibres which preserves the spatial relationship between its input and output. Also see Image Conduit.

Coherent illumination/light. Lighting in which the wave-front is well defined e.g., lies on a plane normal to the direction of travel.

Collimator. Optical device for producing a parallel beam of light.

Colour. Refer to items in this glossary using the British spelling*: colour.*

Colour anomia. Inability of a person to name colours, despite intact colour vision as demonstrated by non-verbal tests.

Colour constancy. Stability in the perceived colour of a surface with varying illumination.

Colour space. An abstract 2D-, 3D- or hyper-space for representing colours so that the similarity relationships that exist among them are preserved.

Colour temperature. The temperature of the perfect black-body radiator whose chromaticity is closest to that of a given light source. Colour temperature is often used as a convenient way to specify the quality of a light source, rather than completely defining its spectral power distribution. Colour temperature is most appropriately applied to sources that have broad, smoothly changing spectral power distributions.

Colourimetry. The science of measuring colour by matching. The main focus of colourimetry has been the development of methods for predicting perceptual matches on the basis of physical measurements.

Colour cube. Refers to a 3-dimensional space in which we plot the RGB colour information.

Colour scattergram. Graphical representation of the colour variation to be found in a scene and consists of a set of points superimposed onto the colour triangle. It is convenient, in practice, to plot the colour scattergram as an image, so that it can be filtered, threshold and processed using the usual image processing software.

Colour Space. A 2- or 3-dimensional space representing colour using a quantitative co-ordinate system. Provides an absolute and objective definition of colour. Common colour-space representations: RGB, HSI, LAB and CIE. (q.v.).

Colour Temperature. A concept in Colour Science describing the *apparent* visual appearance of a source of radiation, not its actual temperature.

Colour triangle. Abstract geometric figure that is useful when analysing and discussing colours. Each point in the triangle corresponds to a different colour in the scene being viewed. Points that are close together usually have similar colours.

Colour. A sensation created in the visual system of human beings (and certain higher animals) by varying wavelengths of light falling on the retinal rods. Cones are not sensitive to colour changes. A variety of factors, including culture, language, drugs, ageing and disease, affect human perception of colour. Colour categories can only be defined subjectively. Colour Science is the study of colour perception in nature and guides the design of printing, photography, television and computer displays, as well as paint mixing and even the automobile and fashion industries.

Coloured. Term used to signify an object or scene that has some discernible colour, other than neutral, which has low values of saturation.

Colourimetry. Experimental techniques in which colour is assessed against objective, quantitative scales, or by comparison with stable reference surfaces.

Coma. Optical aberration of an optical system which gives a point object a pear shaped image.

Complementary colours. Two colours that can be additively mixed to produce an achromatic colour. (See Additive Mixture.)

Composite Video. Electrical signal combining (a) analogue wave-form representing a succession of intensity profiles across an image, (b) horizontal synchronisation pulses, (c) vertical synchronisation pulses and (d) blanking signals.

Computer Vision. The science and mathematical theory of artificial vision systems. The subject is concerned principally with solving "difficult" problems using sophisticated computational procedures. It is academic rather than practical.

Concavity tree. Hierarchical description of a blob in which each Bay (q.v.) and Lake (q.v.) is represented (recursively) by a concavity tree. The nodes in the tree can be labelled in a variety of ways. Combines local and global shape information. Can be used to determine Chirality (q.v.) in an absolute sense. Also see Handedness.

*Concurrent processo*r. Computer system architecture that lends itself very well to inspecting objects on a conveyor belt. It consists of a number (N) of identical processing units but which operate [360/N] degrees out of phase in their execution cycles.

Condenser Lens. Used to collect and redirect light from an odd-shaped source (such as a curved lamp filament), to provide better-controlled illumination. Often used to collect light from a small lamp and project a near-uniform light beam onto an object. May be combined with a concave mirror, behind the light source, to collect more light.

Cone. One of the two main classes of photo-receptor found in the vertebrate eye. Cones produce respond to relatively high levels of light and provide the main sensors for colour vision. There are three types of cones in the normal human eye, each type being most sensitive at a different point in the spectrum.

Confusion line. A line on a chromaticity diagram representing colours that are not discriminable by a subject with a particular defect of colour vision. For example, the protan confusion line represents colours that are indistinguishable by person with Protanopia (q.v.).

Conjugate points. In optics any pair of points such that all rays emanating from one point are imaged at the other.

Connectivity analysis. Determining sets of 4- or 8-connected pixels in a binary image, in order to isolate distinct blob-like objects, which are then measured individually.

Connectivity paradox. An 8-connected arc of unit width should bisect the image plane. In fact, pixels adjacent to that arc, on opposite sides, are 8-connected to each other.

Connectivity. Topological property of a binary image related to the number of 'holes' (lakes) it contains.

Contrast. Synonymous with Spatial Contrast (q.v.) that the darkest pixel becomes black and the brightest white. Stretching the intensity scale improves subjective contrast and hence visibility but does not usually assist feature detection.

Contrast transfer function. Complex function of spatial frequency characterising an optical system; gives a measure of the extent to which an optical system degrades the contrast of a test pattern of equally spaced lines with a square wave intensity profile. Loosely called modulation transfer function.

Convex deficiency. The set of points within a convex hull that are not in the object. It includes *Lakes* (regions totally enclosed by an object), and *Bays* (regions lying between the convex hull perimeter and the object).

Convex hull. Shape obtained by stretching a rubber band around a given blob-like object.

Convolution. Image filtering operation. Typically, a linear weighted sum of the intensities is computed for each M × N Neighbourhood (q.v.) in the input image (e.g., 3 × 3, or 5 × 9, 11 × 7 mask). Operators of this kind are able to enhance edges, blur/sharpen images remove noise and detect small spots.

Correlation. Mathematical measure of the similarity between (parts of) images. The correlation score (S) is formed by deriving the sum of the squares of the differences between intensities within the two images to be correlated. One image is shifted relative to the other to obtain the best fit (i.e., to maximise S). Also called Template Matching. (q.v.).

Crack code. See Chain Code.

Crack detector. Non-linear local operator, intended to detect thin, dark streaks and small spots. Latterly, identified in the terminology of mathematical morphology as: [*dilate; erode; subtract original image*].

Crack. Thin dark feature in a (grey-scale) image.

Cross talk. Process by which an unwanted signal is induced in a circuit because of its close proximity to a neighbouring circuit. The term can be applied to adjacent photo-sensors in a solid-state array.

CRT (Cathode ray tube). Old-fashioned imaging device. Large, heavy, fragile susceptible to magentic fields, short working life. Image geometry is not fixed accurately. Now largely superceded by solid-state sensors in standard applications but is still used for specialised tasks: UV, IR, low-light, in areas *CS-mount.* Standard mounting for a lens to a video camera. The screw thread is identical to that for the C-mount but the distance from the shoulder of the lens to the image plane is 12.52mm. Hence, a CS-mount lens cannot be used on a C-mount camera.

Cumulative histogram. See Histogram.

D

Dark current. Current that flows in the output circuit of an image sensor even in the absence of illumination.

Dark-field illumination. Method of microscope illumination in which the illuminating beam is a hollow cone of light, formed by an opaque stop large enough to prevent direct light from entering the camera lens; the specimen is placed at the apex of the cone and is seen only with light scattered, diffracted or refracted by the specimen.

Data reduction. Selectively discarding unwanted data, while retaining important information, in an image, or sequence of images, by some suitable coding, algorithm.

Decision tree. Hierarchical classification technique based on classical AI.

Dedicated (vision) system. System which is pre-configured for a specific application. Able to function when plugged in with no further programming. Also called *Turn-key System.*

Denisyuk process. A technique for producing white-light holograms.

Depth map. See Height Map.

Depth of field (Dof). Width of that region on either side of the focal plane, where the image produced by an optical system remains in focus. Normally, a large Dof is advantageous. Normally, a small lens aperture and bright object illumination will improve the Dof.

Depth of focus. The range of image distances over which the image remains sharp for a given object distance.

Depth perception. Ability of a vision system to measure/judge distance from the image sensor (i.e., eye/camera) to the various parts of the scene being viewed.

Descriptive syntactic process. A pattern recognition technique which models an object by a set of features and by the spatial relationships between these features.

Deuteranopia. One of the two varieties of red-green colour blindness (also known as green-dichromacy). People with deuteranopia results have lost the function of the M-Cones but display essentially normal visual sensitivity throughout the spectrum. (Also see Protanopia.)

Diascopic illumination. Form of illumination in which an object is viewed in transmitted light.

Dichoptic matching. A colour matching experiment in which different coloured stimuli are presented separately to the two eyes.

Dichroic filter. Optical filter used to transmit certain wavelength of light and reflect others. Dichroic filters are often built in to quartz-halogen-tungsten lamps, to reduce IR content of output beam.

Dichromacy. Term relating to people possessing two independent channels for conveying colour information. Most "colour blind" people are dichromatic having lost the function of type of cone types. They are not strictly colour blind, since their vision is sensitive to a single chromatic dimension as well as to brightness.

Diffraction pattern sampling. Inspection procedure which compares interference patterns, produced by diffraction, rather than by "direct" viewing.

Diffraction. Wave phenomenon of light whereby the intensity distribution in a wave is spatially redistributed after encountering an obstacle. It accounts for the ability of waves to go round corners.

Diffraction-limited. An optical system is said to be diffraction-limited when its performance is limited only by the wave nature of light and not the more usual optical aberrations. The finite aperture of a lens limits its resolution.

Diffuse lighting. Illumination technique, projecting light onto a matt surface first. This acts as the illuminator for the object being viewed. Baffles avoid direct illumination of the object. Avoids sharp shadows and glinting due to Specular Reflection (q.v.).

Diffuse reflection. Light returned from a matt (i.e., non shiny) surface is diffuse; light is scattered in all directions (above the object surface). It is not strongly polarised.

Diffuser. Translucent material, e.g., polypropylene, used to produce diffuse illumination.

Digital camera. Video camera whose output is already digitised and formatted as a digital image. Interfacing to a computer is simple.

Digital image processing (DIP, or Image processing). Mathematical theory and practice relating to the manipulation of digital images. The term is used in two ways: (a) specifically, to referring to image-to-image mapping procedures and (b) generically, to encompass other processes, such as coding, compression, description and analysis. Computer Vision (q.v.) is usually regarded as being concerned with higher-level functions, such as scene modelling and understanding.

Digital image. Image represented by an array of pixels. Each pixel in a Monochrome (q.v.) digital image is assigned one integer value (typically 8 bits), representing its intensity. Colour digital images require the storage of three integers per pixel representing its RGB colour components. These formats allow easy storage and processing within a computer.

Digital signal processor (DSP). VLSI integrated circuit, designed for high speed arithmetic processing and often imbedded in a dedicated vision system.

Digital-to-analogue converter (DAC). VLSI circuit used to convert digital data (e.g., processed images) into Analogue (q.v.) form, for display on a monitor.

Digitisation. Process of sampling and converting a video, or other analogue, signal into a digital value (i.e., integer) for subsequent storage and processing. (See Analogue-to-Digital Converter.)

Dilation. Morphology operator for binary or grey-scale images. White/bright regions become larger. (Also see Erosion.)

Diopter. Measure of the power of a lens, equal to the reciprocal of its Focal Length. (q.v.) Usually applied to Add-on Lenses (q.v.).

Dispersion. (a) Separation of a beam of light (e.g., by a prism) into its component wavelengths. (Also called chromatic dispersion.) (b) Scattering of light as it travels through a transparent material (e.g., glass, plastic) or fluid (e.g., air, water). Minute material defects, suspended particles and impurities, bubbles, droplets, mist, aerosols, emulsions, smoke, fumes are primary causes of scattering.

Distal. Located away from the point of origin or attachment.

Distortion. Defect of an optical system in which magnification varies with angular distance from the axis, causing straight lines to appear curved.

Dither coding. Display technique, enabling monochrome images to be represented on a binary (i.e., 2-level) screen. Each image pixel (intensity I) is assigned a group of display pixels (binary), arranged in a square. Of these, a number proportional to I are selected at random and switched on. The remainder are off.

Dominant wavelength (of an optical stimulus) The wavelength of the monochromatic light, which when mixed with a specified achromatic light in suitable proportions, subjectively matches the stimulus. The dominant wavelength varies with the choice of achromatic reference. (Illuminant C (q.v.) is an obvious option.) Dominant wavelength is the colourimetric equivalent of Hue. (q.v.).

Dot-matrix code. Method of recording binary data on a packet, product, etc. in the form of a 2D array of spots, which can be read by a simple vision system.

Duality. Relationship that exists between certain pairs of morphological operators. (e.g., Erosion and Dilation, q.v.) If P produces the same result as the sequence [*negate, Q, negate*], then operations P and Q are said to be duals of one another.

Dust. Airborne pollution causes serious damage to vision systems, since it contaminates optical surfaces. (e.g., lamps, diffusing reflectors, lenses, etc.). It is a mistake to use unfiltered compressed air to eliminate dust, since it will deposit oil.

DUV. See UV-C.

Dyadic operator. Image processing operator which combines two input images. See Monadic.

Dye laser. Type of tunable laser in which the active medium is a dye such as acridine red, with very large molecules. Lasing action takes place between the ground state and the continuum of higher excited states.

Dye penetrant. Liquid dye used for detecting cracks or surface defects in non-magnetic materials.

Dynamic aperture. The effective transverse aperture of a linear image sensor which is being mechanically scanned in the transverse direction.

Dynamic range. A characteristic property of any measuring instrument; it is equal to the ratio of the maximum to minimum measurable values of the physical quantity which the instrument was designed to measure. No camera can yet match the dynamic range of the eye, which is about 10^{14}:1.

E

Edge detector. Computational procedure for enhancing edges in images.

Edge point. In a binary image, a white pixel which has a least one black neighbour, or vice versa. In a grey-scale image, a pixel whose intensity value is significantly different from that of at least one of its neighbours. For colour images, edge pixels can be similarly defined, in terms of differences in intensity, hue or saturation.

Electromagnetic (EM) spectrum. A wide range of wavelengths, extending from microwaves to x-rays and gamma rays is potentially useful for imaging. The visible spectrum, VIS (q.v.), forms just a small part of this.

Electron gain. The number of electrons at the output stage of photomultiplier for each photoelectron generated at the photocathode.

Electronic speckle pattern interferometry (ESPI). Holographic technique in which only a speckle pattern characterising an object is recorded as opposed to the full interference pattern used in normal holography; the lower resolution required enables a TV camera to be used as the recording medium with all the added flexibility of computer processing of the image.

Electron-volt. The amount of energy required to move an electron through a potential difference of one volt. (Used to measure energy of sub-atomic particles and photons.)

Emitron. Early form of video camera developed by EMI Ltd., based on the principle of the iconoscope.

Encoder (shaft or position). Provides positional/rotational information for control of image acquisition for web and conveyor inspection systems.

Endoscope. Tube-like instrument widely used in medicine and industry, to view inside regions providing limited access. Now being challenged by small flexible probes, fitted with miniature cameras and LED illumination. Also see Borescope.

Episcopic illumination. Form of illumination in which an object is viewed in reflected light.

Equiluminant. (Equal in luminance) Two light sources may be equally bright to a human observer, although chromatically different (i.e., they have different spectral power distributions).

Erosion. Dual morphological operation of Dilation. (q.v.) Defined for binary and grey-scale images. White/bright regions become smaller.

Error rate. See False-Positive, False-Negative.

Euler number. Topological property of a binary image. Equal to the number of distinct blobs minus the number of holes (lakes).

Extension tube. Short cylindrical threaded tube, inserted between a camera and its lens. Reduces the minimum working distance but is not recommended for use with zoom lenses due to the loss of focus when altering magnification.

F

False positive/negative: Error in a vision system which incorrectly determines that the object being inspected is *acceptable/unacceptable.*

Farnsworth-Munsell 100-hue test. A standard test for deficiencies of human colour vision in which the subject is asked to arrange a set of 100 coloured chips around a circle. People with normal colour vision will usually arrange the chips with very few deviations from the predicted order. On the other hand, people with abnormal colour vision will produce a different arrangement, thereby providing useful information about the nature of their defect.

Fast Fourier transform (FFT). Fast procedure for computing the Fourier transform of a digitised signal or image. Produces an image which is quite unlike the original in appearance. The input is approximated by a linear weighted sum of an harmonically-related series of sinusoids of varying phases.

Feature extraction. Process of measuring image features, in order to characterise an object/image. This data will be used, in a Pattern Recognition system, to classify it.

Feature vector. List of numeric measures of an object (e.g., area, shape factor, number of lakes, etc.) that can be used to classify it.

Feature. Abstract image attribute, such as top-most edge point, centroid, limb-end of the skeleton, centroid of largest bay, etc.

Fibre optics. Flexible bundle of glass, plastic or quartz fibres, with a cladding of lower refractive index. Light is transmitted along individual fibres by total internal reflection. Used for illumination and imaging. See Coherent Fibre Optic Bundle and Image Conduit.

Fibrescope. Optical instrument, similar to a Borescope (q.v.), but uses a flexible, coherent optical fibre bundle. Used to view inaccessible objects.

FIC. See Flexible Inspection Cell.

Fiducial mark. Line, cross or target-like feature, used as a reference for locating/measuring pattern features on a printed document, textile, etc. Usually printed on the edge and removed from finished product by trimming. Occasionally embedded in the pattern itself.

Field curvature. Aberration of an optical system causing the surface of sharpest focus to be curved.

Field of view. (FOV) Cone in space that a vision sensor (eye or camera) can observe. Described by two angles, measuring horizontal and vertical limits of sight. Might also be given as distances measured across the plane normal to the central line of sight.

Field. A frame in an interlaced scanning system, consists of two parts: odd-field and even-field. In an odd-field, odd-numbered lines are scanned. Similarly, for the even field.

Filter. A device or algorithm that selectively transmits certain signals, while attenuating others. In Digital Image Processing (q.v.), a (software) filter might typically accentuate, or blur, regions where the intensity gradient is high. In optics, a colour filter (multi-layer dielectric film) can be used to absorb light within a given band of wavelengths, before it reaches the image sensor. Correct use of optical filters can help to simplify the image processing in a vision system Most optical filters used are wavelength (colour) selective but polarising filters are used to suppress glinting due to specular reflection.

FIR. See IR-C.

Fixture. A device or jig to hold and locate a work-piece during processing or inspection operations.

Flange Focal Length (or the *Flange Focal Distance*) is the distance between the locating surface of the lens mount and the image plane. Its value is practical, not theoretical.

Flexible inspection cell. Lighting and viewing arrangement that provides a variety of lighting conditions, cameras and lenses. Useful for Remote Prototyping (q.v.) of vision systems.

Fluorescence. Emission of light, or other EM radiation, at one wavelength by matter, when it is irradiated at a shorter wavelength. Unlike Phosphorescence (q.v.), the emission lasts only while the stimulating radiation is present. Most people are familiar with UV-to-VIS fluorescence but this is not unique, as the phenomenon also occurs at other wavelengths, e.g., x-ray-to-violet, blue-to-red. VIS-to-IR. Fluorescence plays an important role in the perceived colour of many objects. Many biological materials fluoresce. The unnatural brightness of "day-glo" paints is due to fluorescence.

Fluorescent lamp. Cheap light source, providing a spectrum that is a reasonably good approximation to day-light. Often in the form of long tube. To avoid Aliasing (q.v.) with the camera, it is necessary to drive fluorescent tubes using a high-frequency inverter, operating at about 50KHz. Failure to do so will produce hum bars in the video image.

Flying-spot laser scanner. Scanner used for optical inspection of fast-moving web materials, when very fine detail must be detected. A pencil- or fan-shaped laser beam is scanned across the web, probably by galvanometer mirrors, or a rotating multi-faceted mirror. Light scattered from the surface is collected by a suitable photo-detector (e.g., photo-multiplier tube).

f-number (or f-stop). The ratio of the focal length of a lens to the diameter of its input aperture. For a given lens, reducing its f-number by closing its aperture, increases the image brightness and reduces the Depth of Field. (q.v.).

Focal length. Distance from the Focal Point to the principal point of a lens, or mirror. This is a constant defined by the lens material and geometry.

Focal plane. Plane perpendicular to the lens axis at the focal point.

Focal point. Point at which rays parallel to the axis of an optical system converge or from which they appear to diverge. Most optical systems have two principal foci, produced by rays incident from the left and from the right.

Focus following. Ranging and tracking technique that uses image processing to find the position of best focus of the camera, as the focal-length of its focus is adjusted, and thereby estimate the object-camera distance.

Foot-candle. Unit of illumination equal to 1 lumen (q.v.) per square foot.

Fourier-domain inspection. Inspection protocol based on parameters derived from the Fourier transform of an image. 1D and 2D periodic patterns and textured images are appropriately analysed in this way.

Fovea The central area of the human retina, containing the densest concentration of photo-receptors (i.e., cones only). It also possesses other adaptations for high resolution vision.

Frame buffer. Digital image store in a frame grabber or image processing hardware.

Frame grabber. Interface unit that connects a video camera to a computer. On command from the associated driver software, it samples the video signal and creates a digital image that is then be transferred to the computer's memory for subsequent processing. Also see Variable-Scan Frame Grabber.

Frame. Video picture, representing a snapshot of a scene, with an effective exposure time of 40 ms (Europe) or 33.3 ms (USA). In an interlaced system, it comprises one odd- and one even-field. See Field.

Freeman code: See Chain Code.

Frei-Chen. Name of a type of Edge Detector. (q.v.).

Fresnel lens. A thin lens constructed in the form of a series of prismatic ridges, giving a conventional lens. Very large lenses can be produced. Image quality is inferior to a lens but may be adequate for many Machine Vision applications.

Front focal length (or *Front focal distance*, *FFD*) is the distance from the front focal point of the system to the vertex of the first optical surface.

Front lighting. Illumination from source(s) on the camera side of an object, enabling its surface features to be observed.

f-stop. See f-Number.

FUV. See UV-C.

G

Gallium arsenide laser. A laser that emits infrared radiation ($\lambda = 900$ nm) at right angles to a junction region in gallium arsenide. Since it can be modulated directly at microwave frequencies, it is useful for optical communication. Cryogenic cooling is required.

Gamma (γ). Numeric parameter describing the power-law relationship between the intensity of the optical input (I) to a camera and its output signal (S). The formula is of the form $S = K.I^{\gamma}$, where K is a constant. If $\gamma = 1$, the camera is linear but produces a lower contrast compared to cameras in which $\gamma > 1$.

Gamma correction. Non-linear transformation, of the form $Y = X^{-\gamma}$ performed electronically and applied to a camera output to make its response approximately linear.

Gamma ray. Short-wave-length, penetrating EM radiation, emitted by certain radio-active isotopes. Wave-length is shorter than that of x-rays. Gamma-rays are highly dangerous, being a prime cause of cancer. Although conceptually very simple, gamma ray imaging requires highly sophisticated handling techniques. Gamma-ray cameras are used in astronomy and for medical imaging. Potentially very useful for industrial inspection, providing a flexible alternative to x-rays but are not popular on account of the dangers.

Gauging. Non-contact dimensional examination of an object to determine whether it conforms the specified physical dimensions.

Geometric transform. Type of image processing operator in which the transformed image is still recognisable but is rotated, distorted or warped.

Glancing illumination. See Low-Angle Illumination.

Glinting. Shiny, specular reflections from polished, glossy, wet, or oily surfaces.

Global operator. Image processing operation applied to the whole image. c.f. *Region of interest.*

Gradient (of intensity). Gradient (of intensity). Strictly, the magnitude of the first derivative of the (continuous) intensity function with respect to the image co-ordinates. When processing digital images, it is necessary to accept an approximation. The direction of maximum gradient is used less often but is valuable for analysing texture and surface geometry, given knowledge about the angle of illumination from a point source. See Edge Detector.

Gradient vector. The orientation and magnitude of the rate of change in intensity at a point or pixel location in the image.

Grassman's laws. Empirical laws governing the results of additive colour mixing. (See Additive Mixture.) Grassman's laws assert the existence of exactly three dimensions of variation in perceived colour: *hue*, *brightness*, and Saturation. (q.v.) In addition, they imply that colour mixing is linearly additive: if stimulus A matches stimulus B, and stimulus C matches stimulus D, then the additive mixture of A and C will match the mixture of B and D, irrespective of their spectral composition.

Grating (Human vision). A convenient test pattern consisting of alternating stripes, which can differ in colour (chromatic grating), or brightness (achromatic grating).

*Grating (*optical element). Array of uniformly-spaced opaque stripes with transparent spaces between. A fine grating can separate (disperse) different wavelengths of light. Also used for *Moiré* and Structured-Light Projection Techniques. (q.v.).

Grey level/scale. Numerical representation of brightness in a monochrome image. Typically, black is represented by zero, white by some positive constant (e.g., $255 = 2^8 - 1$) and grey by intermediate integer values.

Grey-scale image. Consists of an array of pixels, each of which can have more than two intensity values.

GUI. Acronym for *Graphical User Interface.* Macintosh and Windows operating systems both enable GUI operation.

H

Hair. Fine white arcs in a binary image. (One/few pixels wide.) c.f. *Crack.*

*Handednes*s. Refers to the function of the widget from which a blob in a binary image was derived. For example, a certain blob may represent the silhouette of a piece of leather used to make a right-handed glove. If we turn over that piece of leather, its Chirality (q.v.) changes but its handedness does not. (It is still part of a right glove.)

Hardware. Electronic image-processing equipment designed specifically for applications requiring high-speed operation. Probably of fixed/limited functionality.

Hard-wired. Relatively inflexible electronic circuit designed to perform a specific function. While software could perform the same function it would probably be slower.

HDTV (High Definition television). Modern broadcast standard for terrestrial and cable television. Not much used for Machine Vision.

Height map. Digital image in which intensity measures the 3D profile of an object or surface.

Height. Point measurement of object profile. Normally found by measuring distances from the sensor. Used synonymously with *Range or Depth.*

Helium-neon (HeNe) laser. Low-power, red laser. (λ = 612 and 632 nm) Large and fragile compared to modern diode lasers.

Helson-Judd effect. In human vision, the tendency of lighter achromatic surfaces to take on the hue of the illumination under which they are viewed and darker achromatic surfaces to take on the complementary hue.

Heuristic. Intuitive "rule-of-thumb" procedure for solving difficult problems. Often rule-based. May be faster than an Algorithm (q.v.), if one exists. In many situations, no algorithm is known, so heuristics offer only solution. Heuristics can be used to speed up algorithms. A procedure may always give correct result but cannot (yet) be proved to do so; it is an algorithm but this is unknown to us. Hence, it must be accepted on its known merits as an heuristic. Since heuristics are not provably correct in every situation, they are often spurned. It is essential therefore to view their performance on a statistical basis.

High-pass filter. Device or algorithm that retains fine (high-frequency) features in an image, while attenuating low frequency (slow changing) ones.

Histogram equalisation. Procedure for adjusting the intensity scale of a grey-scale image, so that the histogram of the resulting image is nearly flat. One of the prime methods of improving image contrast.

Histogram. Vector summarising the distribution of intensities in a digital image. The ith element (H(i)) indicates how many pixels have intensity *i.* The sum C(i) = [H(0) + H(1) + H(2) + ... + H(i)] is called the *Cumulative histogram* and is the basis for the procedure known as Histogram equalisation.

Hologram. Representation of a 3D surface, obtained using coherent radiation. When an holographic image (on a plane surface) is illuminated appropriately, the observer obtains the impression that he is looking at the original object, albeit with strange colouration. For practical reasons, not yet used significantly in Machine Vision.

Hough transform. Procedure for identifying "broken" straight lines and curved arcs (e.g., circle segments) of known form. It is easy to identify points lying on a line or curve since they all map into a single spot in the transform space. Gaps in the curve merely reduce the contrast between this spot and its back-ground.

HSI (Hue, saturation and intensity). Alternative to the RGB representation for describing colour. HSI was proposed as a model describing human colour perception. Since is possible to calculate HSI from RGB and vice versa, it is fallacious to claim that the former is "better" than RGB; in mathematical terms, any calculation in HSI space can be performed in RGB space.

Hue coefficient. The ratio between the response in one of the chromatic channels to the total chromatic response. A stimulus that is seen as equally bluish and reddish would for example have a hue coefficient of 0.5 for both red and blue while the unique hues all have coefficients of 1.0 for one channel and zero for the others.

Hue. Component in the description of colour, which determines its name. One of the three standard elements of colour appearance. (The other two are brightness and saturation). Its colourimetric equivalent is Dominant Wavelength. (q.v.) Although colour labels such as "yellow," "turquoise," "scarlet," etc. are defined subjectively, they can be predicted reasonably accurately by measuring hue alone. However, other factors (e.g., back-ground colour, gloss, texture and motion) also influence the naming of colours. Hue differences depend primarily on variations in the wavelength of light reaching the eye.

Hueckel. Name of a type of Edge Detector. (q.v.).

Hum bar. Disturbance of a digitised video signal that occurs when the light intensity generated by the lamps changes significantly during the camera's frame-scan period. It consists of a pattern of broad a dark bands modulating the image intensity.

Hunting. Used to describe a control system that oscillates, failing to reach its ideal goal state. Object transport mechanism may exhibit oscillatory behaviour as they try to maintain a constant speed. Also, describes the inability of an auto-iris lens to reach a stable state under certain light conditions.

Huygen's principle. Idea that each point on the wave-front of a light beam may be regarded as a point-source of secondary waves, that spread uniformly outwards, like ripples on a pond but in 3D space. The sum of all secondary waves generated in this way uniquely determines the wave-front at a later time.

I

Iconoscope. Early form of camera tube in which a high-velocity electron beam scans a mosaic of tiny capacitors on which the image is formed as a pattern of electrical charges. The scanning beam discharges the capacitors sequentially, thereby generating the video signal.

Illuminant point. That point on the chromaticity diagram that indicates the colour of a light source.

Illumination. Incident radiation impinging on an object or surface. The term is applicable to all parts of the EM spectrum. It is commonly found that the spectral content of the illuminating beam includes UV and/or IR, as well as VIS. This may reduce image quality significantly. Illumination includes wanted light and troublesome ambient light, which is highly variable and effectively constitutes noise.

Image acquisition sub-system. That part of a vision system concerned with the mechanical handling of the object/material being examined, illumination, optics, sensing (camera) and pre-processing, finally forming a digital image. The importance of the image acquisition stage cannot be over-emphasised.

Image analysis. Extraction and analysis of information regarding the contents of a digital image, leading to a final decision about further action to be taken (e.g., guide a robot to pick up an object, accept/reject a component, process it further) Image analysis may be extremely simple (e.g., find the centroid of a blob), or more complicated (read a product label) The term is sometimes subsumed under the umbrella of Image Processing. (q.v.).

Image capture. Process of converting a camera output, usually a video signal, into a digital image. A device for this is usually called a Frame-Grabber. (q.v.).

Image conduit. Fused coherent fibre-optic bundle, often in form of straight or L-shaped "pencil." Sometimes available as frustrum, used for changing image size or aspect ratio. It may have twist (e.g., 90°, 180°).

Image distortion. Used to describe warping effects of an optical system, or (CRT) camera scan non-linearity. While distortion can be corrected by software, if the warping function is known or can be measured, this places an extra burden on the image processor.

Image enhancement. Image processing operations which improve the visibility of low-contrast image detail. Usually performed for display to human beings, rather than machine analysis.

Image format. Describes the dimensions of the light-sensitive area of an imager. It is usual to quote the diagonal dimension. Common formats: 1″, 2/3″ and 1/2″.

Image formation. Generation of the image of an object on the camera's photo-detector array. The quality of this image depends on a variety of factors. See Image Acquisition.

Image intensifier. Electron tube, with a light-sensitive electron emitter at one end electron-accelerating electrodes and a phosphor screen at the other end. Acts as an "optical amplifier," for imaging in low-light conditions. Devices of this type are often built into extremely sensitive tube cameras, which give usable images on a cloudy, moonless night.

Image interpretation. Making decisions, based on the information obtained from Image Analysis. (q.v.) Relies heavily on Artificial Intelligence, Fuzzy Logic and Pattern Recognition techniques.

Image memory. High-speed, storage area in a frame-grabber card, or in a computer. Since it is dedicated to image retention, it may have certain special features, for example, the ability to output one image for processing, while another is being received from the camera.

Image orthicon. Camera tube. An optical image is focused on the rear of a photo-emissive cathode which emits photo-electrons at each point in proportion to the amount of light falling on it. These photo-electrons are accelerated and focused on a metal target, producing a secondary emission and creating a positive-charge image. The rear of the target is scanned by a low-velocity electron beam, which supplies it with just enough electrons to neutralise the charge image. The remaining electrons form a beam modulated in accordance to picture brightness that returns towards the electron gun on a path parallel with the outward beam. The return beam strikes the first dynode of a photo-multiplier to form the picture signal.

Image plane. Focal plane of the camera lens. perpendicular to the optical axis. The photo-detector is placed here, to obtain the sharpest possible image.

Image processing. See Digital Image Processing.

I*mage transform.* An image processing operator in which each pixel is replaced by a function of, many or, all of the pixels in the original image, e.g., autocorrelation.

Image. According to the Oxford English Dictionary "An optical appearance or counterpart of an object, such as is produced by rays of light either reflected as from a mirror, refracted as through a lens, or falling on a surface after passing through a small aperture." Also used when referring to a Digital Image (q.v.).

Incandescent lamp. Common light bulb. Simple cheap light source. Relies on hot filament heated by electric current. Gives directional illumination which causes shadows. Emits a lot of infra-red. Not commonly used in industrial applications.

Incident light. Light impinging on an object from the light source.

Incoherent illumination. Light in which the phase relation between nearby points in space varies randomly. See Coherent Illumination.

Industrial vision systems. General purpose systems can be configured by either the supplier or the user, for different tasks and in different industries. Special-purpose systems are designed for a particular task and are likely to be fast and efficient. However, they cannot be diverted easily to a different application. A system installed in a factory is called a *Target system*, to distinguish it from a laboratory-based (interactive) system used to design/optimise it.

Infra-red imaging. Image formation, using IR wavelengths, which are longer than those for visible red light but shorter than microwaves. (approximately 0.78 μm^{-1}.) See NIR, IR-A, IR-B, IR-C.

Integral transform. Type of image transform, analogous borrowed from classical mathematical/time-series analysis. Most common types: Discrete cosine Fourier, Walsh and Haar transforms.

Integration. Solid-state and CRT imagers accumulate photo-electric charge formed by irradiating the sensor during a time interval specified by timing signals. (i.e., the filed/frame period). The resultant signal is determined by the product of (a) the time-integral of the light level, (b) the area of the photo-detector element, (c) the exposure time and (d) the conversion efficiency.

Intensity. In optics, intensity measures the amount of light reflected from a surface. Intensity is not sensitive to colour. The term is also applied in image processing, to the values associated with pixels in a digital image. Intensity may be measured by a VIS, IR or UV camera, range (3D) sensor, x-ray sensor, or computed. Visual scientists often use a system of units (*photometric units*) that scale the physical power (*radiometric units*) by matching the spectral sensitivity of the eye.

Interferometer. Optical set-up, commonly used for very accurate measurement of distance. A beam of Coherent Light (q.v.) is divided into two separate beams, possibly using a beam splitter. These are then directed along different paths, before being reunited, thereby forming an interference pattern from which appropriate measurements are made.

Interlaced scanning. Method for scanning used in broadcast television. A Complete Frame (q.v.) consists of the odd-numbered lines (odd-field) followed by the even-numbered lines (even field).

Interline transfer. Type of CCD image sensor with special scanning circuitry to minimise image smear.

Intrascope. A flexible endoscope using fibre-optic bundle. Capable of navigating and imaging deep inside holes, crevices, etc.

Invariant hue. The perceived hues of monochromatic light that do not change with intensity. There are three invariant hues: blue, green, and yellow. (See Bezold-Brücke Hue Shift.)

IR-A. Infra-red radiation in the wave-band λ = 0.78–1.4 μm. Near IR (NIR).

IR-B. Infra-red radiation in the wave-band λ = 1.4–3.0 μm.

IR-C. Infra-red radiation in the wave-band λ = 3.0 μm–1 Far IR (FIR).

Iris. Mechanical diaphragm which can be controlled manually or automatically, to adjust the lens aperture. See Auto-Iris Lens.

Ishihara test. A test for colour blindness using a set of pseudo-isochromatic plates.

Isocon. High-sensitivity image orthicon.

Isoluminant. Synonym for Equiluminant (q.v.).

Isomerization. The change in conformation upon absorption of a photon that the chromophores in photo-pigments undergo.

*Isophot*e Intensity contour. Curve formed by joining together points of equal intensity in an image.

L

LAB. An acronym for the LAB colour co-ordinate system.

Lake. Imagine that a blob in a binary image is an island. A lake is an area of water totally enclosed by land. One type of constituent part of the Convex Deficiency (q.v.) of the blob.

Lambertian reflection. Diffuse light returned from an ideal matt surface.

Laplacian Operator. The sum of the magnitudes of the second partial-derivatives of the image intensity function. An approximation to the Laplacian operator is used to high-light spots, streaks and find edge regions of a grey-scale image.

Laser (Light Amplification by Stimulated Emission of Radiation). A laser produces a highly coherent, parallel beam of monochromatic light. It is used principally for range measurement and holography. Not normally used for wide-area “flood” lighting, since the high level of coherence causes speckle effects as the beam travels through air. Common types used: diode and HeNe laser. Safety precautions are important for high-power lasers.

Laser illumination. Lighting an object with a laser source for frequency selection, pulse width (strobe) control or for accurate positioning.

Laser Radar. See LIDAR.

Latency. See Processing Speed.

L-cone. One of three cone types that contribute to human colour vision. The L-cones have their peak spectral sensitivity at a longer wavelength than the other two cone types: *M-cones* and *S-cones.*

LED (Light emitting diode). Small, efficient, low-voltage, low-power, cold light source. Approximates to a point source of light. Often red but can be supplied at any VIS wave-length. Narrow spectrum light emission. Tri-colour (RGB) LEDs are available but their beams are not well structured and need external optical focussing. Varying the drive currents of the RGB diodes alters the subjective impression of colour but this does not sweep the spectrum as a monochromator does. Blue LEDs with overlying phosphors produce approximation to white light, with bluish tinge. LEDs can be used in a strobe, for medium-speed applications. Complex multi-LED arrays can be built for special applications.

Lens format. The approximate size of the image projected by a lens onto the Focal Plane. (q.v.) Usually, the lens projects an image slightly larger than the designated image size to ensure the sensor array is fully covered. The camera and lenses should both be of the same format size. A large format lens can be used on a small format camera. However, to avoid Vignetting (q.v.), a large format camera should not be used with a smaller format lens.

Lens speed. Term borrowed from photography. Actually, "speed" is misapplied when discussing to video, since the light-integration period is fixed, by the frame rate. See f-Number. (q.v.).

Lens. Transparent material, usually glass or plastic, with curved surfaces, to divert light rays, so that they either converge or diverge. Several lenses are often used in tandem, for controlling illumination and imaging. Common types: standard (35 mm), CCTV (non-specific meaning), cylindrical (magnifies in one direction only), enlarger (controlled magnification), condenser (collects light in ill-conditioned light beam to generate illumination in a controlled direction) in defined direction, macro (short working distance), micrographic (viewing small objects), video (non-specific meaning), zoom, telecentric (depth of focus is very large), auto-iris (self-adjusting aperture), telephoto (long working distance), wide-angle (viewing cone has wide angle), fish-eye (viewing cone angle 150–180°), Fresnel (moulded plastic lens with prismatic ridges), catadioptic (lens-mirror combination, light-weight, long-focus telephoto), aspherical (lens, often moulded, which ha non-spherical surfaces, to reduce aberrations), micro-lens array (array of minute lenses, each one slightly different. to achieve certain special effects).

LIDAR (Light Detection And Ranging). Similar system to radar but uses time of-flight of a pulsed laser beam instead of microwaves, for measuring range and mapping 3D surfaces.

Light Emitting Diode. See LED.

Light tent. Arrangement for Omni-Directional Lighting. (q.v.).

Lighting. Synonymous with Illumination. (q.v.).

Lightness. Synonym for Brightness. (q.v.).

Line of light. See Structured Light.

Line pairs per mm. Measurement of spatial frequency, used to describe the resolving power of a lens. Good standard lens can resolve 100 line-pairs mm^{-1}.

Line scan camera. Solid-state video camera consisting of a single row of pixels. Also called a linear-array camera.

Linear array. See Line Scan Camera.

Loca-area histogram equalisation. Non-linear, local-operator filter. Used principally for enhancing texture in a grey-scale image, by eliminating slow back-ground intensity changes. Has a serious effect on visibility of edges. Name is derived from the theoretical conceptual basis of the technique and has little in common with the procedure known as Histogram Equalisation. (q.v.).

Local operator. Image-processing operator in which each intensity value is replaced by a function of those pixel intensities found in a defined neighbourhood. For example, the local average, or median value, of the intensities might be computed for each 5×7-pixel area in a digital image.

Location. Address of a in a digital image Also, XY-coordinate position of a defined image feature (e.g., blob centroid).

Look-up table (LUT). Table of numbers held in RAM or ROM, used in hardware or software to speed up common functions such as Fourier transform, intensity mapping (e.g., logarithm, exponential, square, square-root), Gamma Correction (q.v.), Histogram Equalisation (q.v.), pseudo-colour image display and implementing finite state-machines. (See SKIPSM.)

Low-angle illumination. Useful to enhance minor surface irregularities such as pits, scratches, gouges. Also called glancing illumination.

Low-pass filter (LPF). Digital, analogue or optical filter which passes low frequencies, while attenuating high frequencies. When applied to images, LPF blurs edges, reduces the effects of noise and the contrast of small spots and narrow streaks. Regions where the intensity is changing slowly are unchanged.

Lumen. Unit of luminous flux. The amount of light emitted per second into unit solid angle (1 steradian) by a uniform point source with intensity equal to one Candela. (q.v.).

Luminance. The optical power weighted by the overall spectral sensitivity of the eye, per unit area of a light source.

Luminosity. See Brightness.

LUT. See Look-Up Table.

Lux. Unit of illumination. Equal to 1 lumen per square metre.

M

Machine Vision (MV). MV is concerned with the engineering of integrated mechanical-optical-electronic-software systems for examining natural objects and materials, human artifacts and manufacturing processes, in order to detect defects and improve quality, operating efficiency and the safety of both products and processes. It is also used to control machines used in manufacturing.

Machine Vision system. (*MVs*, See Vision System.)

Magnification (of a lens). Ratio of the length of a linear feature of a feature in the image plane to the length of the same feature in the object plane.

Manual iris lens. Lens with a manual adjustment for the iris opening (aperture), to set a fixed f-Number. (q.v.) Normally, used in fixed lighting conditions.

Mask. Has several meanings: (a) Pixels covered by the mask are transformed in some pre-defined way (e.g., set to a constant value), while other pixels are unchanged. (b) Pixels covered by the (rectangular) mask are removed. (Called cropping.) (c) Synonymous with Weight Matrix. (q.v.) (d) Physical structure placed in an optical system to block the transmission of certain light rays. (e) In an optical system forming a Fourier Transform (q.v.), unwanted spatial frequencies can be eliminated by masking as in (d).

Mathematical morphology, Also called Morphology. Non-linear local or N-tuple operator. The input image (binary or grey scale) is scanned by overlaying a small template shape, called a Structuring Element. (q.v.). The output image indicates how the structuring element fits, or does not fit, at each point within the input image. See SKIPSM.

Matrix-matrix mapping. General class of image processing operations in which one digital image matrix (or array) is transformed into another. Common types: monadic (one input image), dyadic (two input images), local operator/N-tuple, Mathematical Morphology (q.v.), global.

M-cone One of the three cone types contributing to human colour vision. The peak spectral sensitivity of M-cones lies those of the other two cone types: L-cones and S-cones.

Mechanical handling system. Hardware that ensures that objects/materials pass the camera in a controlled manner. Motion may be linear or rotational, indexed or continuous. Occasionally, the camera is moved past a stationary object. Sometimes, the object and camera are both stationary. Panning is then achieved using scanning mirrors, mounted on gimbals.

Median Filter. Non-linear filtering method for reducing camera-noise and other noise-like effects in a image. Each pixel intensity is replaced by the median value of the intensities found among pixels immediately surrounding it, in a fixed neighbourhood.

Metamerism. Inability of the human eye to distinguish colours with quite different spectral compositions. For example, light with a 2-peak spectrum may produce a similar colour sensation to narrow-band radiation with a single spectral peak.

Metrology. The science of measurement.

Michelson interferometer. Optical instrument in which a monochromatic light beam is split into two component beams. These are reflected from separate mirrors to be reunited at the beam splitter where they combine to produce an interference pattern.

Micron (micrometer, μm). Unit of length: 10^{-6} m, 10^4 Angstroms. Frequently used to measure EM wave-length.

Microspectrophotometry. A technique for obtaining measurements of the spectral absorption of a single photo-receptor cell. Useful as a means for investigating colour vision without behavioural tests.

Minimum object distance (MoD). Shortest lens-object distance that gives a sharp focus. The smaller the focal length of a lens, the shorter is its MoD, although this can be altered with use of Extension Tubes (q.v.) or Add-On Lenses (q.v.). See Diopter.

MIPS (Millions of Instructions per second). Measure of computer processing speed. Usually a more meaningful indication of "real" speed than raw clock speed.

Mired (micro reciprocal degree). Unit used to measure the reciprocal of colour temperature; 1 mired corresponds to a surface having a colour temperature of 10 K.

Mirror. Smooth, highly polished surface, for reflecting light. It may be plane or curved, in one or two dimensions. Also see Anamorphic Mirror. Mirrors are fabricated by depositing a thin coating (e.g., silver, aluminium or gold) on a glass or plastic substrate. To produce optimal image quality, avoiding ghost images due to reflections from the uncoated surface, first-surface mirrors are coated on the front face. Unlike domestic mirrors which are rear-coated, first-surface coating is easily damaged by rough handling. Mirror-like surfaces on an object can cause serious problems for an inspection system, due to glinting (specular reflection). Cheap plastic mirrors are useful because they can be machined easily. Prisms are sometimes used in lieu of mirrors, particularly where precise alignment of two orthogonal mirrors is required. Very large. low-precision mirrors can be made by stretching aluminised Mylar film over a suitable frame.

Modulation Transfer Function (MTF). When a 1-dimensional sine-wave pattern is passed through an imperfect optical system, the contrast in the resulting image is a function of the period of that pattern. The MTF is the contrast as a function of period and represents the ability of an optical system to reproduce various levels of detail. For practical convenience, a set of parallel black-white bars is sometimes used instead of a sinusoidal test pattern.

Moiré fringes or patterns. Pattern which appears when two nearly-identical sets of parallel lines, arrays of spots, concentric circles, etc. are superimposed. Effect seen on shot silk. Moiré patterns are an artefact of human perception and should not be confused with interference fringes caused by the finite wave-length of light.

Moiré interferometry. Experimental method used to obtain 3D profile information of an object or surface. Two identical patterns (usually sets of parallel lines) of known pitch are used. The first creates a shadow on the object. The second is placed in the imaging path, and is therefore superimposed on the shadow cast by the first. This forms a Moiré pattern, in which distance between the dark bands (fringes) is directly related to object-camera range. However, it is impossible to determine whether a surface is convex or concave from a single Moiré pattern. This ambiguity can be resolved by varying the inter-line spacing, in two separate experiments, to change the sensitivity.

Monadic point-by-point operator. Image processing operator which acts on only one image. Each pixel in the transformed image is obtained from operations on only the corresponding pixel in the original image.

Monochromacy. The condition of possessing only a single channel for conveying information about colour. Monochromats are strictly colour blind and perceive only variations in brightness.

Monochromatic. Refers to either light, or the scene being viewed. Monochromatic light contains electro-magnetic radiation of a single wavelength (e.g., light from a laser). The term is also used to describe light having a narrow range of wavelengths. For example, that pair of narrow spectral bands giving light from a sodium lamp its characteristic yellow colour would be referred to as being monochromatic. Surfaces that reflect/emit light with a narrower spectrum would also be referred to as being monochromatic.

Monochrome. Used to refer to images, whereas monochromatic refers to light, or the scene being viewed. A monochrome image contains no information about colour. The signal from an RGB colour camera generates three separate images, each of which is referred to as being monochrome. In effect, these measure the amount of red, green and blue light in a coloured scene. A colour image can be represented, for the purposes of display, printing, or digital processing, by three or four monochrome images, called its colour separations, or channels.

Morphology. See Mathematical Morphology.

MRI Magnetic resonance imaging. A non-invasive technique for 3D imaging MRI has been mostly used for detecting and localizing damage to the brain and other soft body tissues. Potentially very useful for MV but very expensive.

Munsell colour system. A widely used system for describing colour appearance. The sample is matched by eye against a set of stable reference swatches. It may be necessary to use interpolation to classify a given test sample.

M×N neighbourhood. Contiguous set of pixels in an image, arranged within an M×N rectangle. Their intensity values might be combined in some way, for example by computing their average. See 4-Neighbour and 8-Neighbour.

N

Nanometer One billionth of a meter. (10^{-9}m or 0.001μm). Practical unit for measuring the wavelength of light and atomic spacing.

Neural Network. Principal approach to Statistical Pattern Recognition. Abstract computing structure which processes information based on a crude model of biological nervous systems. Decisions are made about a complex event, pattern or image, based on a set of parallel numeric inputs. Each neuron in the network, which may consist of several interconnected layers, forms a threshold linear-weighted sum of its inputs. The decision surface of a multi-layer network is piece-wise linear. Self-adaptive, error correcting learning rules are known, which allow a network to optimise its performance on a classification task that is specified only by a set of labelled samples.

Neutral. Used to signify an object or scene that has is composed only of grey, white or black regions. It does not have any colours such as yellow, red, etc.

Newvicon. Type of Vidicon (q.v.) with a double layer target, giving an improved resolution

NIR. See IR-A.

Noise. Irrelevant or meaningless data resulting from various causes unrelated to the prime application requirements. In Machine Vision, noise is caused by varying ambient light (e.g., sun-light, fluorescent tubes providing environmental lighting), dirt on the Widget, optics or light source, as well as the usual sources of noise in electronic equipment: earth loops, EM radiation, capacitative coupling, induction, etc.

Normalisation Process of adjusting the output range of an image processing operation so that is identical with that at its input. By normalising in this way, image processing modules/ routines can be concatenated, in any order without causing overflow.

N-tuple operator. Image processing operator in which each pixel is replaced by a value derived by evaluating a function of only a selected few (N) of its neighbouring pixels. See Local Operator and Mathematical Morphology.

Numerical aperture (NA). Measure of the resolving power of a lens. Equal to $\mu \sin(U)$, where μ is the refractive index of the medium adjacent to the objective lens and U is the half-angle of the maximum cone of light picked up the lens. If the object is at infinity, NA = 0.5/ (f-number).

NUV. See UV-A.

Nyquist limit. Spatial frequency equal to half the sampling frequency. If an image falls on an array of photo-detecting elements with spacing D µm, the image is said to be sampled at a spatial frequency of 1/D and the Nyquist limit is 1/(2D). Using this array it would be impossible to discern objects of diameter 2D µm, or less, reliably. Similarly, if a pattern of parallel lines of width less than 2D and spacing 2D were projected onto this sensor array, the image would be unclear. (Moiré Patterns (q.v.) would be formed.) In practice, a higher sampling frequency than 1/(2D) is required to avoid this effect. The Nyquist limit also applies to temporal sampling; sub-Nyquist sampling is responsible for wheels appearing to rotate back-wards on television and ciné film.

O

Object plane. Plane through the object being examined (the widget), normal to the camera's optical axis. Features in the object plane are focused by the optical system onto the image plane and hence are projected onto the photo-sensor array.

Object. The item to be measured, counted, sorted, inspected or manipulated. To avoid ambiguity, the specific term "Widget" (q.v.) is preferred.

Objective. Element of a compound lens that is closest to the object being examined (i.e., widget).

Oblique illumination. Grazing illumination; angle relative to camera's optical axis is a little less than 90°. Emphasises object features by producing shadows.

OCR (Optical character recognition, or Character Recognition). Recognising (i.e., "reading") previously unknown characters on a document, packet, etc. Cheap OCR software is available for standard flat-bed scanners and desk-top computers. Also see OCV.

OCV (Optical Character verification, or Character Verification). Verifying the correctness, quality and legibility of *known* printed characters on a document, packet etc. Unlike OCR (q.v.), the character sequence is known beforehand.

Off-the-shelf. Multi-purpose Machine Vision system which is not pre-configured, or optimised, for any specific application.

Oil mist. Serious environmental contaminant for optical surfaces.

Omni-directional lighting. All round lighting. Light impinging on the object comes from all points on an hemisphere.

Opening. Non-linear image filtering (morphology) operator, equivalent to an erosion operation followed by dilation, Has the effect of removing small spots and narrow streaks. The structuring element determines the shape and sizes of the features that are removed.

Opponent process theory. Based on the hypothesis that subjective colour appearances are the result of recoding the outputs of the eye's photo-receptors (cones) into three channels: two opponent chromatic channels (*yellow-blue* and *red-green*). In addition, there is one achromatic opponent channel (*white-black*). These three channels are created by forming linear combinations of the outputs of the three types of cone in the retina. The theory correctly predicts that the blueness (redness) of a source may be cancelled by adding to it light that enhances its yellowness (greenness).

Opsin. The protein component of a photo-pigment in the eye. Different opsins give rise to photo-pigments with different spectral absorption characteristics. (Also see Chromophore.)

Optical Computing. To date, only limited functionality can be implemented efficiently in an optical computer. While it is possible to form the Fourier Transform (q.v.) of a complete image on a transparency in parallel in real time at the speed of light, seemingly simpler operations, such finding the centroid of a blob, presents considerable difficulty. Optical computing is an attractive but elusive ideal for researchers in Machine Vision.

Optical transfer function. See Modulation Transfer Function (MTF).

Orientation. The angle or degree of difference between the object co-ordinate system major axis relative to a reference axis as defined in a 3D measurement space.

Orthicon. Type of CRT camera in which a beam of low-velocity electrons scans a photo-emissive mosaic that is capable of storing a pattern of electric charges.

Oscillating mirror scanner. Beam-steering element in a flying-spot scanner uses a laser beam projected onto an oscillating mirror.

P

Panchromatic. Photographic film, solid-state sensor array or camera tube that is sensitive to all visible wavelengths. The term is applied even if the response is not constant for all VIS wave-lengths.

Pantone. Colour matching system in which colours are labelled by numbers.

Parallax. Change in the apparent positions of two objects when viewed from different vantage points. The nearer object appear to move in the opposite direction to the observer.

Parallel processor. Computer which has a large number of identical processors each of which can operate on data (such as a complete row or image) at the same time.

Pattern Recognition. See Neural Network. Many other computational methods exist for learning to make decisions, when there is no explicit formula, or algorithm, for doing so.

Perceptron. Basic processing element used in neural Networks. (q.v.) Forms a thresholded linear-weighted sum of its inputs.

Phase contrast microscope. Compound microscope that has an annular diaphragm in the front focal plane of the sub-stage condenser and a phase plate at the rear focal plane of the objective. This makes visible differences in the optical path (i.e., path length, or refractive index) in transparent or reflecting media.

Phosphor. Material that glows visibly in response to some form of non-visible energy supplied to it, by for example, the electron beam in a cathode ray tube, radio-active material (gamma-ray), UV or x-ray source. Some materials continue to glow for a short period after the source of energy has been removed. This can be useful for distinguishing phosphorescence and Fluorescence. (q.v.).

Photodiode array. Solid-state array in which the photosensitive elements consist of photodiodes.

Photodiode. Reverse-biased semiconductor diode in which incident photons create hole-electron pairs, thus creating a current that is proportional to the level of illumination.

Photometry. Measurement of light which is visible to the human eye.

Photomultiplier. Very sensitive light-detector, capable of identifying the arrival of a single photon. It consists of a cold light-sensitive cathode, together with a series of electron multipliers, within an evacuated glass envelope.

Photophore. Light emitting (bioluminescent) organ found in animals such as fire-flies and deep-sea fish.

Photopic response. The colour response of the eye's retinal cones.

Photopic vision. Vision under relatively high light levels when the outputs from the cones are dominant.

Photo-pigment. Pigment molecules in a photo-receptor (cone) in the eye undergo changes when they absorb photons. This causes the photo-receptor cell to "fire," sending a signal into the surrounding network of neurons. Each photo-pigment tends to absorb photons within a specific range of wavelengths, thereby giving rise to the different spectral sensitivity characteristics of the cones.

Photo-receptor. Light-sensitive neuron in the retina of a human or animal eye. Photo-receptors interact with light, causing them to "fire" and generate an electrical signal, which is then transmitted to other neurons nearby. The human retina contains two broad classes of photo-receptors: rods (for monochrome night vision) and cones (for colour vision in high light levels).

Pin-cushion distortion. Imperfection of an optical system in which a rectangle appears "pinched" on all sides. Opposite of Barrel Distortion. (q.v.).

Pin-hole camera. Simple image-formation technique in which a single small hole is formed in an opaque screen. If the hole is large enough to avoid diffraction effects, rays pass through the hole onto the camera's photo-detector array. Simple to analyse the image-formation process by straightforward ray geometry. Unlike glass lenses, the pin-hole produces no aberrations (ignoring diffraction) but is very inefficient at light gathering.

Pipe-line image processor. Data processing architecture, which can perform a series of operations simultaneously on different items in a stream of data, thereby achieving considerable speed-up, compared to a serial processor.

Pixel (Pel, or Picture element). Smallest addressable portion of a digital image. Within the boundaries of a given pixel, the intensity and colour can be considered constant.

Pixel counting. Simple technique for characterising objects in a binary image, by counting the number of pixels contained within its boundaries. (Equivalent to finding the blob area.)

Plumbicon (leddicon). Form of vidicon in which the target consists of a photo-conductive layer of lead monoxide. Once used for broadcast-quality colour cameras.

Polar vector representation (PVR). Code used for describing a curve, such as the periphery of an object. Each "break point" on a piece-wise linear arc is represented by the polar co-ordinates of the next point with the current point as reference. Thus a PVR sequence consists of a series of the form $[(R_1, \theta_1), (R_2, \theta_2), (R_3, \theta_3),..., (R_n, \theta_n)]$, where R_i $(i \leq n)$ denotes the length of the ith linear edge segment and θ_i its orientation.

Polariser/Polarised light. Linearly polarised light has its E-vector (electric-field vector) lying in one plane, perpendicular to its direction of travel. It is created by a type of filter (polariser) which absorbs the light rays polarised in the orthogonal direction. Polarisers are usually fabricated from stretched plastic sheets with aligned, parallel bi-refringent crystals. Polarizers can also be constructed using parallel wires, or arrays of very fine conductors formed by metal-evaporation techniques on a glass substrate. A prism with light striking its face at the Brewster Angle (q.v.) is polarised. Circularly-polarised light also has its E-vector lying in a plane normal to the direction of travel but it rotates as it travels.

Polarization. Refers to the spatial orientation of the electric-field vector of an electromagnetic wave. If all rays have the spatial orientation of this vector, the beam is said to be polarised. Most light sources, such as the sun, incandescent lamps, discharge tubes, fluorescent lamps, flames, etc. emit non-polarised waves. Certain physical processes, such as scattering in the atmosphere and reflections from glossy surfaces, achieve partial polarisation. Optical-quality polarisers achieve a far purer polarisation effect.

Polychromatic scene. Contains a finite number of Monochromatic Regions (q.v.), each one being clearly distinct from all of the others. This is a specialised use of the term in this book. Whereas Chrominance (q.v.) is continuous in a Pan-Chromatic Scene (q.v.), it assumes only a finite number of discrete values in a polychromatic scene.

Positioning equipment. Electro-mechanical device used to bring the widget into the camera's field of view, or to move it when multiple or views are required.

Positron emission tomography (PET). A method for medical imaging that uses tracers that emit positrons. The tracer is introduced into the subject's blood and then its concentration is measured by collecting the emitted positrons. PET is currently too expensive for use in Machine Vision.

Post-objective scanner. Type of flying-spot scanner in which the scanning element is placed after the objective lens, which focuses the beam into a spot.

Precision. Accuracy claimed for a measurement. We may be able to estimate the position of a feature, such as the centroid of a blob in a given binary image, with a precision that is better than one pixel. However, this is a spurious assertion if quantisation effects lead to much larger changes in this parameter as we move the widget slightly. See Repeatability.

Pre-objective scanner. Type of flying spot scanner in which the scanning element is placed before the objective lens, which focuses the beam into a spot.

Pre-position lenses. Pre-position lenses are specially designed with facilities for computer control of aperture, zoom and focus, without operator intervention.

Prewitt. Name of a type of Edge Detector. (q.v.).

Primary. Light from a set of primary light sources can be added together to produce any other colour. For human beings with normal vision, three primaries are sufficient. However, there are indefinitely many such sets of three. For the purpose of defining the CIE Standard Observer (q.v.) and for precise colourimetry, the concept has been extended to include "imaginary" primary light source that are not physically realizable.

Primary visual cortex. An area of the occipital lobe of the human brain that performs the first stage of cortical visual processing. It receives inputs from the retina via the Dorsal lateral geniculate nucleus and sends outputs to other areas of the visual cortex. Also referred to as V1, striate cortex, and area 17.

Principal planes. Two planes passing through the principal points of an optical system, normal to its axis.

Principal points. Two points on the axis of an optical system. If the object distance (U) is measured from one and the image distance (V) from the other, the equations relating U and V are mathematically identical to those for a thin lens.

Prism. Optical device with two or more polished faces from which light is either reflected or refracted. Many types of prism exist, of which the triangular form, used for decomposing light into its spectral components, is the most familiar.

Processing speed. Loose term that is inaccurately used to measure the throughput rate of a vision system. The latter is normally expressed in parts-per-minute. This single parameter does not give any indication of the time required by a vision system to receive, analyse and interpret image information for an individual piece-part. The latter is called *latency* and may be considerably larger than the reciprocal of the throughput rate. (Parallel and Concurrent Processors (q.v.) are able to process image data from more than one widget at a time.)

Profile. The 3D contour of an object.

Programmable Colour Filter (PCF). Real-time video filtering device, consisting of a look-up table, implemented in a random access memory, whose inputs are the digitised RGB signals. The contents of the look-up table are generated from a monochrome image. The output of a PCF is a monochrome video image, but this may often be displayed to good effect using pseudo-colour.

Protanopia. One of the two varieties of red-green colour blindness (also known as red-dichromacy). Protanopia is thought to result from the loss of function of the L-Cones. (q.v.) People with this condition display a marked loss of sensitivity to light at the long wavelength end of the spectrum. (Also see Deuteranopia.)

Pseudo colour-triangle. Computer-generated image, superimposed onto the colour triangle. A series of very useful programmable Colour Filters (q.v.) can be generated by creating pseudo colour-triangles, using an image processor, or simple graphics program.

Pseudo-isochromatic plate. An array of coloured dots for testing for colour blindness. A normal subject will see a certain figure in the pattern, which is apparent to a person with a colour vision deficiency.

P-tuple (or N-tuple) operator. An image processing operator in which each pixel is replaced by a function of only a selected few (P) of its neighbouring pixels.

Purity. A pure light source emits monochromatic radiation. If this is mixed with light that has a broad spectrum, the purity is reduced. Measured by Saturation. (q.v.).

Q

Quad-tree. Hierarchical representation of a high-resolution image. It consists of a series of lower-resolution images, each of which is obtained by merging compact regions in the next highest layer. Useful for speeding up certain image processing calculations.

Quartz-halogen-tungsten lamp. Small intense source of white light produced by an electrically-heated tungsten filament, enclosed in a quartz envelope which contains a halogen vapour (e.g., iodine) at low pressure.

R

Radiance. Measurement of radiant flux, per unit solid angle, per unit of projected area of the source. (The usual unit is the watt steradian^{-1} m^{-2}.)

Radiometry. Measurement of light within an optical spectrum.

Random access. The ability to access chosen pixels, lines or ROIs (q.v.) from an imager as needed asynchronously, without waiting for the appropriate moment in a scanning cycle.

Range map. See Height Map.

Raster scan. Image/scene scanning pattern, usually from left to right, while progressing more slowly from top to bottom. Often comprised of two fields composed of odd-numbered and even-numbered lines.

Rayleigh criterion. Mathematical condition which states that the resolution of a diffraction-limited optical system of aperture D used to view an object using light of wave-length λ is given by $1.22\lambda/D$.

Rayleigh scattering. Scattering due to numerous small particles of uniform size in suspension. The intensity of Rayleigh-scattered light is proportional to λ^{-4} (λ = wavelength).

Real time processing. The popular and mistaken view is that this refers to the ability of an inspection system to complete the analysis and take appropriate action on one widget before the next one arrives for inspection. This is an incomplete view, as it does not distinguish between throughput rate and latency. (See Processing Speed.) The concept of real-time cannot be defined without reference to the application requirements. The requirements for a real-time robot control system are more straightforward; we need only specify the system band-width, or the maximum speed of movement of the robot.

Reflectance (of a surface). The proportion of incident light that a surface reflects. This is a function of wavelength. (See Spectral Reflectance.)

Reflection. (a) Specular. Optical process by which a light beam incident on a smooth conducting surface causes another beam to leave it on the same side. The reflected beam is generated by the surface so that its E-vector cancels that of the incident beam. Hence, the polarisation is unchanged. (b) Diffuse (Lambertian). The energy within the incident light beam is scattered through a solid angle of $4\pi/3$ steradian.

Polarisation (q.v.) and Coherence (q.v.) are both lost. This is a typical effect of light striking a rough dielectric surface. In practice, light reflected from surfaces such as plastic, polished wood, paint, etc. has a strong specular component and exhibits diffusion as well.

Refraction. Change of direction of a ray of light when passing from one transparent medium to another.

Refractive Index. Property of a medium that measures the degree that light bends when passing between it and a vacuum. In a material of high refractive index light travels more slowly than in one which has a low value.

Region of interest ROI. Area (usually rectangular) within an image in which an image processing operator is applied. To save time, computational effort is not applied elsewhere.

Registration. (a) Refers to the relationship between the actual position of a widget and the nominal position expected for image acquisition. Accurate registration requires that the X, Y and θ co-ordinates (orientation) all be controlled and significantly reduces computational effort and processing time for inspection. (b) When two or more images of a scene are obtained from slightly different views, joining them together to form a mosaic requires that they be registered. Many of the impressive images of the surfaces of Moon, Mars, etc. that are released by NASA are mosaics composed of accurately registered subimages. For practical reasons, the construction of mosaics is not normally used in Machine Vision.

Reject mechanism. Device used on a manufacturing line to remove defective widgets from the product conveyor. This may employ an air blast, a solenoid actuated pusher, an electromagnet (for ferrous widgets), or a flipper-like deflecting plate. The unceremonious dumping of faulty widgets into a reject bin may mean that they are further damaged, making detailed examination by a human inspector impossible. In this event, the vision system must act without human back-up.

Remote prototyping. Principle of designing an inspection system without the vision engineer visiting the factory where it will be installed. See Flexible Inspection Cell.

Repeatability. Ability of a system to reproduce the same measurement results for an identical widget on different occasions. See Precision.

Resolution. (a) Digital image: the number of rows and columns. (b) Intensity scale: the number of resolvable shades of grey. (c) Optical system: the smallest angular separation of two object points which produces two distinguishable image points.

Reticle. Optical element used for calibration, or instrument alignment. Usually, a glass plate with a pattern consisting of rulers, crossed lines, grids, arrays of spots, concentric circles, etc. Familiar to microscopists but not often used with Machine Vision systems, since the reticle image is superimposed onto that of the widget. Similar effect can be obtained using software, if the camera has previously been calibrated.

Retina. (a) The inside layer of the back of the eye that contains the photo-receptors and associated neurons. The earliest stages of visual processing take place in the neurons of the retina. (b) Light-sensitive surface of a video camera that converts a visual pattern into an electronic image.

Retinal. (a) Relating to the Retina. (q.v.) (b) The Chromophore (q.v.) contained in human photo-pigments.

Retrofocus lens. Compound lens system consisting of a diverging lens followed by a converging lens (reverse of telephoto principle). This gives a back focal length which is greater than the true focal length, facilitating convenient camera design.

Retroreflective material. Sheet material with a coating which returns a beam of light along its path of incidence. Available as an adhesive tape from automobile accessory shops.

RGB (Red, Green and Blue). Standard solid-state and CRT colour video cameras use three sets of photo-detectors, behind red, green and blue optical filters. Hence, both types of camera generate RGB signals naturally. Although some cameras have additional electronics which converts these signals to HSI, this does not add any information. Hence, any calculation that is possible in HSI, or any other, colour-co-ordinate system can also be performed in RGB space.

Rhodopsin. The photo-pigment in the rod photo-sensors in the eye.

Ring-light. Bundle of optical fibres, or a set of small lamps or LEDs, arranged around the perimeter of a circle. Light may be projected forwards (i.e., normal to the plane containing the circle), radially inwards (i.e., towards the centre), or radially outwards (i.e., away from the centre)

Roberts. Name of a type of Edge Detector. (q.v.).

Robot. According to the Robot Institute of America (1979), a robot is "a reprogrammable multi-functional manipulator designed to move material, parts, tools or specialised devices through variable programmed motions for the performance of a variety of tasks." Term is also used to refer to autonomously guided vehicles.

Rod. One of the two main classes of photo-receptor found in the vertebrate eye. Rods are very sensitive to low light levels. However, they have only a minor effect on colour vision in daylight.

ROI (Region of interest). Portion of an image that is to be analysed.

Rotating mirror drum scanner. Type of scanning element in a flying-spot scanner in which the scanning is performed mechanically by reflecting a laser beam from the facets of a rotating polygonal drum.

Rotation. (a) Widget is sometimes rotated in front of a line-scan camera, to obtain polar or cylindrical co-ordinate scan pattern. (b) Image rotation is a surprisingly difficult calculation requiring interpolation. Best avoided if possible, to avoid quantisation artefacts around edges.

RS-170. Electronic Industries Association (EIA) standard governing monochrome video signals. Provides 30 complete images (frames, two fields) per second. Widely used in North America and Japan.

RS-232-C. Electronic Industries Association (EIA) standard governing serial communications over a twisted-wire pair. Can provide effective low-speed, 2-way, digital communication for up to about 50 m.

RS-330. Electronic Industries Association (EIA) standard governing monochrome video signals. Provides 25 complete images (frames, 2 fields) per second. Equivalent to CCIR. (q.v.), which is widely used in Europe.

RS-422; RS-423; RS-449. Electronic Industries Association (EIA) protocols for low-speed, serial, digital communication. Intended to replace the widely used RS-232-C Standard (q.v.) eventually.

Run code (or Run-length encoding). Representation of a binary image, in which each chord (i.e., segment of a row in which the intensity does not change), is represented by the number of pixels in it. It consists of a sequence of the form: [($R_{1,1}$, $R_{1,2}$, $R_{1,3}$,. . .), ($R_{2,1}$, $R_{2,2}$, $R_{2,3}$,. . .), ($R_{3,1}$, $R_{3,2}$, $R_{3,3}$,. . .), ...], where $R_{i,j}$ represents a black (j odd) or white (j even) chord in the ith row. This is an efficient coding, if the image contains just a few simple blob-like objects. The idea can be extended to cover grey-scale and colour images but the efficiency is usually poor.

S

Salt-and-pepper- noise. (a) Noise in a binary image that consists of occasional random inversion of intensity. (b) Similar effect occurring in grey-scale images, as a result of electrical noise disturbing the digitisation process.

Saticon. Type of vidicon with high resolution.

Saturation. (a) Colourfulness, or strength of colour. Highly saturated red contains only light from the red part of the spectrum and is said to be of high purity. Pink and other pastels colours are non-saturated and have a considerable amount of white light present (b) Popular colour co-ordinate used in Colour Science, usually specified together with Hue and Intensity. (q.v. Also see HSI.)

Scanner. See Flying-Spot Laser Scanner.

Scattering. Redirection of light by diffuse reflection from a surface, by dispersion as it travels through a transparent or fluid medium. See Diffuse Reflection and Dispersion.

Scene Analysis. Extracting features and deriving measurements from images. Intimately linked to image processing; there is no clear demarcation between the two.

Scene. The object being examined (called a widget) and its background; that portion of space observed by a vision system for inspection, measurement, identification, etc.

S-cone. One of the three types of cone that contribute to human colour vision. The peak spectral sensitivity of the S-cones is at a longer wavelength than that of L-Cones and M-Cones.

Scotopic vision. Human vision under relatively low light levels when the rods in the retina produce the most significant signals.

Segmentation. Computational procedure that divides an image into its constituent parts, usually based on some quality such as intensity, colour, texture, or a combination of these. Segmentation is a classification process, which identifies regions in the image as being similar, if they share some defined criterion.

Shading. The variation of the brightness or relative illumination over the surface of an object, often caused by colour or reflectance variations or surface curvature.

Shape factor. Convenient shape parameter. Ratio of the area of a blob to the square of its perimeter. Maximum value is $1/(4\pi)$ (= 0.079577) for a circle.

Shape from shading. 3D shape-analysis techniques that attempt to reconstruct an object's shape from the variations of intensity across its visible surface. This is only possible if the position of the light source is known and certain assumptions are made about the optical properties of the object surface.

Shape. (a) Physical object that can be adequately represented by a blob-like figure in a binary image. There is no internal detail of any importance. (b) Abstract quality relating to a 2-dimensional blob-like object, or the silhouette of a 3D object. Many parameters describing shape have been proposed, often simply to improve computational convenience. However, shape cannot be described adequately using just a few parameters.

Sharpening. Image processing operation which enhances edges. Can be achieved by unsharp masking, i.e., subtract a Low-Pass Filtered Image (q.v.) from the original.

Shutter. Electrical, mechanical or liquid-crystal device, used to control the timing and duration of the interval when the camera's photo-detector array is exposed to light. A fast shutter can be used to eliminate motion blur, without the risks inherent in Strobed Lighting. (q.v.).

Silhouette. High-contrast grey-scale image, usually obtained by illuminating an opaque widget by back-lighting. Has a strongly bimodal distribution.

Simple lens. Has a single element.

Simultaneous contrast. Phenomenon of human vision in which the perceived colour of an object tends to take on a hue opposite to that of the surrounding area. For example, a grey figure on a red background will appear to have a greenish tint.

Size. Ill-defined characteristic of an object. The size of a blob-like object may be characterised in various ways: area, dimensions of its minimum enclosing rectangle, diameter of its circumcircle, area of its convex hull, etc.

SKIPSM. (***S**eparated **K**ernel **I**mage **P**rocessing by* [*finite **S**tate **M**achines.*]) Fast implementation of a range of morphological and other operators. It is able to perform all operations in the same time, irrespective of the size of the structuring element.

Smart camera. Self-contained vision system contained in the camera body, including lens, image sensor, image processing and decision making functions, interface electronics and software.

Snow. Type of noise in a grey-scale or colour image, with the visual appearance of snow. See Salt-and-Pepper-Noise.

Solid-state array. Type of image sensor fabricated normally in the form of a linear, or rectangular, array of photosensitive elements on a single integrated circuit. See Charge Coupled Device (CCD).

Spatial contrast. Difference in some visual property (e.g., brightness, colour or texture) between adjacent areas of a scene or image. Black objects on a white background display high spatial contrast.

Spatial frequency. A measure of how rapidly some visual property (e.g., brightness or colour) changes in space. Images with fine detail (e.g., small spots, thin lines or texture), or sharp edges, have high spatial frequency. Those where changes are more gradual have low spatial frequency. See Modulation Transfer Function.

Spatial Light Modulator (SLM). Transparent (usually LCD) screen used in optical computing systems to introduce an image into the image-processing path. It may be used as the basis for forming the Fourier Transform (q.v.) of an image, os a Mask. (q.v).

Speckle. Phenomenon in which the scattering of Coherent Light (q.v.) by a rough surface, or inhomogeneous transmission medium (e.g., turbulent air), generates an interference pattern of random intensity distribution, giving the surface a granular appearance. Small-scale temperature changes in air at room temperature are sufficient to cause phase changes that will produce speckle patterns.

Spectral analysis. Decomposition and measurement of the energy content of a light beam as a function of wave-length.

Spectral characteristics. That spectrum characterising a light beam. It specifies the energy content as a function of wave-length.

Spectral colour/light. Colour of a monochromatic, or nearly monochromatic, light, When white light is dispersed by a grating or prism, the resulting “rainbow” is composed entirely of spectral colours. Colours with a wide spectrum, are said to be *extra-spectral.*

Spectral power distribution. Energy content of an optical signal, measured as a function of wavelength.

Spectral reflectance. The Spectral Power Distribution (q.v.) of light reflected from a surface. Varies with angles of incidence and viewing.

Spectral response. Output signal level of a light sensor as a function of wave-length of the light incident on it.

Spectral sensitivity. Sensitivity of a photo-receptor/photo-detector expressed as a function of wavelength.

Spectrum. Electro-magnetic spectrum, or EM spectrum. Expressed as optical energy as a function of wave-length. The visible (VIS) wave-band for human beings is normally taken to be 0.4–0.7 μm. Outside these limits the response is so low that it rarely has a significant effect. Many animals respond to light outside this range, especially shorter wavelengths. See VIS, IR, UV and x-rays.

Specular reflection. Reflection of light (e.g., from a smooth polished or metallic surface) in which the angle of incidence is equal to the angle of reflection. This gives rise to Glinting. (q.v.).

Speed. Image blur may be caused by high widget-camera speeds. Stroboscopic illumination or high-speed shutters can be used to "freeze" motion. Can also use line-scan camera, or oscillating mirror in front of the camera to compensate for motion.

Spherical aberration. Optical aberration produced by lenses with spherical surfaces. Rays of light parallel to the optic axis, but at different distances from it, are focussed at different points along it.

SRI algorithms. (Stanford Research Institute,1970s) Set of routines for analysis and identification of blob-like objects. Main steps are: (a) Form a binary image. (b) Isolate and identify each blob. (c) Measure parameters of each blob in turn. (d) Perform additional measurements, defined by the user.

Stadimetry. Range-measurement technique, based on the apparent size of an object known size in the camera's field-of-view.

Statistical Pattern Recognition. The pattern to be classified (e.g., an image or feature within an image) is represented by a fixed number of parallel measurements (*descriptors*), forming a *pattern vector.* The objective is to design a device (*classifier*) that can predict the output that would be obtained from a *teacher* were it available. The teacher defines the correct labelling for each pattern. The classifier must be designed by analysing a finite set of pattern vectors (*training set*), each of which is labelled by the teacher. Each label indicates to which one of a small number of classes the original pattern belongs. For example, the desired classification might simply be "*acceptable*" or "*faulty.*" No other information is available to guide the design of the classifier. Thereafter, the teacher is not available and the classifier takes over the labelling process. See Neural Network.

Stereo Photogrammetry. See Shape from Shading.

Stereoscopic imaging (Stereo). (a) Passive stereo: Two cameras, with known horizontal displacement and viewing angles, observe the same scene. By identifying the same features in each image, some inferences can be made about depth/3D shape information. (b) Active stereo: Uses a structured light source and one or two cameras (e.g., a steered laser beam) to provide 3D range data.

Stroboscopic (Strobe) illumination. Short-duration, intense pulses of light, often repeated at regular intervals. Used for observing a scene during a short interval of time. Often used to "freeze" movement and eliminate image blur. Common strobe light sources: xenon flash tubes, LED arrays, or a pulsed laser. A typical strobe unit, might use a light pulse lasting 10–100 μs, which is repeated once during each frame period of the inspection camera (25 or 30 pulses/s).

Structural (Syntactic) Pattern Recognition. Analysis of the geometric relationships between features in an image to perform recognition and classification functions. Also see Statistical Pattern Recognition.

Structured light. Pattern of light projected onto a widget, to help identify/measure it. Arrays of points, single lines, sets of parallel lines, grids, individual and concentric circles, intensity "staircase," stepped and continuous "rainbows" are the most common types of projected pattern. By observing the deformation of the projected pattern when viewed from a different direction, the range and slope of an object surface can be measured.

Sub-pixel resolution. When locating certain image features (e.g., straight edges and centres of circular holes), it is common practice to employ techniques for model fitting that allow us to obtain a degree of Precision (q.v.) that is better than one pixel. Industrial systems often achieve a precision of 1/10 pixel size.

Subtractive mixture. Pigments modify light by absorbing a portion of the incident light, depending upon the wavelength. Thus, as light passes through a multi-layer film, its spectrum will be progressively modified. Since each wavelength is modified by a different amount in each layer, the film effectively forms a subtractive mixture of light. (See Additive Mixture.)

Successive contrast. A visual image influences the view of the world immediately afterwards. After-images are created by changes in *successive contrast.*

Surface channel CCD. Type of CCD in which the potential distribution used to confine the charge packets is created by the electrode voltages only. This gives a poor charge-transfer efficiency.

Surface spectral reflectance. (See Spectral Reflectance.)

Synchronisation pulse (more commonly Sync pulse). Pulses accompanying a video signal (part of a composite video signal) which trigger/signal crucial events, such as the start of a line, field or frame scan. See Composite Video.

Synchronous operation of a camera. A camera operating at the mains-power frequency (typically 50 or 60 Hz). This avoids strobing effects caused by the camera and light source operating at slightly different frequencies. See Hum Bars.

Syntactic Pattern Recognition. See Structural Pattern Recognition.

System performance. No single metric is sufficient. Commonly quoted parameters: Accuracy (q.v.) Repeatability (q.v.), Precision (q.v.), error rates (False-Positive (q.v.), False-Negative (q.v.)), throughput rate (for piece-parts: parts-per-minute. For webs: area inspected per minute), Latency. (q.v.).

Systems integration. Art of constructing an harmonious assembly of optical, lighting, mechanical hardware (transport mechanisms, jigs, mounts), electronics (opto-electronics, analogue and digital), software and environmental-protection enclosures, to produce a system that meets the agreed specification and is functionally and ergonomically acceptable to the users (factory workers not managers).

T

T mount. Camera-lens interface. 1″ diameter thread. Often preferred over C-Mount (q.v.) for industrial applications.

Tail-end system. Parts of a vision system concerned with operator interface/display, input/output and communications functions. Form an integral part of a Machine Vision system.

Target system. See Industrial Vision System.

TDI camera Modified version of the Line-Scan Camera (q.v.) that can operate with far lower light levels. Sensor possesses several rows of pixels. As a widget/web moves past the camera, the charge from one row is passed to the next, allowing incoming light to be integrated over several line-scan periods. Requires careful synchronisation between clock and the transport mechanism.

Telecentric lenses. Telescopic lens system with a pin-hole aperture located at the focus of the objective, which must be must be larger than the widget. Accepts only collimated light. Image size does not depend on widget-camera distance. Hence, is useful in metrology.

Telephoto lens. Compact lens for viewing distant scenes. Its overall length is less than its focal length.

Template Matching. Technique for shape matching. Template may be a contiguous blob, or a sparse array of separate pixels. (See N-Tuple.) It is shifted to every possible position over the image. At each position, the goodness of fit is estimated. If the that parameter is within a specified range, the feature represented by that template is assumed to be present. Also see Mathematical Morphology.

Texture. Enigmatic property of a surface, due to its geometry (and lighting angle) or innate colouration. Difficult to characterise in an objective way, since there exist few words to describe it.

Thresholding. Image-processing operation which converts a grey-scale image into a binary image, by setting all pixels above a defined value to *white* and all others to *black*. Despite its simplicity and intuitive appeal, fixed-value thresholding is unreliable and should always be preceded by appropriate filtering and careful control of the illumination level.

Throughput Rate. See Processing Speed.

Tracking. Ability of a lens to remain in focus as it traverses its entire zoom range.

Transition. As we travel along a row/column in a binary image, positions of black-to-white or white-to-black intensity changes (see Run Code).

Translation. Lateral movement of a widget by mechanical means. No change of orientation is implied.

Translucent. Material which transmits some light but that which does emerge is diffused; images are not transmitted clearly. Frosted glass is translucent, whereas window glass is transparent.

Transmittance. Ratio of the radiant power emerging from an optical element to the incident radiant power. Maybe expressed on a logarithmic scale, in decibels.

Transparent. Material which transmits some light, preserving image form. While some wavelengths and polarisations may be heavily attenuated, others preserve image structure. Window glass and plastic sheet are transparent. See Translucent.

Triangulation. Method of determining distance by off-setting a structured Light Source (q.v.), compared to the camera-widget axis. Camera-widget distance (range) can be calculated if the geometry of the optical system is known.

Trichromacy. The human eye effectively has three types of colour sensors, which respond in different ways to various wave-lengths. Provided these are stimulated appropriately, all possible sensations of colour can be produced. To a good approximation, this may be achieved by judiciously mixing red, green and blue lights. Mixing paint (e.g., red, yellow and blue, or cyan, magenta, yellow and black paint/ink) has a roughly similar effect. However, not all colours (e.g., purples and "gold") cannot be reproduced either by mixing light or pigments. The concept of trichromacy in humans is a convenient working hypothesis for Machine Vision, rather than a rigorous truth. While normal human colour vision is trichromatic, some animals (e.g., pigeons) have tetrachromatic vision. (They require the mixing of four primary lights to reproduce a given colour sensation.) Other organisms and some colour-deficient people are dichromatic: they require only two primary lights.

Tri-stimulus colourimetry. Experimental technique for measuring colour by matching a given light source with an Additive Mixture. Any two lights with the same tri-stimulus values appear similar to a person. Once the tri-stimulus values for Spectral Lights (q.v.) are determined individually, it is possible to predict the tri-stimulus values for any mixture of them.

Tri-stimulus values. (See Tri-Stimulus Colourimetry.)

Tritanopia. Yellow-blue colour blindness. Tritanopia results from the loss of function of the S-cones.

Tube-type camera. See CRT.

Tungsten filament lamp. See Incandescent Lamp.

Turn-key (vision) system. See Dedicated (Vision) System.

U

Ultra-sound. High-frequency acoustic waves, beyond human perception. In theory, useful for internal inspection of solid objects but practical problems prevent it being used in Machine Vision. Requires close acoustic coupling (i.e., immersion in a liquid), between the transducer-sensor and the object being examined. Image resolution is poor, as the wave-length is relatively large. Widely used in medicine as a safe alternative to x-rays.

Ultra-violet (UV). Term applied to that part of the electromagnetic spectrum containing radiation in the wavelength range of approximately 100–400 nm, i.e., between visible blue light and X-rays.

Unique hue. Red, green, yellow, and blue are thought to be basic components from which all other hues are composed and are therefore called *unique hues.*

Univariance. A single photo-detector site in the human eye (a single cone in the retina), or a camera (a single photo-transistor), is incapable of distinguishing between an intense light at a wavelength to which it is insensitive and a weaker light at a wavelength to which it is more sensitive. Therefore, chromatic vision, in people, animals and machines requires multiple types of photo-detector.

Unsharp masking. High-pass filtering operation in which a blurred version of an image is subtracted from the original.

UV-A. Ultra-violet radiation in the wave-band $\lambda = 315–380$ nm. Near UV (NUV).

UV-B. Ultra-violet radiation in the wave-band $\lambda = 280–315$ nm. Mid UV.

UV-C. Ultra-violet radiation in the wave-band $\lambda = 100–280$ nm. Deep/far UV (DUV or FUV).

V

Validation. Rigorous testing of a vision system. Needed to verify that it performs as claimed.

Variable-scan frame grabber. Device capable of accepting a variety of non-standard video input formats. Also see Frame Grabber.

Vari-focal. Low-cost zoom lens. Unable to track accurately. See Tracking.

Video. Signal generated by a television camera, computer, or other device in the same format. Various standards exist, most notably CCIR (called RS-330 in North America) and RS-170. See Composite Video.

Vidicon. Type of CRT (q.v.). A range of broadly similar photo-conductive camera tubes, using a transparent signal plate and a low-velocity scanning electron beam. Noted for its versatility and good performance for a modest cost.

Vignetting. Dark shadows around the corners of a video image. Created by using an optical system that produces an image that is too small to cover the camera's light-sensitive surface.

VIS. See Visible Light.

Visible light (VIS). Region of the electromagnetic spectrum in which the human retina is sensitive: wave-lengths of approximately 0.4–0.7 μm.

Vision engine. Plug-in accelerator, designed specifically for image processing and analysis functions. To achieve maximum speed, some flexibility has to be sacrificed.

Visual cortex. Those cortical areas primarily concerned with the processing of visual information. The visual areas of the cortex are primarily located in the occipital lobe: the rear, lower part of the cortex.

Vision system. (Synonym for Machine Vision system*)* An engineering system, usually containing equipment for most or all of the following functions: mechanical translation (of the Widget (q.v.), optics or camera), lighting, image formation (optics), image sensing (video camera or scanner), fast analogue and/or digital video-signal processing, image analysis (implemented in software) and user interaction (for programming, calibration, display of results and testing).

W

Wave-length. Parameter relating to visible light, which identifies its colour. Term is also applicable to characterising a much wider range of electro-magnetic radiation, including (in order of decreasing wave-length): radio waves, microwaves, IR, visible light (VIS), UV, x-rays and gamma rays. Usually denoted by λ. Related to frequency (f) and velocity of propagation (c) by the relationship c = f.λ. Also see Spectrum.

Weber's law. Natural vision systems often respond so that, for a given observed parameter, S, the following ratio is held constant:

$$[\textit{minimum perceptible change in S}]/[\textit{absolute value of S}].$$

This accounts for the fact that the smallest detectable intensity difference between two lights is larger if they are both bright.

Weight matrix. Matrix of constant coefficients defining the multiplicative constants employed by a local or N-Tuple Operator. (q.v.).

Well. Morphological operator equivalent to Closing (q.v.) followed by subtraction of the input image.

Widget. Object to be inspected. Has a specific meaning in the context of this book.

Windowing. Performing image processing operations only within a predefined area (window) of an image. Also see ROI.

Woods glass. Type of glass that transmits UV but is relatively opaque to VIS.

X

Xenon lamp. High intensity arc discharge bulb. Light from has a similar spectrum to that of daylight. Suitable for strobe lights. Dangers: high UV content, high flash rates can induce photo-sensitive epilepsy.

X-ray. A portion of the electromagnetic spectrum beyond the ultraviolet with higher frequency and shorter wavelengths. Able to penetrate solid objects for internal, non-destructive evaluation.

Y

YAG laser. Yttrium-aluminium-garnet laser, capable of providing continuous IR radiation with power output of several watts. Dangerous!.

Z

Zone plate. Transparent plate with a pattern of concentric opaque rings, designed to block off every other Fresnel half-period zone. Light from a point source passing through the plate produces a point image much like that produced by a lens.

Zoom lens. Compound lens which remains in focus as the image size is varied. May be motorised or manually operated. See Vari-Focal Lens.

Zoom ratio. Ratio of the longest and shortest focal lengths of a zoom lens. May be as high as 40:1 for a broadcast-quality lens.

Appendix B: MV Questionnaire

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_43,

B.1 Why a Questionnaire is Needed?

The *Machine Vision Questionnaire* (*MVQ*) is intended to assist in formalising the requirements and specification for a vision system that will perform a new inspection function, or one that has hitherto been performed by other means. The questionnaire raises a wide variety of issues that should be considered by a vision engineer, so that he/she can quickly decide whether Machine Vision is likely to satisfy the application requirements. Past experience has shown that, with careful initial analysis of the application requirements, a great deal of time and money can be saved; asking the right questions at an early stage can help to avoid frustration. The MVQ contains questions that help to establish technical feasibility and likely benefits of Machine Vision, as early as possible. The answers might also provide a basis for writing a detailed specification and contract for the design, construction and delivery of a vision system.

The MVQ outlined in this appendix concentrates on technical issues. In addition, a large number of managerial/contract details should be agreed between the equipment supplier and customer before work begins in earnest. These include maintenance, servicing, warranty, provision of spares, documentation, ownership of intellectual property, possible future upgrading of the system, safety, legal responsibility, ISO 9000/14000 certification, etc.

B.2 History

The *Machine Vision Application Requirements Check List* was originally devised by Nello Zuech, Vision Systems International, Yardley, PA 19067, USA. It was included in his book "*Understanding and Applying Machine Vision*," CRC Press, Boca Raton, FL 33487, USA, ISBN-13 9780824789299, 1999. Nello Zuech's version of the *Machine Vision Application Requirements Check List* was published without restrictions on use.

An updated version of the *Machine Vision Application Requirements Check List* was subsequently made available and published via a web site created by Image Labs International, Inc., Bozeman, MT 59715, USA. URL http//www.vision1.com/vsi/mvaques.html, accessed 9th October 2008. The Image Lab version was published without restrictions on use.

The *MVQ* printed in this appendix was prepared by Bruce Batchelor and derives inspiration from the *Machine Vision Application Requirements Check List*. It is also published free of copyright; permission is granted to use the *Machine Vision Questionnaire* freely without restriction.

B.3 Machine Vision Questionnaire

Note: *Widget* is used to denote the *object to be inspected.*

B.3.1 Current Production and Inspection Processes

1. Name/and part number of the widget.
2. Latency time between image acquisition and the final action (e.g., accept/reject widget)
3. What is the expected life of the widget?

4. What is the maximum acceptable pay-back period for capital expenditure on QA equipment?
5. How is inspection currently performed?
6. How the current inspection process is deficient.
7. Goal(s) for the proposed automated visual inspection/visual control system
    - Avoid accidental damage to machines due to jamming on faulty products
    - Improve process efficiency
    - Improve process efficiency
    - Improve process safety
    - Improve product reliability
    - Improve product safety
    - Match production speed
    - Reduce waste of materials
8. What is the current reject rate for bad widgets, according to your established factory-floor inspection methods?
9. What is your best estimate for the real rate of occurrence of faulty widgets. (You could, perhaps, cite careful non-real time, laboratory analysis?)
10. Why do the answers to the two previous questions differ so much?
    - What is the false reject rate?
    - What is the false accept rate?
        - Is there any realistic chance of reducing these by improving the current inspection method?
        - Which is more problematical, *false reject* or *false accept*?
11. Production mode
    - Batch production
    - Continuous process
12. Change-over of manufacturing system to alternative product
    - Time required for change-over
    - Frequency of change-over
    - Skill levels involved needed for the change-over
13. Where widgets go after inspection
    - Good widgets (“widget heaven”)
    - Faulty widgets (“widget hell”)
14. Are widget design or production process changes anticipated?
    - How do you envisage the present product range to change in the foreseeable future?
    - Anticipating future products, are there an any additional inspection functions that you would like the proposed Machine Vision system to perform?
15. Is every widget inspected?
    - Sampled inspection (specify the sampling rate)
        - 100% inspection
16. How inspection is performed
    - Manually, as part of manufacturing process
    - Manually, unaided, dedicated inspector
    - Manually, with standard charts, pictures, swatches, etc.
    - Manual application of instruments
    - Automatically (state how)

17. When a faulty widget escapes detection, what are the effects down-stream on the following?
    - Quality
    - Cost
    - Product safety
    - Process safety
    - Repair/rework
    - Loss of production
    - Serious damage to machine(s) down-stream
    - Jamming of machine(s) down-stream
    - Other
18. If inspection were effective, could any down-stream testing requirements be relaxed?
19. Cost (preferably expressed in quantitative terms)
    - Undetected faulty widget
    - Good widget that is falsely rejected
20. Previous experience/attitudes of staff towards Machine Vision/automation
    - Factory-floor personnel
    - Factory manager
    - Project champion

B.3.2 Describing the Widget

This section should be completed for each type of widget.

21. What is the expected life of the widget?
22. Product volume (total number of widgets/day, all lines making this product)
    - Is this expected to rise in the foreseeable future?
23. Production rate for each line
    - Average production rate (widgets/min)
    - Peak production rate (widgets/min)
    - Number of widgets arriving simultaneously at the inspection point
    - Is this expected to rise in the foreseeable future?
24. Manufacturing process(es) used when making the widget
    - Moulded
    - Cast
    - Forged
    - Stamped
    - Pressed
    - Rolled
    - Pressed
    - Turned
    - Extruded
    - Spun
    - Woven
    - Sintered
    - Cut from stock

- Folded from sheet
- Multi-stage machining
- Other, specify

25. What is the last machining operation, just before the point of inspection?
26. No. of materials making up the widget
    - Single monolithic widget
    - Single multi-material widget
    - Assembly of monolithic widgets
    - Assembly of multi-material widgets
27. Materials used in manufacture (e.g., steel, brass, PTFE, glass, wood, etc.)
28. Variation of appearance within a given batch
    - Fixed
    - Some variability within a batch
    - Very variable
29. Variation of appearance between batches
    - Fixed
    - Some variability
    - Very variable
30. Changes in appearance over time
    - Months
    - Days
    - Hours
    - Minutes
    - Unchanging
31. Coating (at least as important as the substrate material in determining appearance)
    - None
    - Painted
    - Lacquered
    - Chemical coating
    - Powder coating
    - Plated
    - Other, specify
32. Colouring
    - Monochrome
    - Dichromic
    - Trichromic
    - Polychromic (multiple discrete colours)
    - Subtle colouring
33. Dimensions
    - Absolute maximum, widget is allowed to be in any orientation
    - Maximum when the widget is held so that important features are visible
    - Orthogonal axis (90° to maximum visible axis)
    - Along visual axis (include only visible features)
34. Fragility
    - Tough as old boots
    - Medium (comparable to glass bottle)
    - Fragile (comparable to egg shell)

35. Hazards
    - Radiation, specify type and level
    - Biohazard
    - Toxic
    - Sharp
    - Electrical
    - Physical (e.g., liable to explode/implode, presents finger trap, etc.)
    - Heavy
    - Insignificant
36. Internal detail
    - Not relevant, only external features are important for inspection
    - Important internal features can be observed
    - Optically
    - UV
    - IR
    - X-rays
37. Light penetration
    - Opaque
    - Transparent
    - Transluscent
38. Overlay
    - None
    - Printed
    - Photography
    - Lithography
    - Other, specify
39. Patterned surface
    - Regular
    - Irregular
    - Spotty
    - Striped
    - Chequered
    - Blotchy
    - None
40. Photo-active
    - Light sensitive
    - Fluorescent
    - Phosphorescent
    - Photo-chromic
    - None
41. Physical form
    - Spider-like
    - Deep concavities
    - Shallow concavities
    - Convex

42. Stability of posture
    - Neutral
    - Effectively single stable state, guaranteed by mechanical handling system
    - Single stable state, inherent in shape and mass distribution
    - Several stable states
    - No stable state
43. Rigidity
    - Rigid
    - Flexible
    - Articulated
    - Serpentine
    - Chain-like
44. Shape, as seen by inspector
    - Spider-like
    - Linear (e.g., screwdriver)
    - Curved (e.g., banana)
    - Serpentine
    - Coiled
    - Twisted
    - Knotted
    - Compact
    - Round
    - Flat
    - Long and thin
    - Cube
    - Rectangular
    - Other (specify)
45. Surface appearance
    - Mirror-like
    - Bright shiny
    - Dull-shiny (e.g., smooth rubber)
    - Matt
    - Egg-shell
    - Dull (e.g., soot)
46. Surface condition
    - Clean
    - Wet
    - Oily
    - Rusty
    - Oxidised
    - Stained
    - Dusty
    - Biological activity
47. Surface roughness
    - Mirror finish
    - Smooth

   - Rough
   - Very rough
   - Textured – regular
   - Texture – irregular

48. Dimensions
    - Absolute maximum, widget can be in any orientation
    - Maximum when the widget is held so that important features are visible
    - Orthogonal axis (90° to maximum visible axis)
    - Along visual axis (include only visible features)
49. Size, variability
    - Highly variable
    - Some variation
    - Nearly constant
    - Highly consistent
50. Temperature
    - [<20°]
    - [−20°–0°]
    - [0°–50°]
    - [50°–100°]
    - [>100°]
51. Unit value
    - Very low value (≤ 1¢)
    - Low (¢s)
    - Medium (€/$)
    - High value (>10 €/$)
52. Weight
    - [<1 g]
    - [1 g–10 Kg]
    - [>10 Kg]

B.3.3 Faults in the Product

53. Biological damage
    - Micro-organisms
    - Rotting
    - Bird peck
    - Bite
    - Scratch
54. Colour
    - Missing imprint
    - Misplaced colour imprint
    - Low saturation
    - High saturation
    - Wrong hue
    - Faded

55. Contamination, foreign bodies/material
    - Fingerprint
    - Oil
    - Water
    - Rust
    - Fungus, other micro-organisms
    - Dirt
    - Dust
    - Staining
    - Ink
    - Paint
    - Acid
    - Animal debris
        - Bones
        - Insects
        - Rodents
        - Excrement
        - Urine
        - Hair
        - Nesting materials
    - Stones
    - Soil
    - Sand
    - Raw materials used in manufacture
    - Coolant
    - Lubricant
    - Other, specify
56. Dimensions
    - Too big
    - Too small
    - Too high
    - Too short
    - Spacing between features
    - Angle position of features
    - Radial position
57. Grading
    - Inferior grade
    - Superior grade
    - Wrong type
58. Incorrect assembly
    - Part missing
    - Part damaged
    - Part incorrectly fitted
    - Wrong part fitted
59. Light damage
    - Faded

60. Local defect
    - Cut
    - Tear
    - Crack
    - Split
    - Chip
    - Scratch
    - Pit
    - Blow hole
    - Debris
    - Sprue
61. Machining
    - Incomplete
    - Machining step missing
    - Machining error
62. Malformed
    - Bent
    - Broken
    - Twisted
    - Extra material
    - Mould seam marks
    - Sprue still attached
    - Machining fault
63. Misprinting
    - Colour imprint misregistration
    - Smudged
    - Ink spill
    - Oil
64. Number
    - Too few
    - Too many
    - Unable to count
65. Pose
    - Wrong orientation
    - Wrong position
    - Wrong posture
    - Inverted (up-side down)
66. Weave error
    - Weave
    - Broken thread
    - Pulled thread

B.3.4 Vision Task

67. How is inspection currently performed?

68. Explain how it is deficient in meeting the required performance? Why do you need to inspect the widgets or control their production process?
    - Improve process efficiency
    - Improve process safety
    - Improve product safety
    - Improve product reliability
    - Match production speed
    - What is the current reject rate of bad widgets?
69. What is the accuracy of the current inspection system?
    - False reject rate
    - False accept rate
70. What benefits do you hope to achieve by installing a Machine Vision system?
71. Function(s) to be performed by the vision system
    - Detecting local faults
    - Detecting malformation
    - Grading
    - Sorting
    - Checking feature existence
    - Measurement
        - Linear dimensions
        - Angles
        - Position (2 dimensions)
        - Position (3 dimensions)
        - 3D shape
        - Orientation
        - Posture
    - Checking colour
    - Checking texture
    - Other, specify
72. Must every widget be inspected?
    - Sampled inspection is adequate (Specify the minimum sampling rate)
    - 100% inspection is desirable
    - 100% inspection is essential
73. Are widget design or production process changes anticipated?
    - How do you envisage the present product range to change in the foreseeable future?
    - Anticipating future products, are there an any additional inspection functions that you would like the proposed Machine Vision system to perform?
74. Operating mode of the proposed vision system
    - Will the vision system be retro-fitted to a new line or an existing line?
    - Number of widgets to be examined at the same time
    - Number of different types of widget to be accommodated
    - How many lines/machines will vision system(s) be needed for?
    - Is inspection to be performed on-line or off-line?
    - Throughput rate (widgets per minute)
75. Check cleanliness
    - Floor
    - Material deposits around feed chute or hopper

- Stairs
- Tools
- Work space
- Check feed-stock

76. Check transport system
    - Discrete widgets, jumbled in a barrel/hopper
    - Discrete widgets, loaded onto specialised carrier
    - Granular material
    - Linear object (strip/bar/pipe/tube/wire/cable/extrusion)
    - Liquid level
    - Motion
    - Indexing
    - Cleanliness
77. Checking safety
    - Intruder surveillance
    - Operator hands
    - Stairs
    - Gangways
    - Flames
    - Sprays
    - Doors
    - Debris
    - Widgets transport
    - Materials transport
    - Chutes
    - “Waterfalls” of granular material
78. Classify
    - Identify
    - Identify piece widgets
    - Grading natural product species
    - Classifying natural product varieties or species
79. Machine/Robot Control
    - Robot positioning has 1/2/$2^1/_2$/3/$3^1/_2$/4/5/6 degrees of freedom
    - Function
        - Assembly
        - Cutting
        - Drilling
        - Grinding
        - Marking
        - Milling
        - Packing
        - Painting
        - Palletising
        - Polishing
        - Sanding
        - Soldering

    - Sorting
    - Spraying
    - Stacking
    - Turning
    - Washing
    - Welding
    - Other, specify

80. Counting
    - Objects
    - Features on large objects
81. Detecting
    - Broken tool
    - Damaged widget
    - Error in materials feed
    - Incomplete widget
    - Malformed widget
    - Worn tool
82. Finding
    - Objects
    - Features on a complex object
83. Locating
    - Feature
    - Grasping point
    - Object
84. Measuring
    - Angle
    - Linear dimension
    - Area
    - Distance between features
    - Angles defined by widget features
85. Inspecting printing
    - Accuracy of colour rendering (hue and saturation)
    - Character recognition (printed text is not known beforehand)
    - Character verification (printed text is known beforehand)
    - Colour imprint alignment
    - Damaged paper
        - Creased
        - Torn
        - Stained
        - Dirty
    - Deficiency of ink
    - Print quality
        - Character formation
        - Sharpness
    - Smudging
    - Surplus ink

86. Recognise
    - Industrial widgets
    - Natural product, varieties
87. Web fault detection and classification

B.3.5 Viewing Background

88. Access
    - Possible
    - Limited
    - Impossible
89. Colour
    - Monochrome
    - Dichromic
    - Trichromic
    - Polychromic
    - Subtle colouring
    - Can be selected to suit vision system
90. Constancy
    - Constant
    - Constant with minor local changes
    - Major changes
91. Light level
    - Uncontrolled
    - Low
    - Medium
    - Bright
92. Reflectivity
    - High
    - Medium
    - Low
93. Structure
    - Plain
    - Structured
    - Patterned
    - Textured
    - Factory floor
    - Equipment

B.3.6 Environment

94. Access, camera
    - Easy
    - Limited
    - Very difficult

95. Access, lamps
    - Easy
    - Limited
    - Very difficult
96. Acoustic noise
    - None-to-moderate
    - Severe
97. Ambient light level
    - Total darkness
    - Very dark (e.g., moon-light)
    - Dark (e.g., in shadow in living room at night)
    - Bright (room lit by electric lamp)
    - Very bright (close to electric lamp)
    - Sunlight
98. Atmospheric pollution
    - Very little
    - Dust
    - Fumes
    - Smoke
    - Steam
    - Chemical mist (aerosol droplets)
99. Heat from lamps
    - Not important
    - Possible damage to product
    - Possible difficulties with process
    - Critical
100. Shrouding, screen around widget, camera and lights
    - Possible
    - Difficult
    - Impossible
101. Vibration
    - Little
    - Moderate
    - Severe
102. General working environment
    - General factory
    - Laboratory
    - Clean room
    - Outdoor
103. Air quality
    - Dust
    - Smoke
    - Flying debris
    - Water droplets
    - Water mist

- Steam
- Oil mist
- Oil droplets

104. Wash-down requirements
    - Water mist
    - Water jet
    - Steam
    - Chemicals, specify
105. Ambient light
    - Incandescent
    - Fluoresecent
    - Mercury lamp
    - Sodium lamp
    - Other artificial
    - Daylight (no direct sunlight)
    - Direct sunlight
106. Light pollution from nearby equipment
    - Little
    - Constant lights
    - Flashing lights
107. Temperature range (°C)
108. Humidity
    - Relative humidity (%)
    - Dew point (°C)
109. Radiation
    - EMI
    - IR
    - Nuclear
    - RFI
    - UV
    - X-rays
110. Vacuum, yes/no
111. Compressed air
    - Available/not available
        - Content
    - Water
    - Dust
    - Oil
    - Other
112. Power
    - AC
    - Voltage
    - Frequency
    - Single-phase
    - 3-phase

- Regulated
- Action needed in event of general power failure
- DC
- Voltage (V)
- Voltage tolerance (±V)
- Current limit (A)

B.3.7 Mechanical Handling

113. Widget delivery
    - What is the last machining operation, just before the point of inspection?
    - How will the widgets be transferred from there to the vision system?
    - Rate of delivery (widgets/min)
114. Is this production rate expected to rise in the foreseeable future?
115. Where widgets go after inspection?
    - Good widgets
    - Bad widgets (bad little widgets go to the widget hell!)
116. Repair/reworked of faulty widgets
    - Is this technically possible?
    - Is this economically viable?
    - Can Machine Vision assist in the diagnosis?
117. Type of handling system
    - Linear conveyor
    - Rotary conveyor
    - Robot
    - Chute
    - Free fall
    - Manual
118. Possible to damage widget during handling?
119. Special handling precautions (e.g., keep widget moist/cool)
120. Inspection station expected to perform other functions? (specify)
121. Production rate (widgets/min)
    - Average throughput rate
    - Peak throughput rate
    - Is it possible to smooth the flow through inspection system by delaying widgets?
    - Latency time between image acquisition and the final action (e.g., *accept/reject*)
122. Indexed motion
    - Stationary time
    - Total in-dwell-out time
    - Settling time
    - Precision of placement
        - ± δX (orthogonal to line of motion)
        - ± δY (along line of motion)
        - ± δZ (vertical axis)

    - ± δ angle around X axis (degrees)
    - ± δ angle around Y axis (degrees)
    - ± δ angle around Z axis (degrees)

123. Widgets moving continuously
    - Motion
        - Linear
        - Circular
    - Direction
    - Nominal speed
        - Variation in speed (±percent)
        - Speed, regulation possible?
    - Shudder during motion
    - Maximum variation of widget position across belt
    - Spacing between widgets along the belt
        - Random
        - Nominally fixed
    - Repeatability of spacing between widgets
    - Can the orientation be controlled (e.g., by guide rails)?
124. Widgets touching one another?
125. Widgets overlapping one another?
126. Space available for inspection station
    - Open
    - Restricted
127. Minimum distance from camera to computer
128. Distance from inspection system to interfaced equipment
129. Other physical constraints around installation site (specify)
130. Conveyor
    - Type
    - Structure (e.g., belt, chain, etc.)
    - Colour
    - Appearance (e.g., bright metal)
    - Accumulation of dirt/debris?
    - Other factors affecting appearance
    - By-pass mode required?
131. Is more than one camera likely needed to see all of the significant faults?
132. Will the vision system be fitted to a new line or an existing line (retrofit)?
133. Number of widgets to be examined at the same time
134. How many manufacturing lines must be fitted with a vision system?
135. Is inspection to be performed *on-line* or *off-line*?

B.3.8 Interfacing

136. Operator interface
    - Essential features
    - Desirable features

137. User
    - Educational level/experience
        - Analogue electronics
        - Computers
        - Digital electronics
        - Digital photography
        - Illumination engineering
        - Manufacturing equipment
        - Optics
        - Video
138. Restricting personal access
    - Password protection
    - Face recognition
    - Voice recognition
    - Speaker recognition
    - Finger-print recognition
139. Display of results
    - Summary statistics (specify reporting period)
    - Tabulated data
    - Graphs
    - “Live” image from camera
    - Images recorded from recent faulty parts (how many?)
    - Images recorded from recent good parts (how many?)
        - Marking widget (e.g., spraying faulty widgets red)
        - Must reports be generated without interrupting inspection
    - Hard copy required
    - Electronic copy (format: CD, DVD, memory stick or remote computer)
140. Additional alarm
    - Audible
    - Flashing light
    - Alert remote computer
141. System failure
    - Action required
    - Power-failure action
142. Machines to be interfaced to the vision system
    - Mechanically
    - Electrically
143. Event that will trigger inspection
    - Proximity detector
    - PLC
    - Computer
    - Manufacturing machine (e.g., ejection of widget from moulding machine)
    - Other (specify)
144. Machine–machine interface
    - Interface standard (e.g., RS232, RS422, RS449, IEEE488, parallel, PLC, Ethernet, USB, IEEE1394)
    - Opto-isolation

B.3.9 Other Issues

145. Accessibility. The following are helpful in the design process. Explain any problems.
    - Collecting a large number of representative samples of good and bad widgets
    - Engineering drawings of the widgets
    - Protocols and *accept/reject* rules currently given to human inspectors
    - Diagrams/pictures/swatches currently given to human inspectors
    - Still photographs and/or video recording of the production process
    - Virtual tour of the factory
    - Direct observation of the production process in the factory
146. Calibration
    - Procedure
147. Equipment required (models, charts, swatches, etc.)
148. Computer network, integration of vision system into company intranet
149. Cost
    - Capital
    - Operating costs
150. Documentation
151. Duty cycle (number of hours use per week)
152. Fixtures and cabling
153. Hardware, reliability of supply of spares from 3rd party
154. Intellectual property, ownership
155. Legal issues, specific to customer's type of business
156. License fees for installed software
157. Maintenance and cleaning
    - Procedures
    - Materials
    - Frequency
    - Duration
158. Operator safety
159. Paint colours
160. Post-sales support
    - Help line
161. Power consumption
162. Response time for service
163. Responsibility
    - Backup
    - Installation
    - Software changes
    - Revisions
164. Safety of vision engineer
    - Protocol when vision engineer is visiting factory
    - Vision engineer handling dangerous widgets
    - Additional safety issues (e.g., standard enclosure required)
165. Shipping
166. Spare parts, stock requirements

167. Tests, installation site
    - Supply of good, faulty, and/or marginal widgets
    - Variations of parts (e.g., size/colour variations)
    - Sample size
    - Acceptability criteria
    - Widget position variations
    - Widget orientation variations
    - Lighting variations
    - Environmental conditions
168. Tests, vendor site
    - Supply of good, faulty, and/or marginal widgets
    - Variations of parts (e.g., size/colour variations)
    - Sample size
    - Acceptability criteria
    - Widget position variations
    - Widget orientation variations
    - Lighting variations
    - Environmental conditions
169. Training
    - Factory-floor personnel
    - Engineering staff
170. Verification procedure needed to system is performing correctly
171. Warranty
    - Duration
    - Terms and conditions

Appendix C: Proverbs

Bruce G. Batchelor[1] · *Paul F. Whelan*[2]
[1]Cardiff University, Cardiff, Wales, UK
[2]Dublin City University, Glasnevin, Dublin, Ireland

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_44,

The following observations, comments and suggestions are based upon the experience of the author and his colleagues. While this list is presented in a light-hearted manner, it encapsulates some important lessons that are unfortunately not universally appreciated or applied when designing or choosing a new vision system.

C.1 General

There is more to machine vision than meets the eye.

- ► A machine vision system does not see things as the human eye does.

An eye is not a camera. A brain is not a computer.

- ► Machine vision systems should not necessarily be modelled on, or intended to emulate human vision.

Machine vision is not a scientific discipline.

- ► Machine vision is not an exercise in philosophy but an engineering project.

No vision system should be required to answer the general question "What is this?"

- ► It is better for vision systems to answer more specific questions, such as "Is this widget well made?" Verification (i.e., checking that the widget is well made) is better than recognition, where few or no a priori assumptions are made.

Intelligence ≠ Computing power.

- ► Making the computer more powerful does not necessarily make the system smarter.

Optimal solutions do not always exist.

- ► If they do exist, optimal solutions may be too complex, or impossible to find. We should therefore be prepared to search for and accept satisfactory solutions, rather than optimal ones.

Use a standard solution to a vision problem but only if it is sensible to do so.

- ► Wherever possible we should provide standard solutions to industrial problems, since this helps to broaden the application base.

Avoid the application of machine vision techniques for their own sake.

- ► It is vanity on the part of the vision engineer to do so. There are plenty of other methods of solution available. Most of them are cheaper than vision.

Defect prevention is better than cure.

- ► We should consider using vision in closed loop feedback control of the manufacturing process.

Do not rely on second-hand information about the manufacturing process and environment.

- ► The vision engineer should always see the manufacturing process for himself. If the customer is unwilling to let the vision engineer into the factory, it may be necessary to abandon the application.

Vision systems need not be fully automatic.

- ► While it is more usual to use a fully automatic vision system, it can be used instead to enhance images for subsequent human analysis.

C.2 Systems

No system should be more complicated than it need be.

- ► This is a reformulation of Occam's Razor, which in its original form is "Entia non multiplicanda sunt." In its English translation, excessive complication is attributed to mere vanity. In colloquial use, this is often referred to as the KISS principle. (Keep it simple, stupid.) Simple systems are almost always the best in practice.

All parts of a properly designed machine vision system bear an equal strain.

- ► Of course, it is impossible to measure strain in any formal sense. The point is that no part of a vision system should be made more complicated because a sloppy attitude has been adopted during the design of other parts. A particularly common error is the tendency to concentrate on the image processing, to the detriment of the image acquisition (i.e., pose of the object being inspected, lighting, optics and sensor).

If it matters that we use the Sobel edge detector rather than the Roberts operator, then there is something fundamentally wrong, probably the lighting.

- ► This remark is not about the relative merits of the various edge detection operators but is a statement about the need for a broader "systems" approach. A common error is to pay much more attention to the image processing process but ignore the fact that the image contrast is low because the lighting sub-system is poorly designed.

The following inequality is always true:
$\text{Vision-system} \neq \text{PC} + \text{Framegrabber} + \text{Camera} + \text{Software}$.

- ► To many people, these are the only components needed to build a vision system. However, this neglects many important issues: lighting, optics, systems integration, mechanical handling, ergonomics and standard industrial inspection practice.

Problem constraints allow the vision engineer to simplify the design.

- ► By taking systems issues into account, it may well be possible to design a simpler, faster, cheaper and more robust system.

Vision systems can use the same aids as people to reduce task complexity.

- ► For example, special optical/lighting techniques, X-rays, fluoroscopy, multi-spectral imaging, specialised sample preparation can all be used.

Documentation is an essential part of the system.

- ► A vision system will not survive for long without sufficient documentation.

C.3 Customer

Whatever software and hardware that a machine vision system uses, the customer will want it to be different, so don't tell them.

- ► Many customer companies have a policy of using certain types of computer hardware/software, which will often conflict with the vision system. It is wise to regard the vision system as a closed box.

The customer must not be allowed to tinker with the system after it is installed.

- ► The customer should be dissuaded from making internal adjustments to the system, since this requires rare and specialised skills (lighting, optics, camera, algorithms, systems integration).

The customer's company just does not make defective widgets; the vision system is simple intended "to improve product quality."

- ► Companies are often sensitive about the way that quality (or lack of it) in their products is discussed. This must be borne in mind when designing a vision system and particularly when reporting developments at conferences, in publications, etc.

Everybody (including the customer) thinks that he/she is an expert on vision and will tell the vision engineer how to design the machine.

- ► This is, regrettably, one of the great truths. As a result, everybody will feel it is their right and duty to tell the vision engineer how to do his job. In many instances, prototyping tools need to be used for the specific purpose of convincing the customer that his intuitive approach just does not work reliably.

The widgets that were provided for the feasibility study were specially cleaned and chosen by the customer for the project.

- ► Beware of the pernicious habit of some customers who deliberately, or through ignorance, select good quality products to show the vision company, rather than providing a more representative sample.

Customer education is an integral part of vision system design.

- ► A well educated customer can help to reduce the project cost and may well help to reach a better system design.

A little knowledge is a dangerous thing.

- ► The customer will suggest many changes to the system design if he is ignorant of the subtleties which led to the present design. It is best to tell the customer all or nothing. For example, the vision engineer should not tell the customer that the system uses a camera costing $5,000, because the latter will know of a camera that costs only $100 but will not appreciate the benefits of the more expensive device.

C.4 Financial

The vision system must pay for itself in 6 months.

- ► The vision engineer must be prepared to argue against the simple-minded attitude which attempts to judge the value of a vision system solely on financial grounds. When a company buys a vision system, it is investing in the improvement of the quality/safety of its products.

Component cost is not the same thing as system cost.

- By purchasing one relatively expensive component, it may be possible make the overall system cheaper, faster, and more reliable.

Only 10% of the cost of installing a vision system is directly attributable to the requirements of image formation, acquisition and processing.

- The remaining 90% of the project cost is due to making the system work properly in the factory.

$1 spent on inspection is worth $10 in improved profits.

- Investing a little in automated visual inspection can lead to significant gains in improved efficiency.

C.5 System Specification

The specification of the vision system is not what the customer wants.

- Do not try to take short cuts in the initial dialogue. The vision engineer should be prepared to spend a considerable amount of time finding what the customer really wants.

The system specification must be agreed and fully understood by all concerned.

- All specifications should be in writing with negotiable and non-negotiable specifications noted before the design proper begins.

No machine vision system can solve the problem that the customer forgot to mention when placing the order.

- Undertake a proper and complete design study for each type of product.

The specification of a vision system should indicate its functionality and performance.

- It should not be used merely as a marketing tool.

Beware when the customer says “By the way! We would like to be able to inspect these objects as well.”

- We repeat the point just made above: undertake a proper design study for each type of product.

Simple accept/reject labelling is easier than classifying defects by type.

- If the customer wants to classify defects, they should be made aware that this could have a major bearing on the cost of the inspection system. Detailed classification of defects can greatly increase the speed/cost of the vision system.

It may not be possible to classify defects reliably.

- The classification process may not always be clear-cut. A certain product may, for example, have a combination of faults. The vision system supplier and customer must agree beforehand what bounds are to be imposed on the classification process.

Specify the operating environment.

- It is relatively easy to make a system that works well in the laboratory. However, it is much more difficult to build a target system that will work reliably in a hostile factory environment.

Defect types must be realistically prioritised.

- ► The ranking of defect types in order of importance can have a major influence on the approach taken, and hence the final cost of the solution. For example, it may be the case that 90% of defect types can be detected for a cost of 90% of the total project budget, whereas detecting the remaining 10% of defect types would cost another 90%. (This is an example of the 90:90 rule.)

C.6 Choosing Inspection System Design Samples

Maximise the number of product samples.

- ► The feasibility study, the target system design process, the testing and evaluation of the target system and any demonstrations to the customer should all be based on a large number of representative sample parts. These samples should cover the full range of part variability.

Choose design samples following proper statistical sampling techniques.

- ► Their selection should be made according to a carefully planned and agreed protocol.

If necessary, choose inspection samples manually using agreed criteria.

- ► If samples are chosen manually they will need to be cross-checked to ensure that the variation found in manual inspection is minimised. It is critical that the vision engineer establishes a reliable training set.

The customer said his widgets were made of brass. He did not think to state that they are always painted blue and oily.

- ► To the vision engineer, the surface finish is more important than the underlying material. This contrasts sharply with the customer who often regards surface finish as being of mere cosmetic value.

Classify sample defects.

- ► There are many different ways in which a product can fail to meet its criteria. Any specific application knowledge that the customer can add concerning the type and origin of the fault, will be useful in the design process.

C.7 Vision Company

A sales-person who says that their company's vision system can operate in uncontrolled lighting is lying.

- ► No. We are not exaggerating. The human eye cannot. No machine can either.

A happy vision team has (at least) seven players.

- ► This consists of engineers who specialise in mechanical handling, lighting, optics, video sensor technology, electronic hardware, software, vision system integration.

C.8 Alternative Solutions

What a person cannot see, generally cannot be detected by the machine vision system.

- The human eye is remarkably adept and versatile. In contrast, a vision system is clumsy and unsophisticated, although it may be faster and more reliable. It is a good maxim to admit defeat sometimes as this will gain customer confidence, in the long term.

It may be cheaper to hire a person to inspect the widgets.

- However, a machine may be faster, more consistent and reliable. Be prepared to argue this point with the customer.

Machines can do some things better than humans.

- Machines can sense outside the visible spectrum (X-rays, IR, UV). Line-scan cameras and laser scanners can produce high resolution images that cannot be seen directly by the eye. Depending on the technology used, a machine vision system would be expected to achieve a substantially higher inspection efficiency, and it can theoretically do this for 24 hours a day, 7 days a week. Machine vision can also be useful at detecting gradual changes in continuous processes that appear over long time periods. For example, inspecting gradual colour variations in the production of web materials. Such a gradual change in colour is unlikely to be detected by a human operator.

People can do some things better than machines.

- So far, no machine has been built that can reliably guide a car through busy traffic, safely and at speed. No machine can yet judge the aesthetic qualities of a person's dress or a fine painting.

Even the best human inspector is only 70% efficient.

- This is one of the best arguments in favour of using machine vision. A person is easily distracted, for example by a good-looking member of the opposite sex walking past. The performance of a human inspector falls as a results of boredom, dissatisfaction with employment, distress due to a recent argument, illness, fatigue, hunger, discomfort, pain, alcohol and drug ingestion.

Machines can work in situations that people cannot tolerate.

- Machines can work in radioactive, chemical and biological hazards, where there are high levels of noise, IR, UV, X-ray and microwave radiation, or it is very hot. Machines can tolerate flashing lights, which would induce epileptic fits and migraine attacks in people. A camera can operate under very high, very low, or suddenly changing pressure, and can also be used safely where there is a danger of explosion, or brittle materials are likely to shatter suddenly. A camera can be placed close to a laser cutter, which would be dangerous to a human being. A person cannot inspect the inside of a working jet engine, nor even a drain pipe.

Human inspection often comes free.

- Packing and assembly operators can inspect objects without adding (significantly) to the overall cost of the manufacturing process.

Neither a human inspector, nor a fully automated vision system, will always get the best results.

- It is sometimes better to employ a person working in symbiosis with a machine vision system.

C.9 Mechanical Handling

However deformed the widgets are, they must all pass through the inspection system without jamming.

► If the full range of defective widgets cannot be fed properly through the inspection system, then it is of no use whatsoever. It is an irony that one of the main aims of automated visual inspection is to preventing jamming of a mechanical sub-system, such as an assembly machine.

If the parts feed mechanism of the inspection system can go wrong, it most certainly will and the camera will be crushed.

► Be prepared to sacrifice the camera, lighting and/or optical sub-systems, in the event of a failure of the feed mechanism. Design the system accordingly.

C.10 Lighting

Many hands make light work.

► . . . but not very well. However, some people do apply proper engineering principles to the design of the optical sub-system and inevitably obtain better results.

The lighting is not constant.

► Lighting is never constant in either time or in space.

Never use software to compensate for a poor lighting system.

► It is not cost effective and will result in a poor system design.

It is cheaper to add a light-proof shroud to keep sun-light away from the object under inspection than to modify the software.

► Another universal truth which is often forgotten.

Nothing exceeds the speed of light.

► Any processing that can be done optically will save a lot of computer processing later.

It is all done by mirrors.

► Wishful thinking, in view of the previous remark.

C.11 Image Resolution

Any feature whose diameter is equal to 0.1% of the width of the camera's field of view, requires an image resolution better than 2000 × 2000.

► Nyquist's Sampling Theorem places a fundamental limit on the image resolution. This is often forgotten/ignored by advertisers on broadcast television, who frequently place disclaimer notices about their products on the screen, using printing that cannot be read properly because it is too small. The same principal applies to machine vision.

A (100×100) picture is worth 10,000 words.

- The ancients were very astute when they realised that a digital image requires the storage and processing of a lot of data.

One high-quality image is better than five fuzzy pictures.

- Few people would dispute this point.

Five fuzzy pictures are better than one high-quality image.

- No! This does not conflict with the previous proverb. It may be cheaper and easier to obtain the required information from a small set of low-resolution images than to process one very high resolution image. For example, it may be necessary to see several small features within a large scene. In such a case, it might be appropriate, say to use 5 low resolution images (e.g., 256×256), rather than one image of much higher resolution (e.g., 2000×2000).

C.12 Related Disciplines

Machine Vision $\neq$ Computer Vision.

- Machine vision is concerned with Systems Engineering and the solution of practical problems, such as guiding industrial robots, inspection and process monitoring. On the other hand, Computer Vision concentrates on the concepts and scientific basis of vision. The latter is concerned with generic issues and takes inspiration from and is often used to model human and animal vision.

Machine vision research is not a part-time activity for workers in Image Processing, Pattern Recognition, or Artificial Intelligence.

- Some people think it is, unfortunately. The solutions they offer to industrial inspection problems are, at best, unreliable and over-complicated, because they are unaware of the broader "systems issues," such as image acquisition, QA practices, industrial engineering etc.

C.13 Environmental Protection

Protect the machine from the work place.

- A factory is a hostile place, with lots of dirt, tampering fingers, etc.

Protect the work place from the machine.

- Protect eyes from flashing lights, lasers, etc. Make sure that the inspection machine does not shed bits, such as nuts, bolts, etc. to contaminate food products, pharmaceuticals, etc.

It is cheaper to pay for a shroud to enclose strobed light than to pay compensation for causing epileptic fits.

- Flashing lights can trigger epileptic fits and migraine attacks.

The lens may not fit the workman's camera at home, but he thinks it will.

- Be aware of light fingered workers causing damage by removing pieces of equipment.

"He is a good worker and likes to keep things clean - he washes down all of the equipment using a hose-pipe, every afternoon."

- This is quotation from one factory manager about a dedicated, but uninformed worker who did not realise the potential damage and danger his actions could cause. It is imperative therefore that the vision equipment be made safe and robust.

Adjustment of the camera is achieved using a 1 kg hammer.

- Vision engineers will be horrified at this prospect but it may happen.

Factories are dirty places.

- The electrical power supply is noisy. The air supply, for pneumatic equipment, also carries dirt, moisture and oil. Dirt, dust, moisture, fumes, spray, etc. all abound in the local atmosphere.

C.14 Proving and Working with the System in the Factory

Do not assume that the factory workers are computer literate.

- Software should be designed in such a way that it can be used with minimal computer skills.

The people who will make sure that the machine will not work are standing beside it.

- So, the vision engineer should try to persuade them that it is actually in their best interests (as well as his) to work in co-operation with the treasured vision system, not against it.

A picture is worth 10,000 words.

- Give the workers a "television program" to watch. A visual display, showing performance statistics of the vision system and explaining its operation is well worth having, even though it may not seem to be essential.

People "understand" pictures.

- A visual display is a useful way of building the confidence of factory personnel. It is also a valuable diagnostic tool: a person can easily recognise whether a sequence of images, showing the operation of the vision system is being repeated properly.

The service schedule of the vision system should be compatible with the production line.

- If it is not, the vision system will not fit into the factory environment properly.

For every hour you spend on inspecting products, your smarter competitor spends ten hours improving their process.

- Automated inspection is not always the best way to get the desired results.

Document all experiments to validate the system.

- All laboratory and on-site trials in the customer's premises should be fully documented. This should include details about the hardware and software used, parameter settings, optical and lighting set-ups, lens distance, aperture settings and mechanical handling features, how the products were selected.

Quantify the system performance.

- The ability of the system to perform to the agreed specification should be demonstrated and quantified. Accuracy, repeatability, robustness, feature delectability and tolerance of product variation should all be measured and recorded. All demonstrations should be attended by the vision application engineer(s) who are ultimately responsible for the system design and implementation.

Results may not be reproducible.

- Wherever possible, the results of all system performance tests should be reproducible and statistically characterised as to repeatability. In certain applications, for example the inspection of natural products, the variation in product characteristics make it difficult to implement this approach.

Align, calibrate and then test the system before it is used.

- A badly aligned system, or one which has not been calibrated, is likely to produce erroneous but seemingly reasonable results.

Appendix D: MV Knowledge Base

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_45,

Machine Vision spans many diverse technologies. For this reason, a vision engineer must be flexible in his thinking, even if he does not have detailed knowledge about all of them. This is the very nature of Systems Engineering! The knowledge base on which Machine Vision is built does not consist of a single monolithic body of information. Few people can be expert in all of the "component technologies"; most people coming to this subject have a good appreciation of just one of them. A few can justifiably claim skill in two areas but only very rarely more than that. Bearing this in mind, this appendix is presented to define the scope of Machine Vision, by listing those subject areas that *often* impinge on the design of a system. The author found it impossible to prepare a list that covers every eventuality, or that would be universally accepted by his peers. Every time he returned to the keyboard, to refine an earlier draft, he saw its shortcomings and made major changes, only to repeat the process next day. Eventually, it was necessary to "freeze" the list, with many shortcomings still evident to him. What has a emerged is a personal view of the scope of the subject, expressed in the form of a tree-like structure. Other workers will almost certainly disagree about some of the details that reflect their different experiences. A secondary objective of this exercise was to provide a set of web-search terms that will enable the reader to acquire up-to-date product information.

Fig. D.11

Machine Vision sometimes ''borrows'' Computer Vision algorithms but has a distinct ethos. As academic subjects, Artificial Intelligence and Pattern Recognition have separate identities from Machine Vision, although some vision systems incorporate AI and PR techniques. To be successful, a vision system must be integrated into the factory environment and manufacturing-inspection cycle. Most vision systems are specialised electronic calculators, with a video input

Appendix E: Robot Vision: Calibration

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

E.1 Physical Layout

Like most image processors, PQT (Chap. 23) is able to control a range of electromechanical devices, such as the robot vision cell described in *Fig. E.1*. When such a system is first is built, the cameras and robot are not aligned exactly and it is unlikely and the relationship between their coordinate systems is known precisely. Finding the transformation matrices that enable either of the coordinate systems to be mapped into the other is known as *system calibration*. An experimental procedure for calibrating a system comprising an (X,Y,θ)-table and a pick-and-place arm, with an overhead camera is described in this short appendix.

E.2 Why Calibration is Needed

In nearly all visually guided robots, the image processor and manipulator arm rely upon totally different coordinate systems. It is important therefore that, given the address of a point in vision-system space, the system should be transformed into the different set of coordinates used by the robot. In the same way, the robot may have placed, or discovered, an object in a position that is known in terms of its own coordinates. In this case, the vision system needs to be able to interpret that data so that it can properly interpret images.

When a visually guided robot is first set up, it is necessary to calibrate it, so that the two parts of the system can communicate together effectively. In other words, it is necessary to provide some mechanism so that vision system coordinates can be mapped into robot system coordinates and *vice versa*. To begin, we need to calibrate the system and the predicate calibrate_robot is a procedure for calibrating an (X,Y,θ)-table, which is viewed using an overhead camera.

E.4 Moving the Robot

Let us consider now how *axis_transformation/4* can be used. Normally, of course, the vision system will calculate the position of some feature in an image before the robot is moved. (The

Robot vision cell for parts inspection. (a) Device control. (b) Flexible Inspection Cell. This is able to inspect objects from many different directions, possibly under changing lighting conditions. This particular layout, using a gantry robot, has 4 degrees of freedom. If the vertical movement is limited to just two positions (*up/down*),it has 3$^1/_2$ degrees of freedom, which is the same as an (X,Y,θ)-table with a pick-and-place arm. (➲ Chap. 40, LVM: Flexible Inspection Cell) This appendix relates to the coordination of the robot with Camera 3

objective might be to pick up an object, drill a hole, insert a screw, weld a work-piece, or perform some similar task.) This is how it can be coded in PQT.

```
locate_feature(X,Y),                        % Use vision system to locate a feature
axis_transformation(Xrobot,Yrobot,X,Y)      % Find where feature is in robot space
```

The predicate *move_robot_to/2* allows the programmer to work with the vision system coordinates without ever bothering about the fact that the robot uses a different set of coordinates.

```
move_robot_to(X,Y):-
    axis_transformation(Xr,Yr,X,Y),         % Convert to robot system coordinates
    move_table(Xr,Yr).                      % Move the table
```

Notice that we have defined the software in such a way that *move_robot_to(256,256)* locates the table so that its centre is at the centre of the field of view of the camera. (We assume here that the image resolution is 512*512 pixels.)

We are now in a position to be able to control the robot in a very simple way:

```
locate_feature(X,Y),                        % Use vision system to locate a feature
move_robot_to(X,Y),                         % Move robot to feature found above
pick_up,                                    % Grasp object pick it up. Not defined here
```

In some situations, the robot coordinates may be known. For example, the robot may might encounter an obstacle so that it cannot that it cannot move further in a given direction. Assuming that the robot knows where it is in space, it would then be helpful if the vision system coordinates could be calculated, so that the obstacle might be identified in an image. This task could be achieved in the following way:

```
obstacle(X,Y),                              % Robot locates an obstacle
axis_transformation(X,Y,Xvision,Yvision),   % Transform the axes
interpet_obstacle(Xvision,Yvision)          % Interpret the scene visually
```

We have ignored an important point here: the robot may have no way of knowing where it is in space. However, PQT can keep a track of its movements. The use of *properties* is generally to be preferred to that of *assert* and *retract*, since they can be adjusted more easily and are faster. Here is a revised definition of *move_robot_to/2*:

```
move_robot_to(X,Y):-
    axis_transformation(Xr,Yr,X,Y),         % Convert to robot system coordinates
    move_table(Xr,Yr),                      % Move the table
    set_prop(robot_vision,[Xr,Yr]).         % Store [Xr,Yr] in variable robot_vision
```

set_prop/2 and *get_prop/2* (used below) are not standard Prolog features. In order to find where the robot is, in terms of its own coordinate system, we may use the following predicate:

```
locate_robot(X,Y):-
```

```
    get_prop(robot_position,[X,Y]).           % Recall [X,Y] from stored variable robot_vision
```

whereas, the predicate *where_is_robot* locates the robot in terms of the vision system coordinates

```
where_is_robot(X,Y):-
    get_prop(robot_position,[Xr,Yr]),
    axis_transformation(Xr,Yr,X,Y).
```

The final topic in this section is that of moving the robot, in such a way that an object which has been dropped onto the (X,Y,θ)-table in random position is normalised. Suppose that the vision system, using an overhead camera, has been able to determine that the centred of an object is at [X,Y] (using vision system coordinates) and at orientation A. The normalisation process moves the table so that the centroid is located at the middle of the camera's field of view and rotates the object to an orientation of 0°.

```
normalise(X,Y,A):-
    B is -A,                                   % Calculate negative of A
    turntable(B),                              % Rotate table by angle B
    cosine(A,Cos),                             % Calculate cosine, A is in degrees
    sine(A,Sin),                               % Calculate sine, A is in degrees
    scale_multipliers(Sx,Sy),                  % Consult database for scale multipliers
    X1 is -Sx*((X – 256)*Cos+(Y – 256)*Sin),
    Y1 is -Sy*(–(X – 256)*Sin+(Y – 256)*Cos),
    integer(X1,X2),
    integer(Y1,Y2),
    delta_x(X2),                               % Increment X axis of table
    delta_y(Y2),                               % Increment Y axis of table
    grb,                                       % Digitise another image
    vpl(1,256,511,256,255),                    % Draw cross-lines . . .
    vpl(256,1,256,511,255),                    % . . . at centre of the image
    draw_robot_jaws.                           % See below
```

Of course, it would be helpful to know where the gripper will be placed when the robot tries to pick up an object. No gripper is of insignificant size, so a mis-aimed move might put the object in such a position that it and/or the gripper and robot could be damaged. Let us assume first that the robot gripper has two parallel jaws, which open and shut in a simple pincer movement. It is possible to draw rectangles on the image which represent the gripper jaws in the open/shut state (see ➲ Chap. 38). The user can of course, easily verify visually that the gripper will not collide with the object that is to be picked up. However, a little more processing allows this decision to be made automatically.

```
safe_to_lift(X,Y):-
    move_robot_to(X,Y),                        % Move the robot as described above
    grb,                                       % Digitise another image
    convert_to_binary,                         /* Convert image to binary. Object is white
                                               & background is black.
    swi,                                       % Switch images
```

```
         draw_robot_jaws(open),                      % Draw the jaws
         mni,                          % AND the two images together
         cwp(0),                       % There is no overlap. So it is safe to lift object
         lift_object.                  % Operate pick and place arm. Not specified

safe_to_lift(_,_):-
         message([“Warning: The robot cannot safely lift the object”]),
         !,
         fail.                         % Force failure
```

Appendix F: Object Location and Orientation

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_47,

F.1 The Problem

In this appendix, we present a range of methods that can be used to guide a robot to pick up an object (widget) lying in an unknown position and orientation on a plain-topped table. We shall introduce certain other simplifications:

1. The camera is vertically above the widget.
2. The widget is entirely within the camera's field of view and there is no occlusion by any other object.
3. If there is more than one object in view, no widget touches any other one.
4. There are no artefacts due to poor lighting; there are no significant shadows and there is no glinting from either the widget or table-top.
5. There is sufficient contrast to ensure that features that might be used to locate and orientate the widgets are clearly visible.

The layout of the robot vision cell is outlined in Appendix E. We shall assume that the robot has already been calibrated. (Appendix E)

Let us begin with a simple challenge: the child's toy shown in *Fig. F.1*. Despite the fact that a child of about 2 years of age can place the pieces into the appropriate slots, this presents certain (but not insurmountable) difficulties for a vision system. The problem is that that many of the techniques for locating an object and determining its orientation are unable to cope with all six shapes.

Figure F.2 presents another multi-shape application. There are four objects lying on an (X, Y, θ)-table. The geometric centroid, usually referred to simply as the *centroid*, is able to provide a reasonably good way to find the position of an object, although in the case of the Y-shaped component, the centroid lies very close to the edge. The orientation for three of the objects shown in *Fig. F.2* can be found reliably using the principal axis but not for the 3-pointed "star."

F.1.1 Mechanical Alignment

In Machine Vision, we should not over-rely on image processing; sometimes a simple mechanical handling arrangement will help to fix the orientation within quite narrow limits. *Figure F.3* shows how simple guide rails, placed over a conveyor belt, are able to fix object

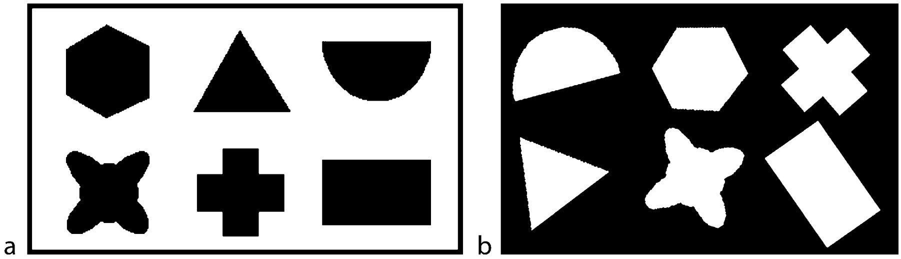

Fig. F.1

Child's toy, represented diagrammatically. (a) A plastic template with holes of six different shapes. (b) Plastic pieces that are to be placed in the slots on the template

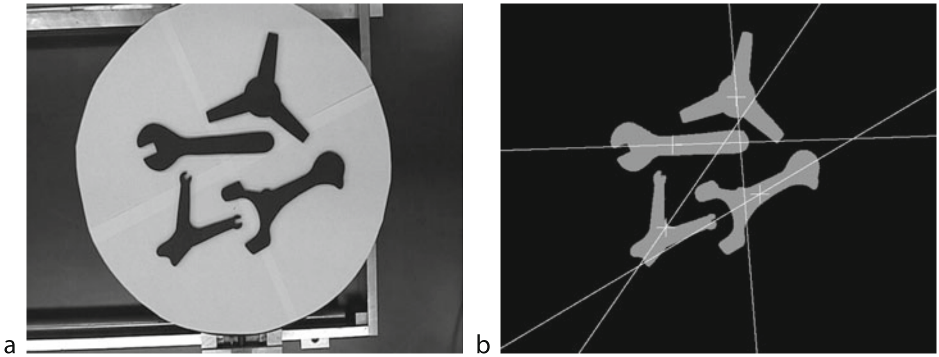

Fig. F.2
Objects on an (X, Y, θ)-table. (a) What the camera "sees." (b) After noise reduction and thresholding a "clean" binary image was obtained. The centroid position (QT function cgr) and the orientation of the principal axis (lmi) were found. The principal axis for each component has been drawn (dpa). This provides a satisfactory way to determine the orientation for three components but not for the three-pointed "star." (This is due to the three-fold symmetry of this object.)

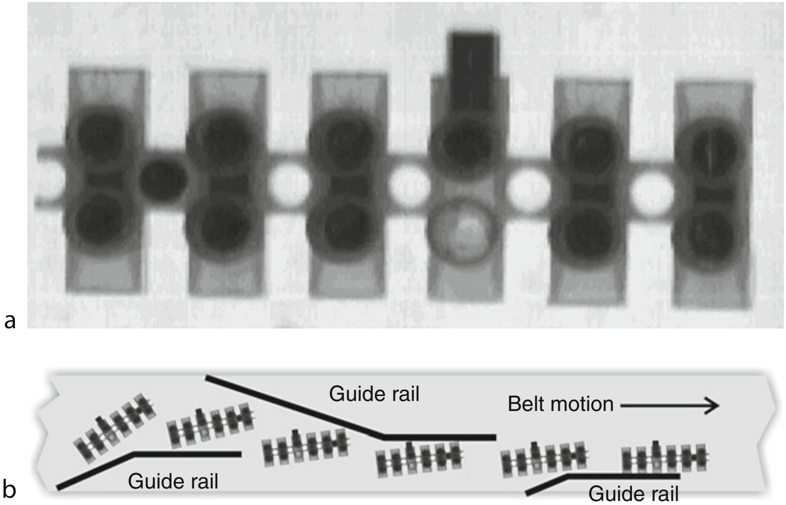

Fig. F.3
Using guide rails over a conveyor belt to limit the angular deviation of objects in front of the camera. (a) A suitable object: an electrical connection block (faulty). (b) Mechanical arrangement

orientation to within a few degrees. In some applications, this may make it possible to improve the speed of vision-based measurement of object position and the orientation. For example, the Radon Transform (QT function *rdn*) can be made much faster if we know that the objects to be inspected will always arrive, within a small angular deviation from the norm. (e.g., ±5%).

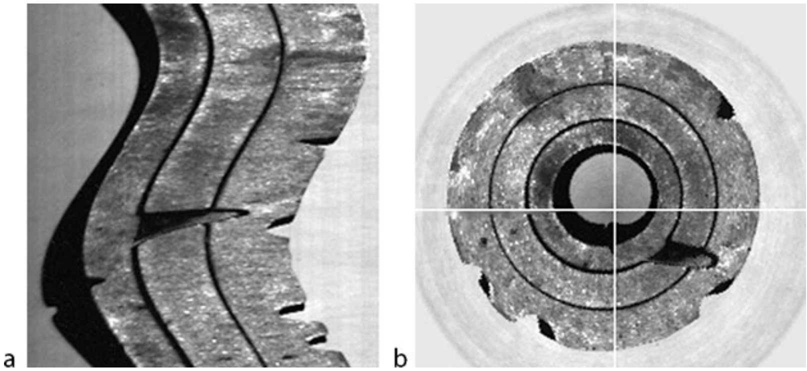

Fig. F.4

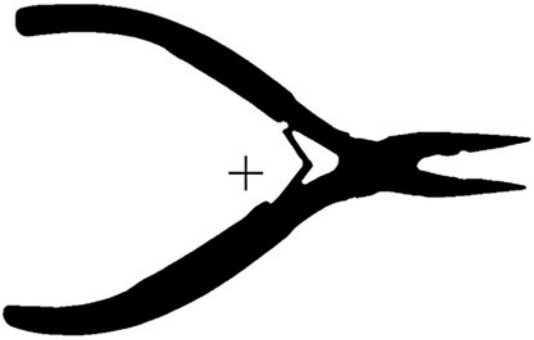
Circular component viewed on a turn-table using a line-scan camera. (a) The image obtained from the camera. Horizontal axis: radial distance from the centre of the turntable. Vertical axis: angular position. (b) The image in (a) was transformed using the QT command ptc

Sometimes, objects are presented for inspection on a turn-table. Using a line-scan camera viewing the light pattern along a turn-table radius, it is possible to obtain a digital image with polar-coordinate axes: angular position and radius (➲ *Fig. F.4*). In the target system that was eventually built for this application, the circular widget was placed centrally on the turn-table, using a robot with a self-centring gripper. The vision system was required to measure the orientation to within ±0.5°. This was achieved by using the image processor to locate shadows cast by low-angle illumination. This emphasises the important point made repeatedly in this book: by optimising the lighting-viewing arrangement, it is often possible to simplify the image processing.

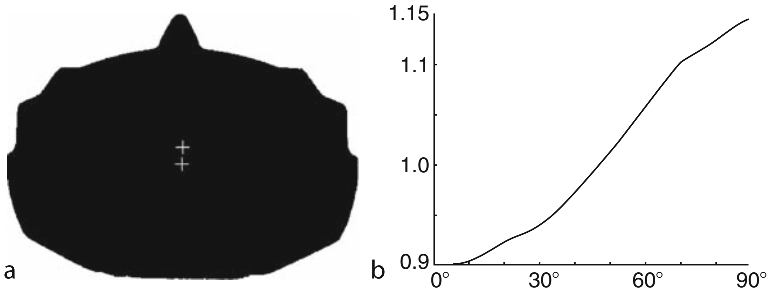
F.2 Finding Object Position

Even the seemingly straightforward task of measuring position is not as straightforward as it first seems. Every object has a finite size; your feet are on the ground but your head is in the air! As a result, there is no unique answer to the question *Where is object XXX*? To achieve safe lifting, we usually pick up an object by grasping it close to its centre of gravity but we pick up a sharp knife by holding its handle. We cannot pick up a horse-shoe by grasping it at its centre of gravity but we may well use the geometric centroid to decide where we should place our hand (➲ *Fig. F.5*). In many application, there are good reasons for trying to pick up an object by placing the robot's gripper close to its centre of gravity, as this minimises the torque exerted by the weight of the widget on the gripper. Unless we know the three-dimensional structure and material composition, we do not know exactly where the centre of gravity is. A reasonable guess, unless we know otherwise, is to assume that it is close to the geometric centroid but these two points may be far apart. Of course, using vision alone, we can only find where the centroid is. *Every application must be analysed individually.*

Centroid The most popular way to obtain position information is by locating the geometric centroid. Numerous examples are given here and elsewhere in this book (See for example, ➲ *Figs. F.2*, ➲ *F.12*, ➲ *F.14* and ➲ *F.16*). The centroid position can be computed rapidly from two simple formulae, which produce precise precise coordinates. Many companies use this fact to justify a claim that their equipment is able to obtain sub-pixel positional information.



■ **Fig. F.5**
The centroid (*black cross*) is not always a suitable grasping point



■ **Fig. F.6**
Minimum-area rectangle (MAR) surrounding the silhouette of an automobile brake pad. (a) The centre of the MAR is indicated by the upper cross and the centroid by the lower cross. (b) The aspect ratio, *R*(*θ*), of the MAR plotted against *θ*, angle of rotation. Within the range 0 ≤ *θ* < 90°, *R*(*θ*) is a monotonic function of *θ*, but *R*(*θ*) = *R*(*θ* + 180*n*), *n* = 1,2,...

Extreme Points/Minimum Bounding Rectangle (➲ *Fig. F.6*). Computing the extreme points in a binary image is a fast way to estimate object position. There are eight such points of interest: *top-left, top-right, bottom-left, bottom-right, left-bottom, right-top, left-bottom, right-bottom*. (QT has functions to measure each one separately, while *mar* derives the coordinates of the corners of the minimum-area enclosing rectangle, MAR). In certain applications, such as handling ill-formed dollops of semi-fluid material (e.g., uncooked dough) the extreme points are actually more useful than a single parameter, such as the centroid, since they limit object size as well. Although these measurements are sensitive to object orientation, they may be useful for determining both object position and orientation. In ➲ *Fig. F.6*, the centre of the MAR is close to the geometric centroid. Such a small offset may not be important. For certain shapes and for a limited range of angles, the aspect ratio of the MAR is a monotonic function of the angle of orientation. Hence, by measuring the MAR aspect ratio and using a small look-up table, the object orientation may be estimated quickly. For shapes that are almost circular, such as a gear, the variation of the position and aspect ratio of the MAR with orientation may not matter at all. Also see ➲ *Fig. F.9*, where calculating the extreme points forms just part of an intelligent heuristic procedure for model fitting.

Bounding Circle Sometimes, it may be advantageous to fit a circle to the object silhouette, then use the centre of that circle as an indicator of position. This is appropriate, for example, when the widget is nearly circular. The QT command *mbc* computes what is erroneously called the *minimum bounding circle*. (➲ *Fig. F.7*) This attempts to fit a circle tightly around as many of the pixels on the outer edge as possible. However, points that are too far inside the circle are ignored. This is, of course, a recursive definition, so *mbc* does not have a fixed execution time. Other ways to fit circles are discussed below.

Largest Internal Circle Robotic grippers do not always close to grasp an object; sometimes they can open instead. (➲ Chap. 38). A three-finger gripper of this type can be inserted into a circular hole to provide a self-centring mechanism for lifting objects. (This is similar to the human action of lifting a jar by inserting the thumb and two fingers into its neck.) The QT commands *lic* and *mic* calculate the maximum size of circle(s) that can be expanded to fit within a given space. The centre of the largest such circle (*lic*) might be used as an indicator of object position (➲ *Fig. F.8*).

Model fitting In some situations, there are no precisely defined visual features, such as holes or sharp corners, available to measure position accurately. Consider an ideal cube: precise positional information can be obtained from its corners. If the corners are rounded, as in standard gaming dice, estimates of position based on corners will be imprecise. However, it is still possible to calculate the position accurately, by observing the edges of the cube. Then, we might conveniently fit straight lines to the sides and observe where they intersect. In some situations, this can provide precise position information. We can use many different models but will limit ourselves to describing the fitting of lines, circles and polygonal curves. On its own, model fitting may not provide a complete answer to object location but it can often be a useful step along the way to achieving that goal.

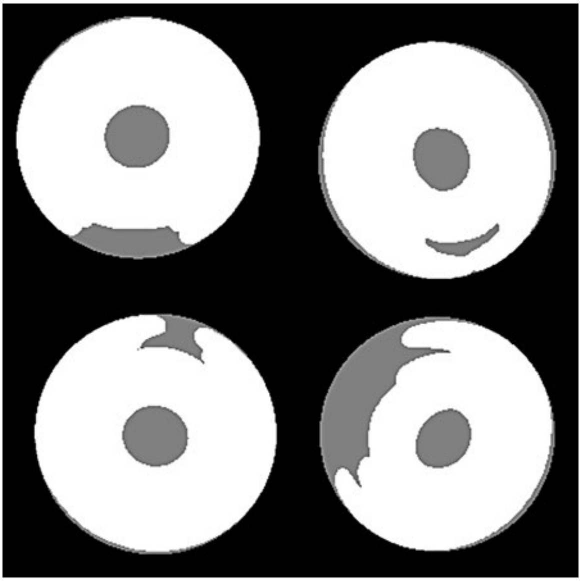


Fig. F.7

Four faulty plastic mouldings for battery tops (*white*) and the minimum bounding circle for each one

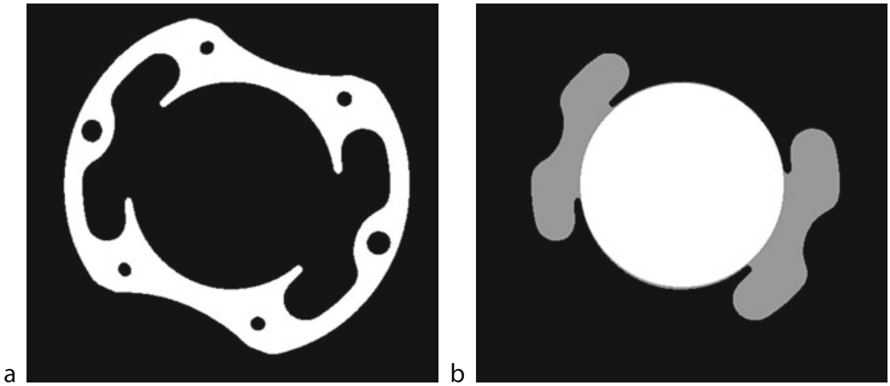

Fig. F.8

Largest internal circle. (a) Original object: metal stamping for the stator of an electric motor. (b) The largest circle (*white*) that can be placed within the hole. The centre of this circle indicates where an expanding gripper should be placed

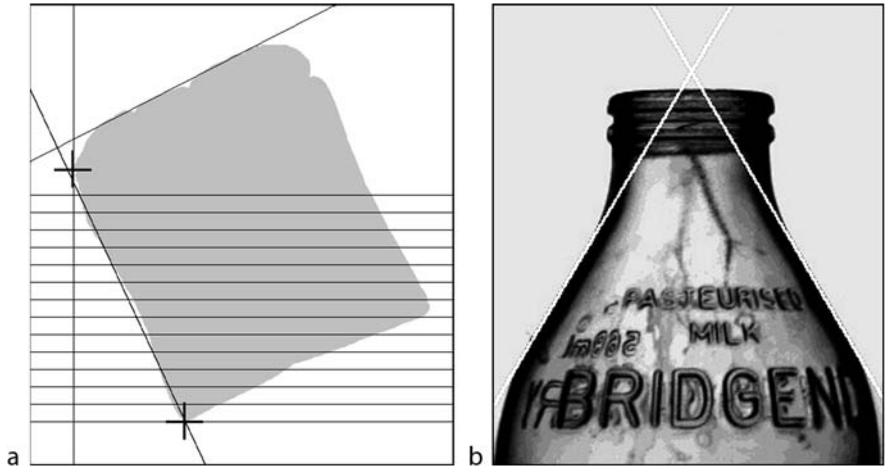

Fig. F.9

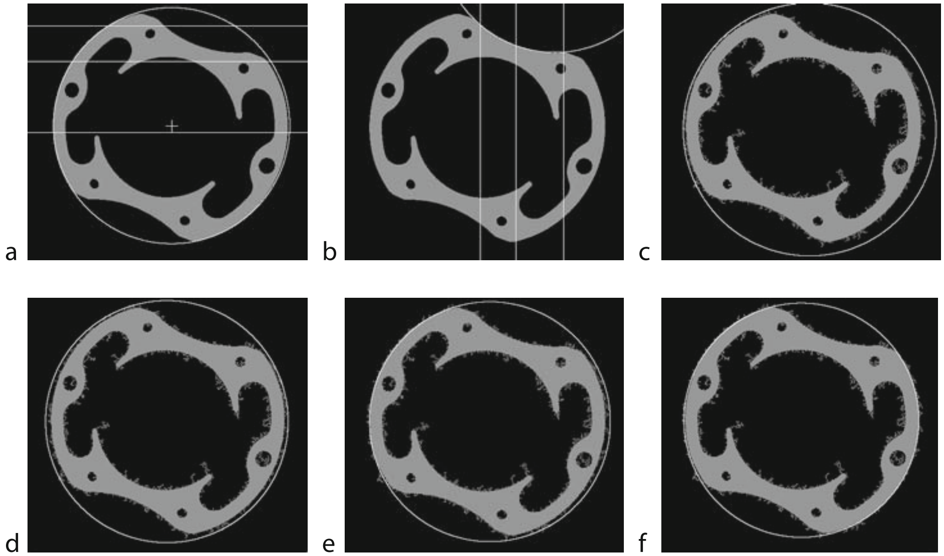
Fitting straight lines. (a) Slice of bread. Upright crosses indicate the top-left and left-bottom extreme points. These fixed the vertical positions for the horizontal scan lines, which in turn determine the data points for linear regression analysis. This enabled the line to be fitted to the left-hand side of the slice. In a similar way, a line was fitted to the top of the slice. The intersection of these two lines provides a useful datum point for further analysis. (b) Glass bottle. Two straight lines have been fitted. Again, their intersection provides a reference point for further measurement

Fitting straight lines This method is suitable for handling objects that have easily identifiable linear features. Two examples are shown in *Fig. F.9*. Since the slice of bread is nearly rectangular, the extreme points mentioned above provide useful cues for locating a set of horizontal scan lines. The points where they intersect the edge provide the data points for standard linear regression (least-squares) analysis. In the second example, two lines have been fitted to the edges of a bottle. Their intersection forms a useful datum point for inspection, location and measurement.

Fitting a circle, geometric method (*using three edge points*) In ➲ *Fig. F.7*, we illustrated one method for fitting a circle to an object silhouette using QT operator *mbc*. In that case, the whole object boundary was considered at first, although some edge pixels were subsequently "discarded." In the method demonstrated here and immediately following, only part of the edge is considered. To begin, *three* edge points are found. There are no general rules for doing this. Application knowledge should be exploited whenever possible and may make the choice of these points quite straightforward. As indicated above, simple mechanical-handling trickery is sometimes able to limit the angular deviation of the widgets from some known norm. This allows trivial edge-sampling algorithms to be used. In other cases, it will be necessary to employ a combination of smart heuristics and sophisticated image processing, to make sure that these three sample edge points are located appropriately. The position and radius of a circle that intersects these three points can then be found using three simple formulae, implemented in the QT operator *fcd*. The operator *fce* selects three edge points using horizontal scan lines



◘ Fig. F.10

Fitting a circle to the outer edge of a stamping for the stator of an electric motor. (a) Using three edge points. Three horizontal scan lines provide three intersection points on the left-hand-side of the stamping. These points are used by the QT command fcd to derive the parameters for the circle. Errors on the right-hand-side are due to quantisation noise. (b) Circle, fitted by mbc to three points found using vertical scan lines. (c) Noise added deliberately. Again fcd was used. The accuracy of fit is poor, particularly for those parts of the edge far away from the sample points. (d) Circle fitted to the noisy edge using the QT operator mbc. Since the circle encloses every white point, the fit is poor everywhere. Without the noise, mbc produces an excellent fit (not shown). (e) That part of the edge consisting of the convex arc on the left was used to fit a circle using fcl. The fit is good there, despite the noise. However, the fit on the right-hand side is poor. (f) Both convex arcs on the edge were used to fit the circle. The fit is good everywhere

placed in positions supplied to it and then applies *fcd*. ➲ *Figures F.10a* and *b* show examples of circles being fitted in this way. This method is well suited to situations where part of the edge of the widget is close to following a perfect circular arc and can be located easily. However, since it relies on only three edge pixels and is therefore sensitive to noise. Hence, even small dirt particles around the edge may cause the circle to fit badly (➲ *Fig. F.10c*). It is also susceptible to producing errors when the widget does not have perfectly circular arcs. For example, the outline of an apple or pizza would probably cause a serious misfit.

Fitting a circle: regression method (*least-squares algorithm*) A circle can be fitted to some or all edge pixels surrounding an object silhouette, using a least-squares algorithm. (QT command *fcl*) This may rely on all or just some of the edge pixels. In the latter case, the sample points may be scattered around the object perimeter or grouped together to form a circular arc. A good fit is less likely to be achieved in the latter case. Since this is a regression (least-squares) algorithm, a good fit can often be achieved in the presence of significant amounts of debris.

Fitting a polynomial curve The following MATLAB function uses a least-squares algorithm to fit a polynomial of order n to a set of m edge points, between the limits $y1 \leq y \leq y2$. Normally, we would expect $m >> n$.

```
function p = fit_polynomial(y1,y2, m, n)
% Fit a polynomial of order n (n ≥ 1) to a binary edge sampled at m pivotal points. [1/4]
global current
global alternate
original=current;                       % Save image for later
[x,y]=hzs(y1,y2, m);                    % Pivotal points
p=polyfit(y,x,n);                       % Calculate polynomial parameters
q=polyval(p,y);                         % Evaluate polynomial
zer                                     % Black image
for i=2:m

Fig. F.11

Fitting curves to the neck-shoulder region of a bottle. (a) Circle fitted to the neck. (b) Circle fitted to the shoulder. (c) 3rd order polynomial

Figure F.11 shows circles and a 3rd-order polynomial fitted to the neck-shoulder region of a glass bottle.

F.2.1 Using the Model

The *XY*-coordinates of the centre of the circle fitted by *mbc*, *fcd* or *fcl* often provide a way of defining the position of the widget. This is obviously so, where the fitted circle encloses the object, as in *Figs. F.7* and *F.10*. In those cases where the edge is locally concave (e.g., *Figs. F.10b* and *F.11a*), we may regard the fitted circle as a possible indicator for positioning one of the fingers of a robot gripper.

The polynomial found by *fit_polynomial* is single-valued and cannot describe a closed curve. Hence it cannot be used on its own to find the position of a widget. This function finds the local trend of the direction of the edge, ignoring minor deviations. Differentiating the polynomial enables us to estimate the possible slippage of a gripper that relies on friction, rather than widget geometry, to maintain a secure grasp. The polynomial might be used to calculate intersection points with other curves (lines, circles or polynomials), in a similar way to that shown in *Fig. F.9*. It is probably not a good idea to use the polynomial to extrapolate far outside the range of its input data.

F.3 Finding Object Orientation

F.3.1 From Object Silhouettes

There are numerous ways to find the orientation of an object. Here are just a few. The most appropriate method can only be chosen after studying the application requirements in detail.

1. Principal Axis One of the most popular ways to determine the orientation of an object is to use the principal axis (lmi). This is very effective if the object is long and thin, like the screwdriver in *Fig. F.12*. It is less effective if the object has no obvious "long axis," as judged by a human being. Calculating the principal axis is quite fast. It is important to note that, in some situations, it may be advantageous to calculate the principal axis on a lake or bay, rather than the object silhouette (*Fig. F.13*)
2. Bay and centroid (*Fig. F.14*)
3. Lake and centroid (*Fig. F.15*)
4. Centroid and furthest edge point (*Fig. F.16*)
5. Two bays (*Fig. F.17*)
6. Two lakes (*Fig. F.18*)
7. Lake and bay (*Fig. F.19*)
8. Two most distant edge points (*Fig. F.20*)

F.3.2 Complex Objects

Finding the orientation of a complex object has no clearly defined rules: each application is different and requires human intuition to design a robust algorithm. If there are just a few

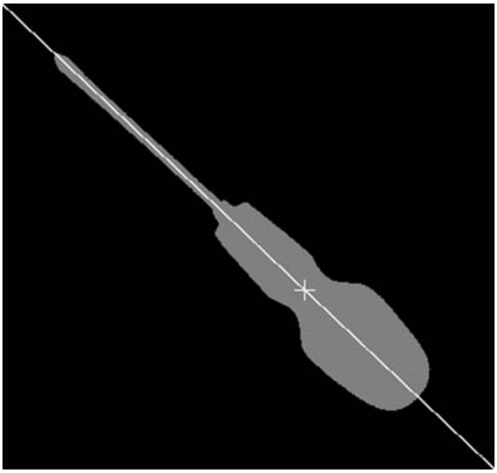

Fig. F.12
Principal axis and centroid

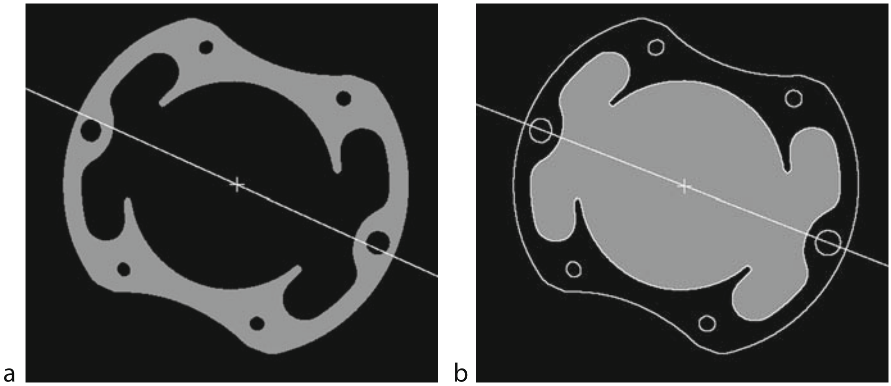

Fig. F.13
Principal axis and centroid, calculated on a lake. (a) Principal axis of the object silhouette. (b) Principal axis of the largest lake is more accurate, in this instance. [QT: enc, thr, blf, exr, big, angle = lmi]

clearly identifiable features, as in the central region of ➲ *Fig. F.21*, it may be possible to perform an initial calculation rapidly but which provides an ambiguous answer. With a little more cunning, it is often possible to resolve this easily. For example, in ➲ *Fig. F.21* simple pattern matching over a small carefully selected area will suffice. It is important to note however, that we have made two implicit assumptions:

1. The size of the object and the lens magnification are both known precisely.
2. Useful features of interest can be resolved accurately in ➲ *Fig. F.21*, if we consider only the central portion of the image. The complicated periphery of this object is simply ignored

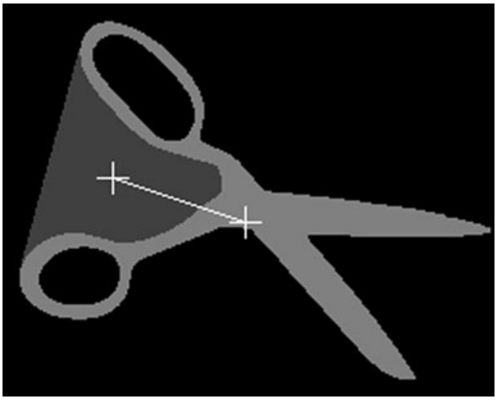

Fig. F.14

Orientation found from the line joining the object centroid and the centroid of the largest bay. QT command sequence: [[a,b] = cgr; chu, exr, big, [c,d] = cgr; angle = 180*atan2((a-c),(b-d))/pi]

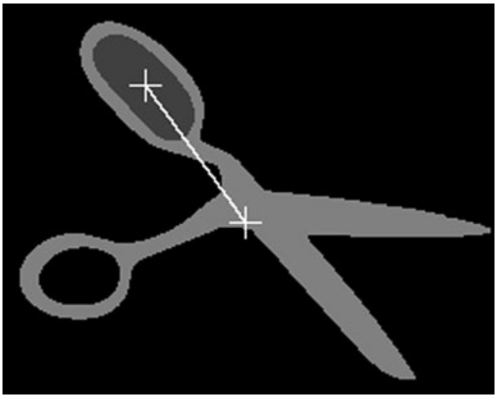

Fig. F.15

Orientation found from the line joining the object centroid and the centroid of the largest lake. QT command sequence: [[a,b] = cgr; blf, exr, big, [c,d] = cgr; angle = 180*atan2((a-c),(b-d))/pi]

during the initial stages. To resolve the ambiguity of orientation, we must perform additional tests. For example, we might devise an algorithm that detects the dark hole on the scanning circle at 2 o'clock.

If we exercise some ingenuity, there are many more "tricks" that we can perform! We cannot describe them all; our objective here is simply to prompt the reader to think of new ideas for him/herself. Consider *Fig. F.22*. The details of the processing that resulted in *Fig. F.22b* need not concern us here. The important point is that a number of significant

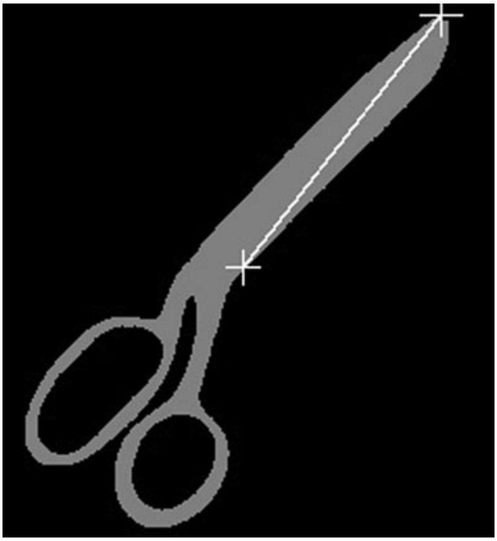

Fig. F.16
Orientation found from the line joining the object centroid and the most distant edge point. QT command sequence: [[a,b] = cgr; dfc,[c,d] = pki, 180*atan2((a-c),(b-d))/pi]

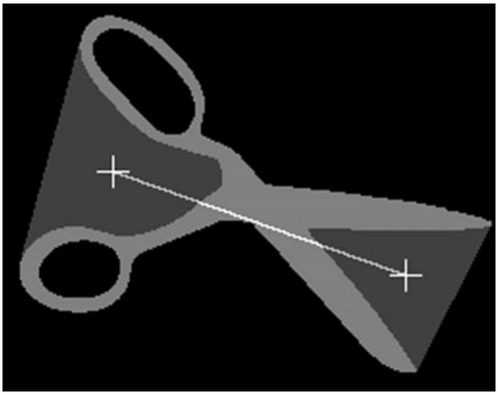

Fig. F.17
Orientation found from the line joining the centroids of two bays. QT command sequence: [chu, exr, big(3), [a,b] = cgr; swi, big(4), [c,d] = cgr; 180* atan2((a-c),(b-d))/pi]

features have been identified and measured. In this example, each feature is represented simply by its *XY*-position and area. The result is the following list:

$$L = [[122, 105, 8341], [122, 192, 818], [45, 71, 619], [45, 138, 609], [199, 139, 603],$$
$$[199, 71, 601], [46, 27, 159], [46, 179, 114], [196, 28, 111], [196, 180, 103]]$$

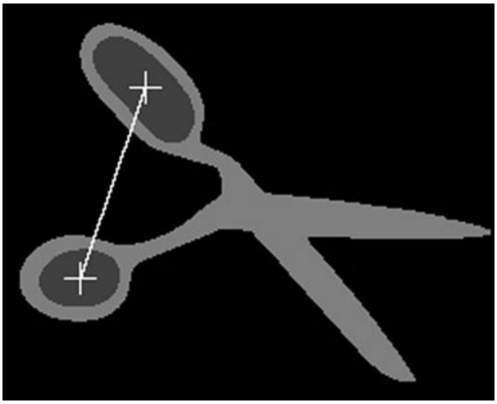

Fig. F.18
Orientation found from the line joining the centroids of two lakes. QT command sequence: [blf, exr, big,[a,b] = cgr; swi, big(2), [c,d] = cgr; 180*atan2((a-c),(b-d))/pi]

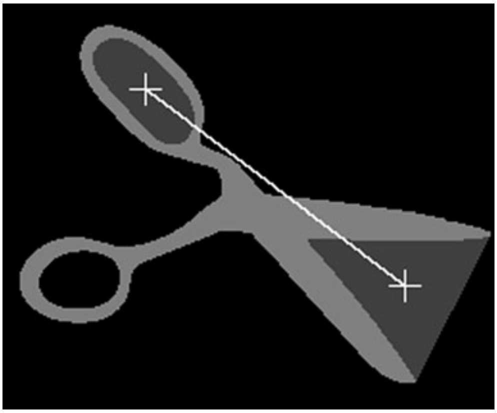

Fig. F.19
Orientation found from the line joining the centroids of one lake and one bay. QT command sequence: [wri, chu,exr, big(4),[a,b] = cgr; rei, blf, exr, big(1), [c,d] = cgr; 180*atan2((a-c),(b-d))/pi]

The format is as follows:

$$[[X1, Y1, \text{Area1}], [X2, Y2, \text{Area2}], [X3, Y2, \text{Area3}],]$$

This is an example of what we shall refer to as a *Star Map*. The position and a brief description is given for each feature, which is thereafter regarded as existing at a single point.

In some applications, the order in which the descriptions of individual feature are added to the star map list is not necessarily fixed or known; it is accidental that, for *Fig. F.22*, the large central well is described by the head of *L* (i.e., first sub-list). This can easily be identified from the list *L*, since the well is much larger than the nine peripheral holes. The fact that there is a single very distinctive feature makes the matching of pairs of lists much faster. In other

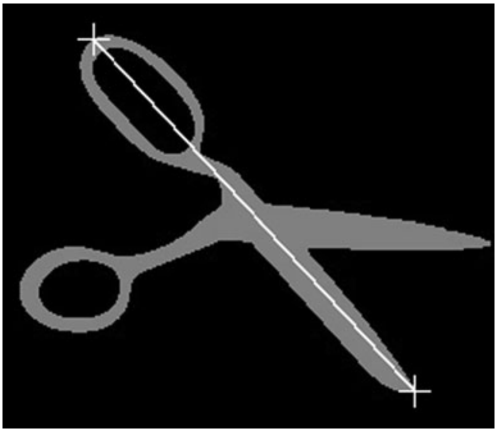

Fig. F.20
Orientation found from the line joining the two most distant edge points. QT command mdp

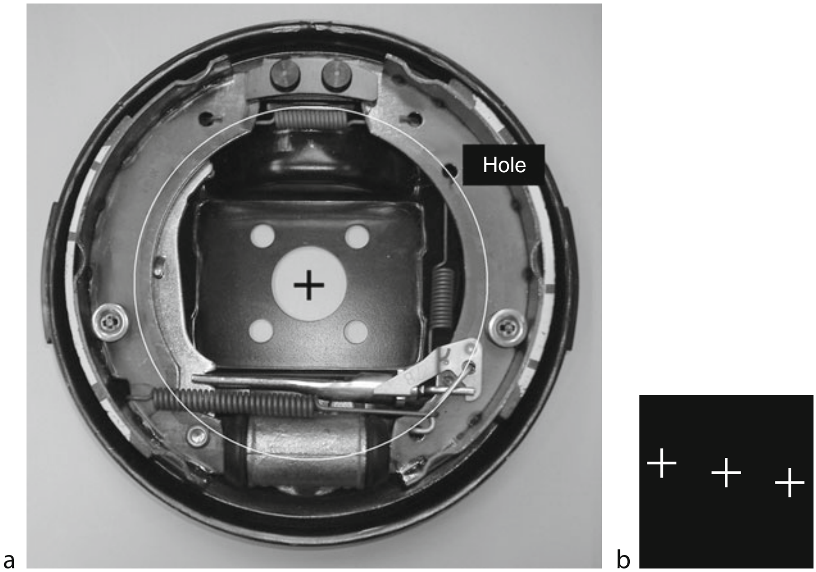

Fig. F.21
Finding the orientation of a complex object (automobile brake assembly) can sometimes be solved by the application of several simple heuristics. (a) The centroid of the central hole is shown as a black cross. The white circle is positioned at the centroid and its radius chosen to intersect the dark hole. By scanning around this circle, the orientation can be determined but with some ambiguity as the circle intersects other dark regions. (b) 3-tuple operator. This is then fitted to the original image by rotating it around the centroid of the central hole. When all three points rest over bright pixels, we signal a possible ''hit.'' Clearly, there are only two such hits as the 3-tuple rotates through 180°. Again, this will ambiguously determine the orientation but this can be resolved easily by referring to the scanning circle in (a)

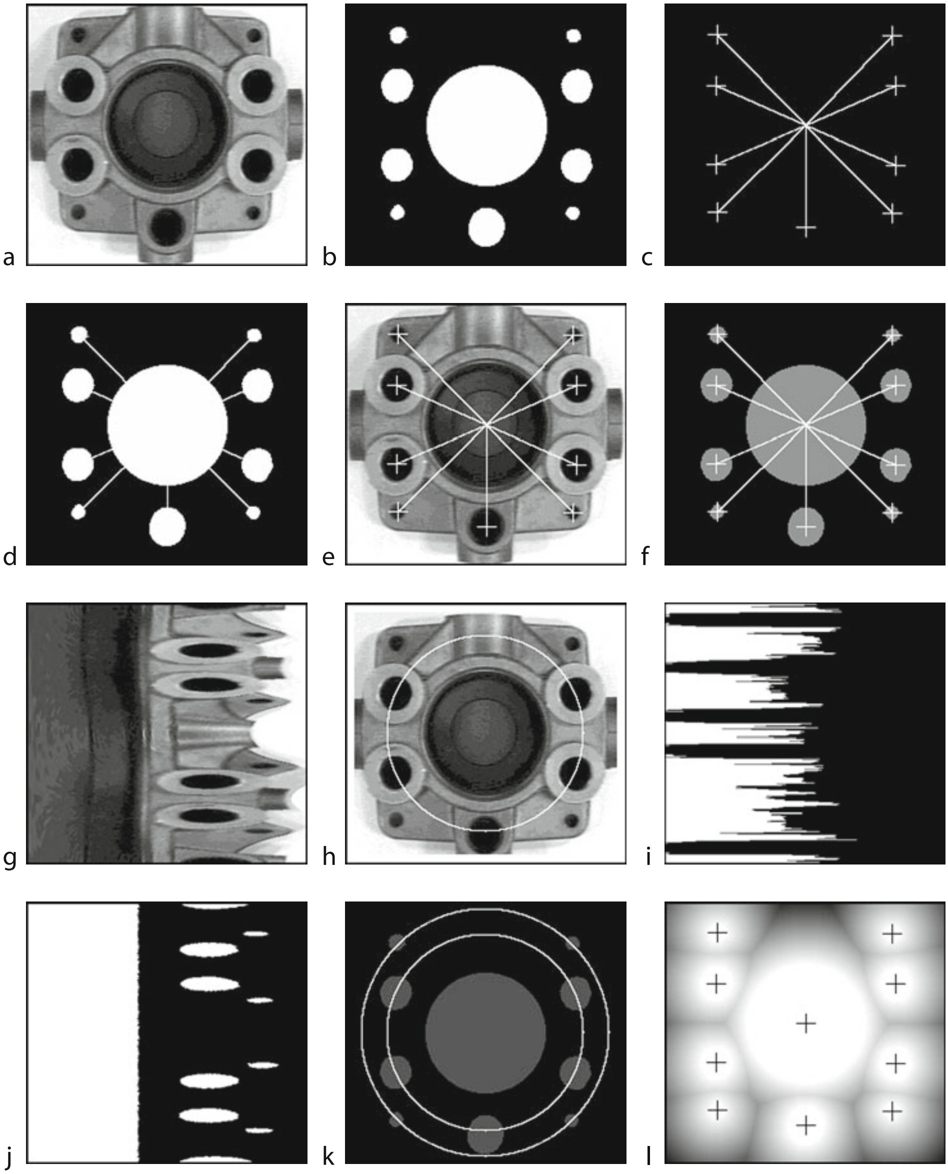

Fig. F.22

A summary of several ideas for determining the orientation of a complex object: an alloy casting for an hydraulics manifold. (a) Original image. (b) Ten features identified: central well and nine peripheral holes. (c) Centroids, joined to create a single "spider." (The crosses are included merely for clarity of illustration.) (d) Object, created by ORing images (b) and (c). It is possible to determine the orientation approximately by finding the principal axis of this object. (QT command lmi) (e) The body and feet of the spider define a 10-tuple filter, whose output is minimal when the spider is in/close to this position. (f) The feet and body of the spider define a binary erosion operator. The output is white only when the spider is in/close to this position.

applications, different image features might be more appropriate. There is no restriction on the number of feature measurements that we include in each sub-list. A bare printed circuit board is well suited to this type of representation. The features that we use in this case might include component lead holes, pads (for attaching integrated circuits, connectors etc.), conductor track bifurcations and corners. If, as in *Fig. F.22a*, there is a single distinctive feature that can provide a well-defined reference point, the feature-measurement list might also include angular positions and distances from it. Several ideas for finding the orientation of the hydraulics manifold casting are summarised in *Fig. F.22*.

Suppose the we have two lists: L_{test} derived from a test sample and the L_{ref} from a reference "golden" sample. It is possible to match L_{test} and L_{ref}, using a variety of algorithms. Prolog is well suited for this type of task, since it involves pair-wise matching of the elements of two lists. *Figure F.23* shows how natural this type of task is in Prolog. On the other hand, matching lists is not natural for QT, or MATLAB. List matching is made easier if we can guarantee that L_{test} and L_{ref} have the same number of members; the same features are always detected. This is not an essential requirement but the computation is faster if this condition is met. Suppose that L_{test} and L_{ref} both have N members, Then, the time to perform the matching rises as $N!$. This would probably not present insurmountable problems for modest values of N (say $N \leq 10$) but would, for example, be problematical if we tried to match two large printed circuit boards by comparing lists describing hundreds of component-lead holes. We can reduce the computational work load considerably, if we sort the lists in some way first. For example, in *Fig. F.22*, there are three distinct types of features: the large central well and two different sizes of holes. We can make a significant saving in computation time if we sort L_{test} and L_{ref} in order of the areas of the blobs. Restricting the orientations of the widgets that L_{test} and L_{ref} represent to within a few degrees would also make a large difference. Even the simple observation that the central well in *Fig. F.22* is much larger than all of the others helps a lot, since we can use its centroid as a "pivot" during the matching process.

F.3.3 Radon Transform

Suppose that the object to handled by the robot has no obvious structure in its outline but has a grid-like pattern on its top surface that it is visible to an overhead camera. The orientation of the grid can be determined using either the Radon or Hough transforms. We shall demonstrate the use of the former (*Fig. F.24*). Both of these transforms generate an image in which bright spots indicate both the orientation and position of large sets of white pixels in the input image

(g) Polar-to-Cartesian axis conversion (ptc), centred at the middle of the well. (h) Circular scan, centred at the middle of the well and applied to the original image (i) Intensity profile around the circular path defined in (h). A similar result can be obtained, albeit more slowly, by following a vertical linear path in (g), just to the right of centre. The five large peripheral holes are clearly evident from this graph. (j) Polar-to-Cartesian axis conversion (ptc), applied to the binary image in (b). (k) Two circular scans, centred at the middle of the well, applied to the binary image in (b). These yield binary signatures which allow the orientation to be determined simply. (l) The grey background is the grass-fire transform (gft) of an image that contains just ten white pixels: the centroids. The 10-tuple spider will produce a maximum output when it is in the position shown here

a

Notation: describing star maps

(i) S_{test} is the set of test map nodes

(ii) S_{ref} is the set of reference map nodes

(iii) $P \in S_{\text{test}}$ (P is a node in the test map.)

(iv) $Q \in S_{\text{ref}}$ (Q is a node in the reference map.)

(v) N_i is the node that is the ith nearest neighbour to P

(vi) A_i is the angle N_iPN_{i+1}. All angles are measured in the same direction (clockwise here.)

(vii) The point P is represented by $X(P) = [A_1,A_2,A_3,...]$, where A_i is the angle N_iPN_{i+1}

(viii) Each point in the test map is described in this way. The result is a set of vectors

$$\{X(P)|P \in S_{\text{test}}\} \qquad \text{... [F.1]}$$

(ix) Similarly, let $\{Y(P) = [B_1,B_2,B_3,...]|Q \in S_{\text{ref}}\}$ represent the set of reference map nodes

(x) To compare two node $P \in S_{\text{test}}$ and $Q \in S_{\text{ref}}$, compute $D_{P,Q}$ where

$$D_{P,Q} = \sum_i (A_i - B_i)^2 \qquad \text{... [F.2]}$$

(xi) To match two nodes $P \in S_{\text{test}}$ and $Q \in S_{\text{ref}}$,, an upper limit is set on $D_{P,Q}$

$$D_{P,Q} \leq \theta \qquad \text{... [F.3]}$$

b where θ(*theta* in the Prolog program) is a positive constant that we must select for each application.

Prolog program to match node pairs

```
match_star_maps(Test,Ref,L):-                          % Makes program easier to use
          match_star_maps(Test,Ref,Test,Ref,[],L).

match_star_maps(_,_,[],[],L,L).                        % Terminate recursion

match_star_maps(Test,Ref,T1,R1,L1,L2) :-
          member(P,Test),                              % Choose a node, P, from test star map, Test
          member(Q,Ref),                               % Choose a node, Q, from test star map, Ref
          get_parameter(theta,Theta),                  % Allows user to adjust theta easily
          match_nodes(P,Q,Theta),                      % Based on [F.1] and  [F.2]
          cull(P,T1,T2),                               % Match found, so remove P from T1
          cull(Q,T2,R2),                               % Match found, so remove Q from R1
          match_star_maps(Test,Ref,T2,R2,[[P,Q]\L1],L2). % Repeat with depleted lists
```

c

Fig. F.23

Coding and matching star maps with Prolog implementing a naive search algorithm

that are aligned in a linear manner. By selecting the brightest of these spots, it is possible to find the orientation of the most prominent linear feature in the input image. The white pixels contributing to the same bright spot in the transform image do not necessarily lie within a single connected blob. The QT command sequence used to generate ➋ *Fig. F.24c* was

$$\text{wri}('\text{grid}'), \text{enc}, \text{thr}, \text{ero}, \text{ero}, \text{ero}, \text{rdn}, \text{enc}, [x,y,t] = \text{pki}; \text{rei}('\text{grid}'), \text{tur}(-x)$$

F.3.4 Correlation

None of the techniques that we have described so far can calculate the parameters necessary to guide a robot to pick up all six objects in ➋ *Fig. F.1*. We cannot leave this topic without describing how this can be done. We shall describe three methods, each based on correlation.

Edge distance profile. Suppose we have already found the centroid. The orientation can be found using the radius (R) expressed as a function of the distance travelled around the perimeter of the object (➋ *Fig. F.25*). A simple approximation to this is obtained by the following formula:

$$D = \sum \left(N_{\text{odd}} + \sqrt{2} N_{\text{even}} \right)$$

Here, N_{odd} is the number of odd-numbered chain-code steps and N_{even} is the number of even-numbered chain-code steps. Notice that $R(D)$ is a periodic, single-valued function (➋ *Fig. F.25*). This graph changes very little when the object is rotated, except that the phase is shifted (Small variations occur due to quantisation effects). Hence, the corresponding curve from a reference object can be fitted using one-dimensional correlation techniques. As a result, this is a fast method for finding object orientation.

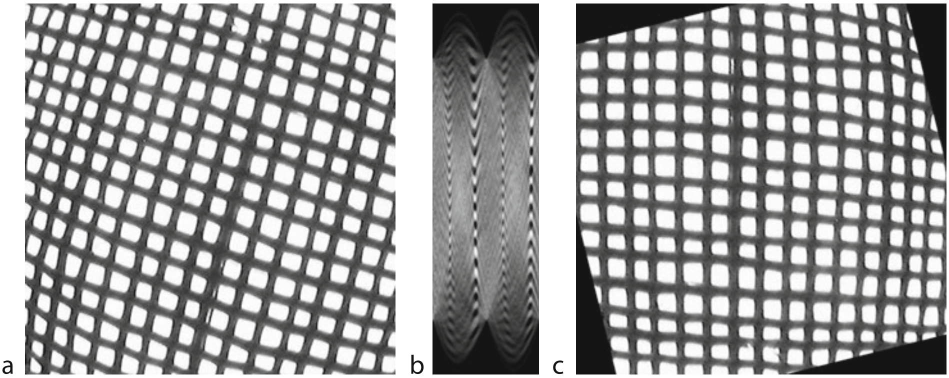

Fig. F.24

Using the Radon transform to determine the orientation of a grid. (a) Original image. (b) Radon transform image. Abscissa, angle. Ordinate, Distance from the centre of the image. (b) The brightest pixel in the RT image was found and its X-coordinate was used to determine the orientation (α) of the grid. The original image was then rotated by an amount -α. Notice that although the grid is not perfectly rectangular, the computation has resulted in an accurate orientation of the vertical wires

Correlation on a polar-coordinate plot (➜ *Fig. F.26b*). The Cartesian-to-polar coordinate-axis transformation (QT command *ctp*) is performed first. This requires a reference point. (The centroid is often most convenient but any other well-defined feature will suffice.) The result is correlated with a similar image derived from a reference object. It is clear in ➜ *Fig. F.26c* that rotating the object by even a very small amount results in a large change in the value of the auto-correlation coefficient. This indicates that this could form the basis for fixing the orientation compared to that of a reference object.

(c) *Correlation in three dimensions.* We have just seen how correlation can be used to fix orientation. We used the centroid to fix the orientation first. It is technically feasible to perform correlation in three dimensions. This could follow the route already established, or it could employ a hill-climbing process, in the hope of improving the speed of processing. However,

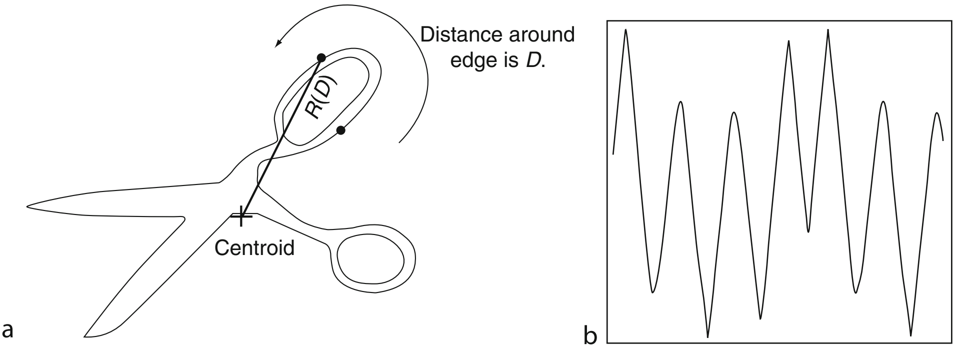

Fig. F.25

Radius plotted as a function of the estimated distance around the perimeter. (a) How the coding is performed. (QT command rdc.) (b) Results for the scissors in ➜ *Fig. F.27a*. Abscissa: D. Ordinate: R(D)

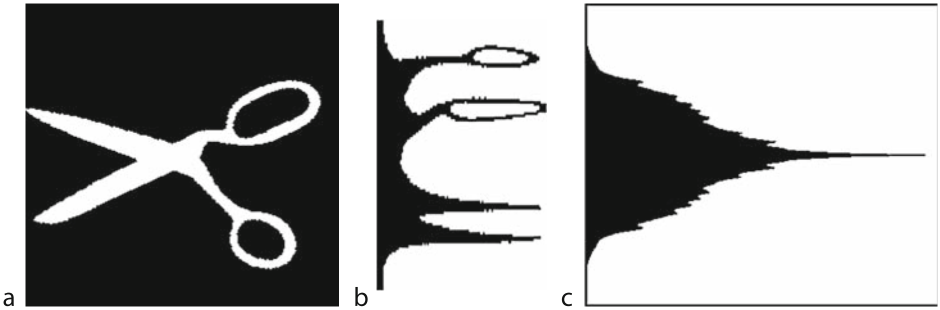

Fig. F.26

Correlation on a polar-coordinate plot. (a) Original image. (b) Cartesian-to-polar coordinate-axis transformation. (c) Two-dimensional autocorrelation function was applied to (b). The intensity profile along a vertical line through the centre of the auto-correlogram shown here has a very sharp peak. This indicates that cross-correlation between polar-coordinate plots, derived from the test and the reference objects, is able to fix the orientation precisely

correlation in three dimensions is not normally recommended, since it is unlikely to be fast enough for use in practice and the process is sensitive to minor changes in shape. For the sake of completeness, we include *Fig. F.27*, which shows that, if the orientation is fixed, it is a straightforward matter to use correlation to fix the *XY*-coordinates.

F.4 Finding Object Chirality

Consider *Fig. F.28*. However either of these objects is rotated or translated in the plane defined by this page, it is impossible to fit one onto the other. It is necessary to flip it over to do so. They are said to differ in their *chirality*. (This term borrowed from chemistry where it refers to pairs of molecules that are structurally identical but are mirror images of one another. The most infamous pair of molecules of this kind is thalidomide.) Many measurements are the same for these two objects, so how can we distinguish them? The numbers in *Fig. F.28* indicate the relative sizes (areas) of the concavities (This includes both lakes and bays.) Now, starting with the concavity with the largest area, we list the order in which we encounter the others, as we travel clockwise. For the object on the left, the sequence is:

$$S_1 = [1, 6, 2, 5, 3, 4] (\text{Object on the right})$$

and for the one on the right it is

$$S_2 = [1, 4, 3, 5, 2, 6] (\text{Object on the right})$$

Notice that these lists are linear representations of cyclic sequences. Hence, S_1 is the reverse of S_2. However these two objects are rotated or translated within the same plane, the lists S_1 and S_2 will remain the same. Hence, we can correlate the list generated from a test object with that from a reference object, to determine the chirality.

This approach is not totally satisfactory, since pairs of concavities may have very similar areas. For example, let us suppose for the moment that the finger holes in the scissors are identical. We might then find that S_1 *is* either [1,6,2,5,3,4] or [1,5,2,6,3,4], while S_2 is [1,4,3,5,2,6] or [1,4,3,6,2,5]. Determining the chirality is still possible but it just takes a little longer as two reference lists have to be matched to that from the test object. Problems are worse if there are two concavities with equal areas that are bigger than all others. Another difficult situation occurs when the concavities all have equal areas. It is then impossible to use this approach to determine chirality. Notice that this condition does not imply that concavities with equal areas have the same shapes; it might still be possible to modify the chirality test to compare meta-concavities, or even meta-meta-concavities. There are many other chirality tests that we can devise. For example, we might compare only bays, or only lakes, to increase processing speed. Alternatively, we might compare such features as the number of meta-bays, aspect ratio, or shape factor (Area/Perimeter^2). It is easiest to devise chirality tests around a single numeric metric. Deciding which one to use can only be done after careful consideration of the application.

F.5 Challenges

In common business parlance, the word "*challenge*" is a euphemism for "*very difficult*" but this is not the intended meaning here. We have described many different ways to determine position and orientation. However, there are numerous other methods that we could employ. *Figure F.29* illustrates a variety of applications, some of which require methods not yet covered

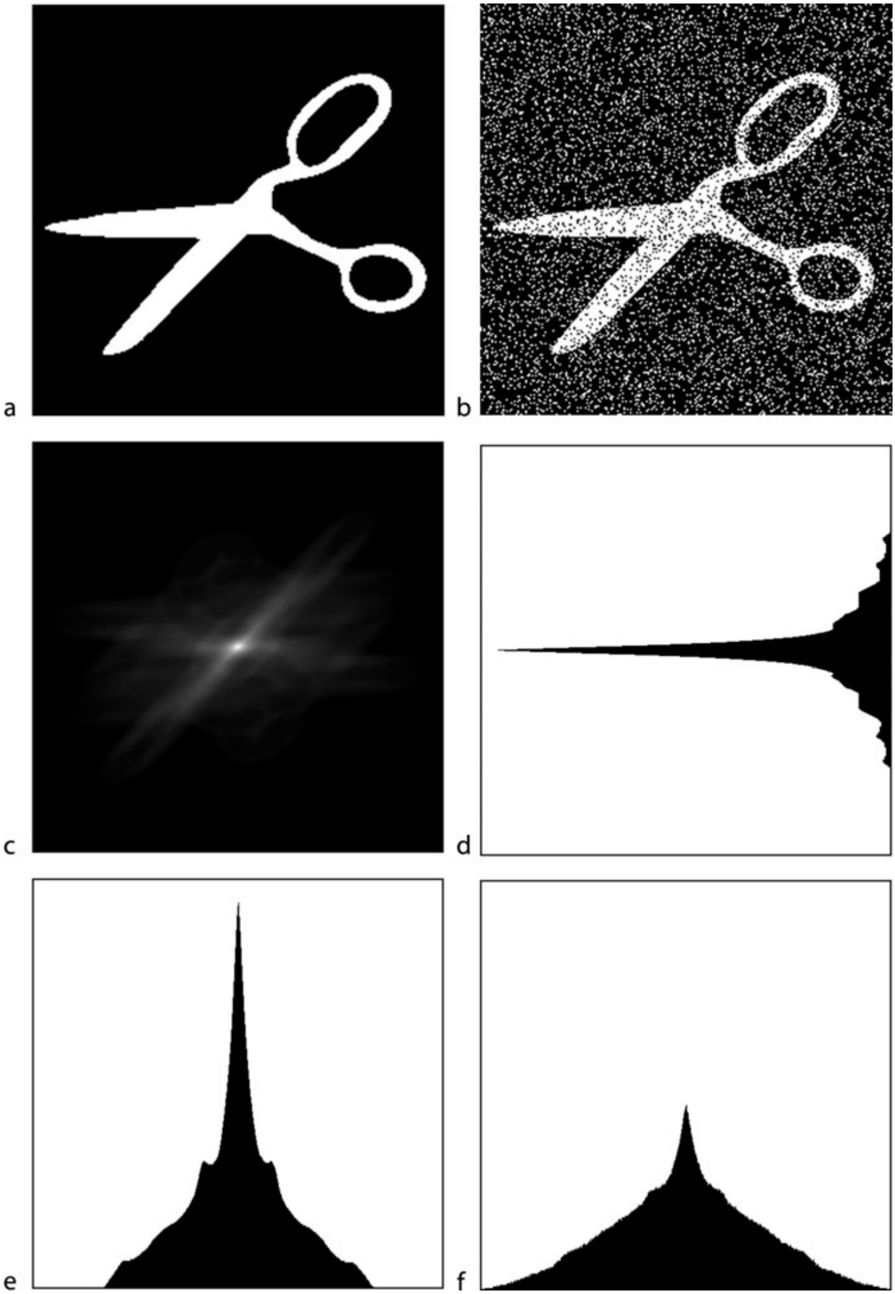

Fig. F.27

Correlation in two dimensions: *XY*-translation, with the orientation correctly fixed. (a) original image. (b) Salt-and-pepper noise added. QT: spn(0.25) (c) two-dimensional auto-correlogram of (a). (d) Intensity profile (vertical section) through the centre of (c). (e) Intensity profile (horizontal section) through the centre of (c). (f) As (e) but computed on the noisy image, (b)

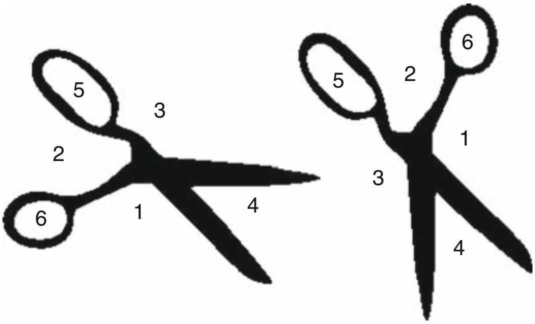

Fig. F.28

Two objects that differ in their chirality. However either of them is moved or rotated, it is impossible to fit it onto the other. It is necessary to turn it over, to do so. The numbers indicate the relative sizes (areas) of the concavities (lake and bays)

in this appendix. They are all soluble using quite simple QT command sequences, although there is no prescription that we can offer that will solve them all. There is one common factor that all of these applications and those illustrated earlier share: they all require that magic ingredient: *human intelligence* (*Fig. F.1*).

Appendix G: Image Catalogue

G.1 Images Accessible Via QT

QT is supplied with a range of images, stored in the folder *BGB_MatLab_Images*. Some of these images form the basis for illustrations found elsewhere in this book. ➜ *Table G.1* describes a selection of these images and gives their corresponding file numbers. (Other images are provided but are not catalogued below, to conserve space.) In order to read the monochrome *Coffee beans* image, use the QT command *rni(4)*. To read the colour *Apples* image, type *rci(294)*. Notice that the folder *BGB_MatLab_Images* must be placed on MATLAB's search path first. A pictorial index is provided below.

Most of the images have direct industrial relevance. However others are included, simply because they model important industrial vision applications. For example, the three *Scissors* images *(no. 48– 50)* exemplifies articulated objects that have a single hinge. *Child's building blocks* (no. 306) resembles printed packing and is a useful model for studying colour recognition. In some applications, the requirements may be surprisingly simple; in images 307, 460, 462, 762, for example, monitoring the relative proportions of mixtures of colours is all that is needed. (How many times have you been frustrated to find that your favourite colour is not available in a packet of Liquorice Allsorts?) In such cases, any suitable analogous task that presents the same important properties as a real industrial application will suffice for learning purposes. For an author, of course, it circumvents copyright restrictions.

Using QT and the images supplied on the DVD, you will be able to repeat many of the experiments reported in this book. Additional test images can be drawn, by hand, generated using a graphics program (e.g. *Adobe Illustrator*™, *Photoshop*™), or using QT's limited set of image-generation functions. (*cir, dic, vpl, wgx*, etc.) For educational and training purposes, images can be captured using a standard digital camera and simple lighting, such as an LED torch. In this case, it is important to realise that, even if the whole image is not appropriately lit, parts of it may suffice for an exploratory study. (Image 28, *Creased fabric*, is an example.) Using ordinary everyday objects as subjects for learning QT and the principles of lighting is both rewarding and fun. Go to the pantry, medicine cabinet, tool-box, children's toy box, etc. for inspiration. Then, follow four simple steps to choose the lighting and viewing conditions:

1. Experiment
2. Observe
3. Adjust
4. Go to step 1

Table G.1

Some of the images accessible from QT

File Number	Object/scene	Lighting-viewing Method	Typical inspection task (e.g. detect/locate/inspect/measure)
0	QT Logo	N/A	N/A
2	Metal mesh	Back	Orientation of mesh
3	Grains of rice	Front	Length and width
4	Coffee beans	Front	Analyse texture to determine type
17	Electrical connector	Back	Faulty assembly
18	Loudspeaker cone with loose wires	Front diffuse	Ends of wires and orientation
19	Coil with loose wires	Back	Ends of wires and find orientation
20	Internal screw thread	Conical mirror	Integrity of thread
21 – 24	Coin (UK, 20 pence)	Diffuse front (21 and 23)/360° grazing (22 and24)	Lettering and monarch’s head. Flat surface for pits and scratches.
28	Creased fabric	Grazing illumination	Susceptibility to creasing
31	Glass bottle with crack	Back	Detect cracks, measure profile
32	Glass vial (brown)	Dark-field	Profile and dimensions
33	Glass bottle	Crossed linear polarisers	Stress in side walls
34	Embossing on glass bottle	Back	Complete and properly formed
37	Hydraulics manifold	Front	Overall inspection
	(plan view)		Holes for debris
38	Hydraulics manifold	Front	Complete inspection of each feature
	(side view)		including checking holes for debris
40	Brake pads (two samples)	Front	Check integrity of assembly.
41	Ferrous automobile with crack	Dye penetrant UV fluoroscopy (Low-level VIS lighting reduces contrast)	Detect cracks
43	Screwdriver	Poor backlighting	Find position and orientation
44	Formal table place setting	N/A – binary image	Object recognition and layout
45	Slice of bread	N/A – binary image	Sides parallel.
			Overspill.
			Rounded top.
			Overall symmetry
46	Four piece parts	N/A – binary image	Guide robot for pick and place
			Position, orientation, chirality
			Sufficient space for gripper
47	Conrod	N/A – binary image	Position, orientation, chirality

Table G.1 (continued)

File Number	Object/scene	Lighting-viewing Method	Typical inspection task (e.g. detect/locate/inspect/measure)
48 – 50	Scissors	N/A – binary image	Gripping points
			Position, orientation, chirality
			Angle of opening.

Pictorial Guide to QT Images

G.2 Sample Infra-Red Images

The spectral response of a silicon photo-detector extends well into the infra-red waveband (➋ *Fig. G.2.1*), suggesting that a standard digital camera can be modified to detect NIR images, by simply removing the built-in IR-blocking filter. (Several "hobbyist" photography web sites show how this can be done.) Some cameras have a mechanical switch to move the filter out of the optical path. Several of the images shown below were obtained using a *Sony Cyber-shot DSC-H9* camera in "*Nightshot*" mode. This disables its internal IR-blocking filter. The author then fitted a VIS-blocking filter with a cut-of wavelength of 720 nm. (He purchased a filter of diameter 72 mm and held it in place with a 74–72 mm step-down converter ring, attached to the lens hood. It is not possible to fit the filter directly to the zoom lens.) This produces a camera that is sensitive only to NIR wavelengths: approximately 720–1,100 nm. Normally in "*Nightshot*" mode (i.e. without the additional filter), the camera senses both VIS and IR, which is also useful on occasions. Nearly all of the functions of the *Sony Cyber-shot DSC-H9* camera are available with this set-up. In particular, the focus and light meter still work as normal.

Of course, before experimentation can begin, an NIR light source is also needed. There are several low-cost options:

- Sunlight (It is difficult to find a lamp much cheaper than this!)
- Incandescent filament lamp
- Bathroom "heat lamp"
- IR LEDs. (The author bought a kit with 36 IR LEDs mounted on a PCB, for under €20. The power supply is a 12 V/0.5 A source.)
- IR flood-light, intended for surveillance CCTV systems

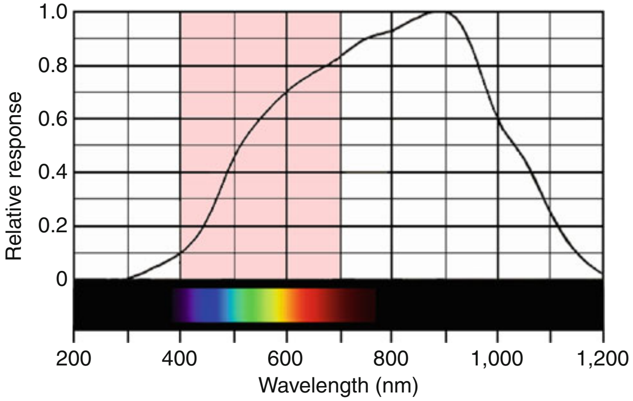

Fig. G.2.1

Typical spectral response of a silicon photo-detector. Notice that the device is more sensitive to IR than it is to VIS (*pink*). This is inconvenient for normal use, so a filter is usually placed in the optical path to attenuate IR. If this filter is removed, a Si-based camera can be made sensitive to both VIS and NIR. To block VIS light, a long-pass filter with a cut-off wavelength just over 700 nm is put in front of the sensor chip

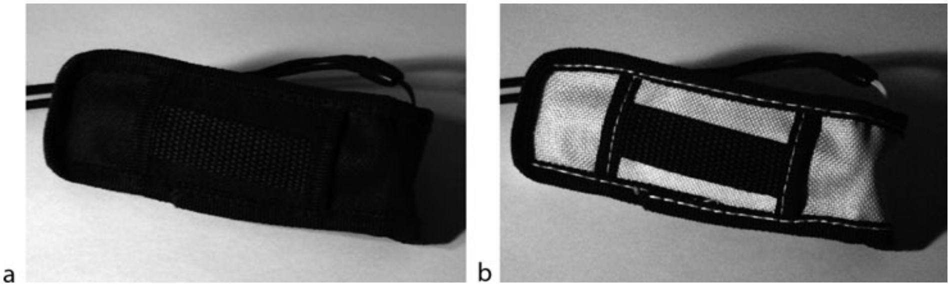

Fig. G.2.2

IR sometimes produces unexpected and spectacular results! This is a canvas case, about 120 mm long. (a) VIS image. (b) NIR image. Waveband approximately 720–1,100 nm (There has been no image processing to enhance the contrast)

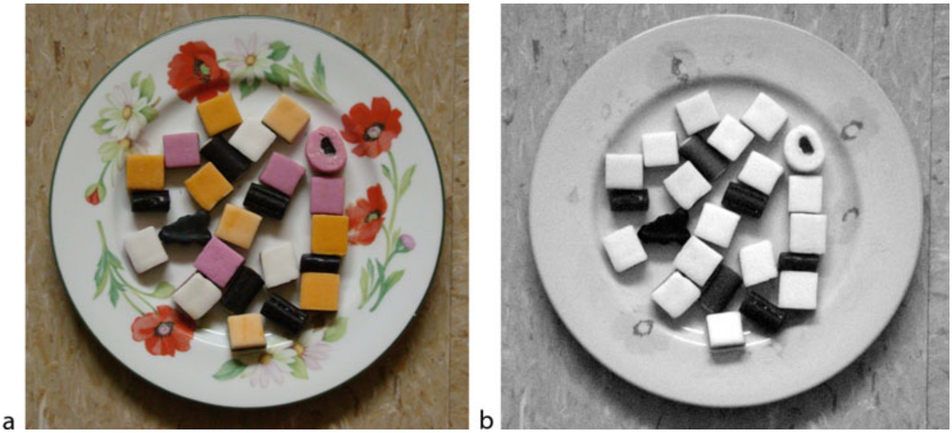

Fig. G.2.3

IR is often insensitive to colouring. Liquorice Allsorts (Yummy!) (a) VIS image. (b) NIR image. Waveband approximately 720–1,100 nm. Notice that the colouring has little effect on the NIR image and that the printed pattern on the plate almost disappears

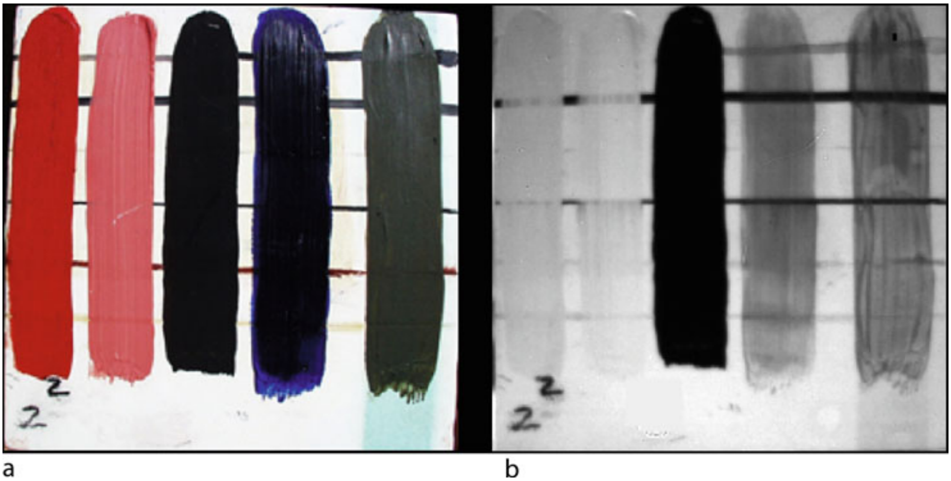

Fig. G.2.4
IR can sometimes see through paint. The ability to do so depends on the material content of the coating. (**a**) VIS image. (**b**) IR image. Waveband approximately 900–1,680 nm. Notice that the "black" (central stripe is nearly opaque and brush marks are enhanced in the right-most stripe). This image appeared in "*Alien Vision*" (From [5]. Reproduced with permission.)

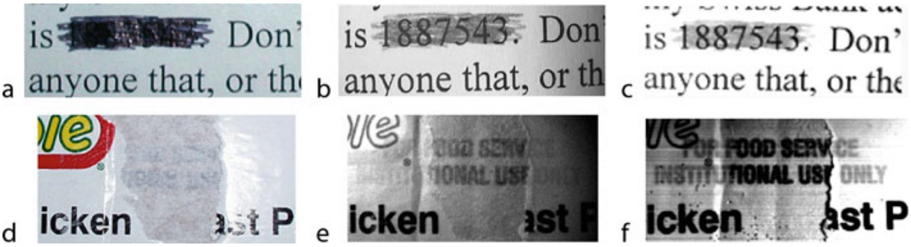

Fig. G.2.5
Another example of seeing hidden details using IR. (**a**) VIS image. Important detail is obscured by black ink from a ball-point pen. (**b**) NIR image. (**c**) SWIR image. (**d**) Another sample. VIS image. Part of the printing is obscured by a thin paper label. (**e**) NIR image. (**f**) SWIR image. (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/ Reproduced with permission)

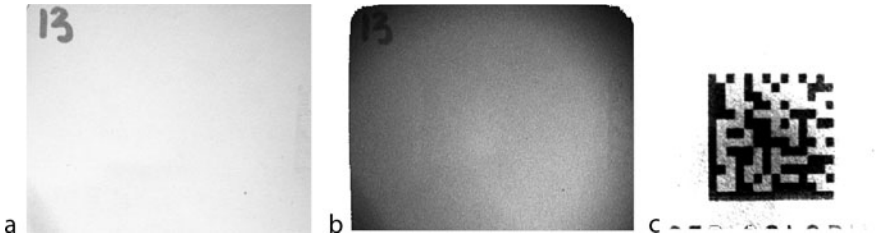

Fig. G.2.6

Another example. The ability to see through paint varies with wavelength. (a) VIS image. (b) Waveband: 840–889 nm. (c) Waveband: 900–1,680 nm. (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/ Reproduced with permission)

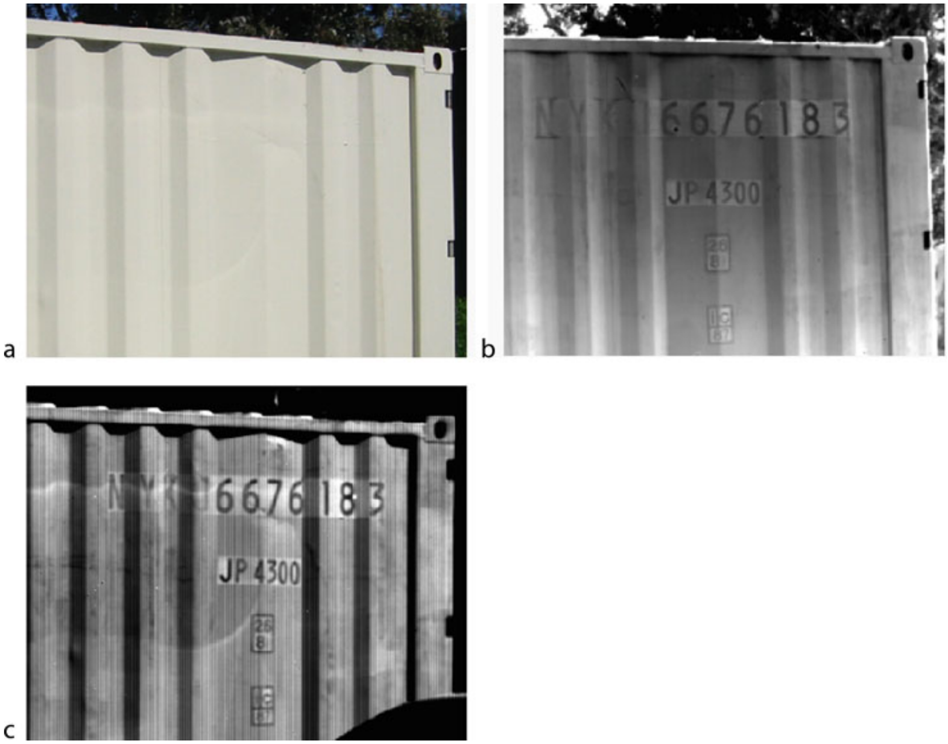

Fig. G.2.7

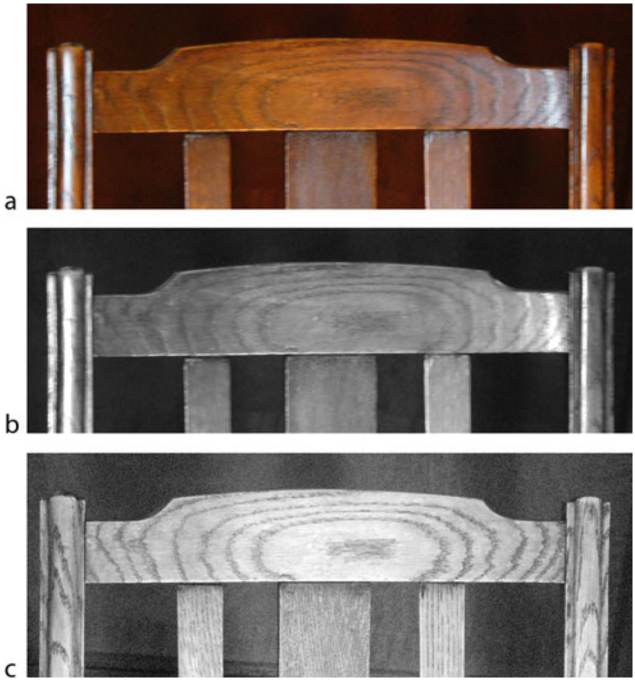
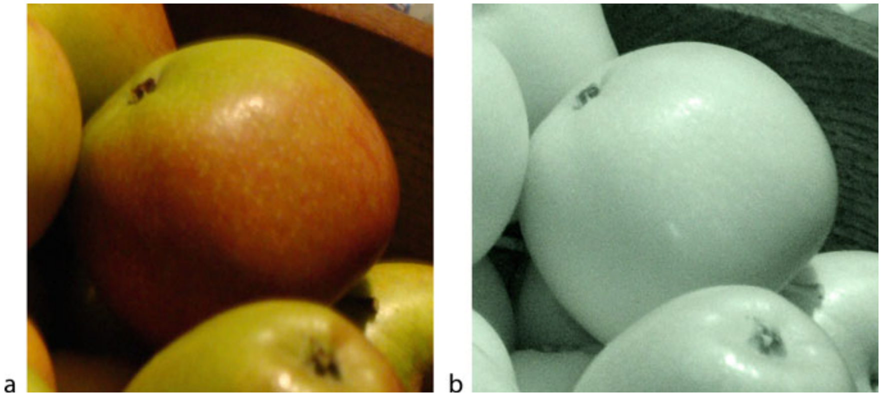
Another example showing that the visibility through paint improves with longer wavelength. Shipping container (a) VIS image. (b) IR image. Waveband: 1,300–1,700 nm. (c) IR image. Waveband: 1,500–2,500 nm. (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/ Reproduced with permission)



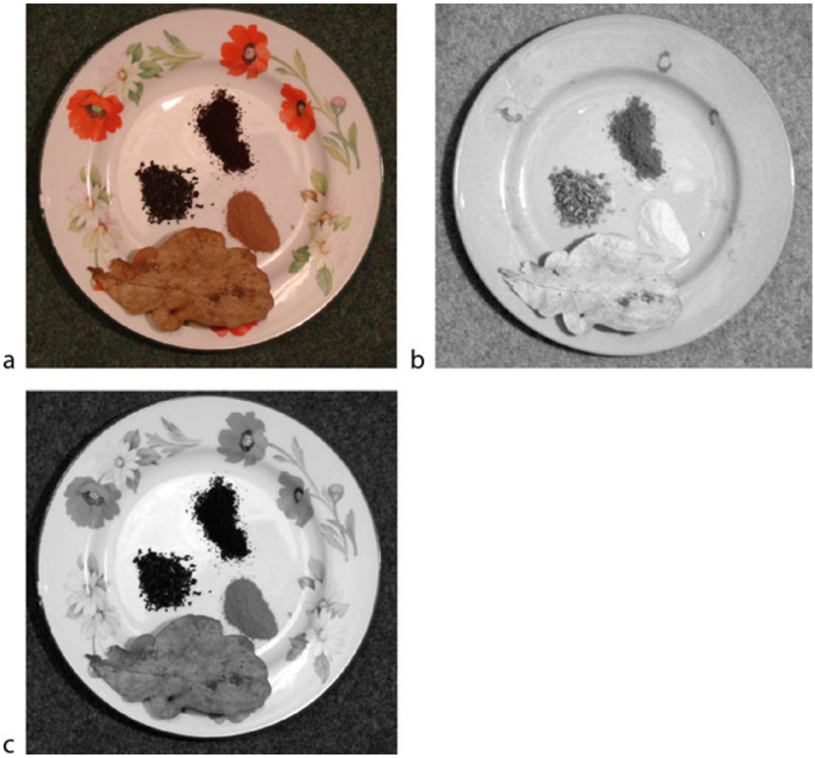
■ **Fig. G.2.8**

Seeing through glossy lacquer is improved by viewing in infra-red. Wood grain. (a) VIS image. (b) Intensity component of the VIS image. (c) IR image. Waveband: approximately 720–1,100 nm. (Image obtained using the Cyber-shot DSC-H9 camera, modified as explained above)

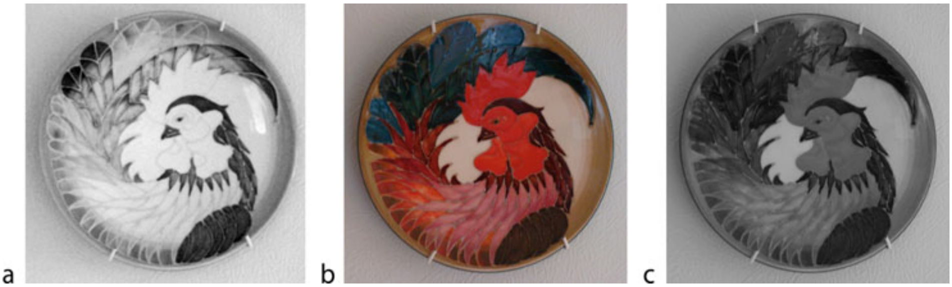


■ **Fig. G.2.9**

Colouration of fruit is often invisible in infra-red. Apples viewed in diffuse natural light. (a) VIS image. (b) Infra-red. Camera response: approximately 720–1,100 nm (Image obtained using the modified Cyber-shot DSC-H9 camera)



◘ Fig. G.2.10
IR response is inpredictable from everyday experience. (a) VIS image. Tea, coffee, chocolate and a dead oak leaf. (b) NIR image, obtained using the modified Cyber-shot DSC-H9 camera. (c) Intensity component, derived from the VIS image



◘ Fig. G.2.11
Decorative ceramic wall plate. (a) NIR image, obtained using the modified Cyber-shot DSC-H9 camera. (b) VIS image (c) Intensity component of the VIS image

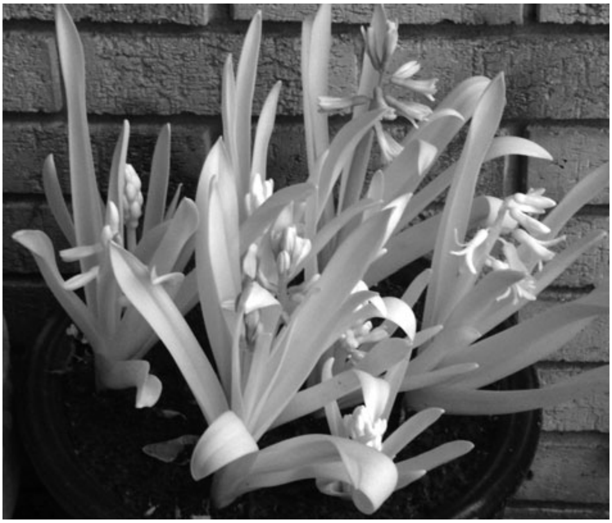


Fig. G.2.12

Foliage and flowers (hyacinths) in NIR (Image obtained using the modified Cyber-shot DSC-H9 camera) Foliage appears bright at these wavelengths. Recall that even dead leaves can do so

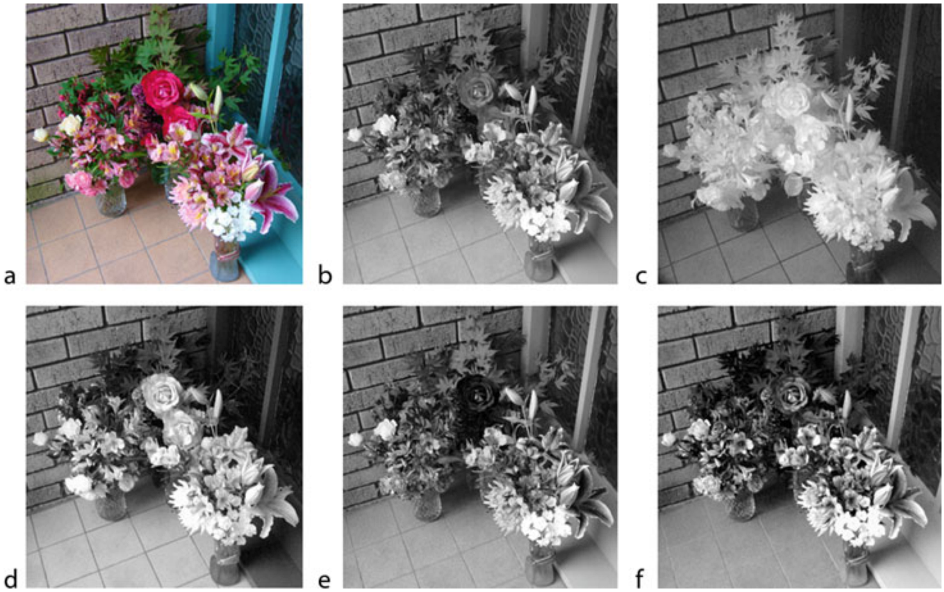

Fig. G.2.13

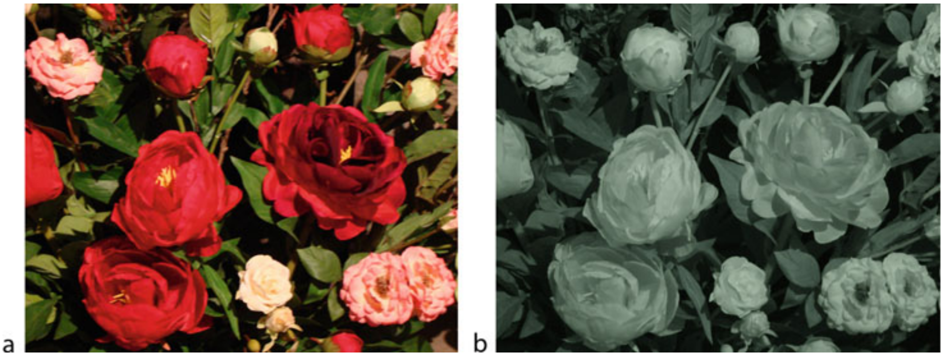
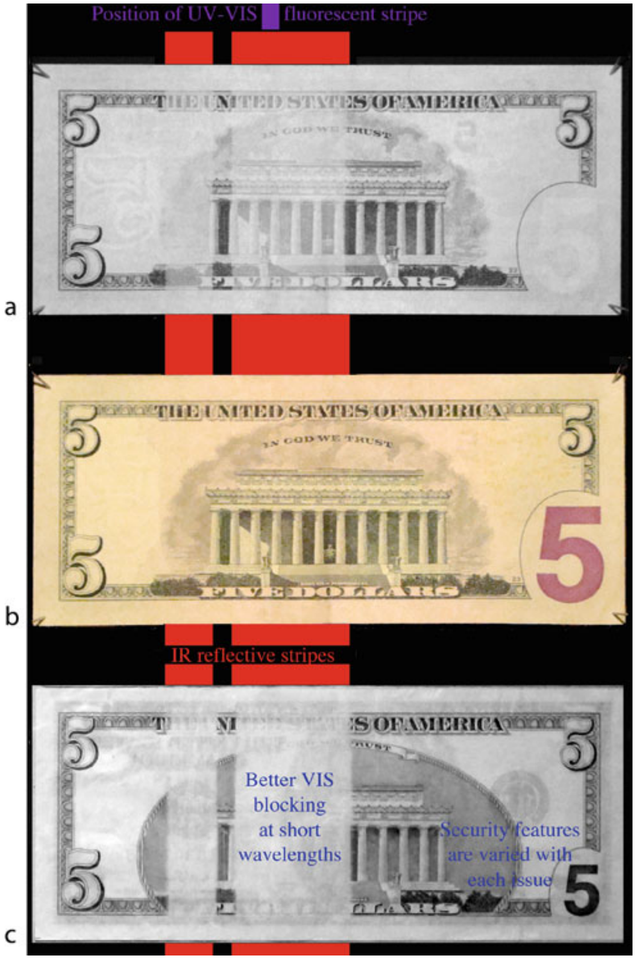
Flowers and green vegetation normally reflects NIR. (a) VIS image. (b) Intensity component. At each pixel, the intensity here is equal to the sum of the RGB values in the colour image. (c) NIR image. Waveband approximately 720–1,100 nm. (d) R-channel. (e) G-channel. (f) B-channel



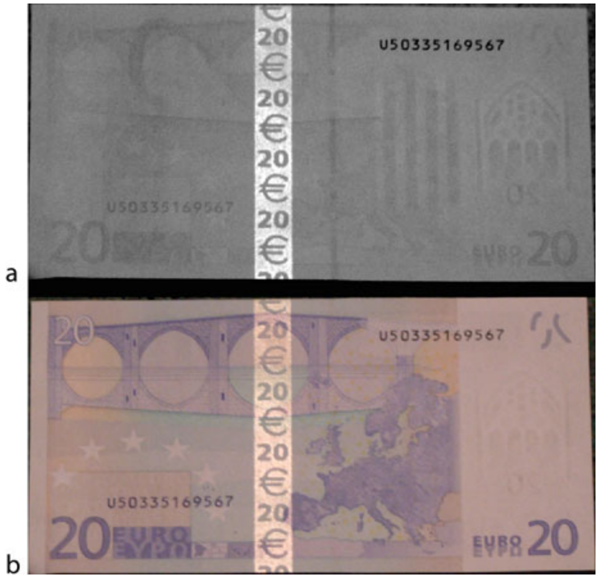
■ **Fig. G.2.14**

Artificial flowers look natural in VIS but are easily identified as being synthetic using infra-red. (a) VIS image. (b) NIR image (720–110 nm) The flowers are bright as they would be for growing plants. However, the foliage is dark, which is quite different from the bright leaves in ➜ *Figs. G.2.12* and ➜ *G.2.13*



Position of UV-VIS fluorescent stripe
a
b
IR reflective stripes
Better VIS blocking at short wavelengths
Security features are varied with each issue
c

Fig. G.2.15
IR reflective ink enhances security on United States currency notes. (The UV–VIS fluorescent stripe is not visible in either VIS or IR.) (a) NIR image (waveband approximately 720–1,100 nm). Notice that the large numeral ''5'' has low contrast and that there are two broad vertical stripes where the picture of the Lincoln Memorial has reduced contrast. (b) VIS image. (c) IR image. The IR reflective stripes are more distinct at longer wavelengths



■ **Fig. G.2.16**

Security feature on a €20 currency note. (a) NIR image, exploiting specular reflection. (b) VIS image again arranged for specular reflection. The note also contains UV–VIS fluorescent security features but these are not visible here

G.2.1 Sample Thermal IR Images

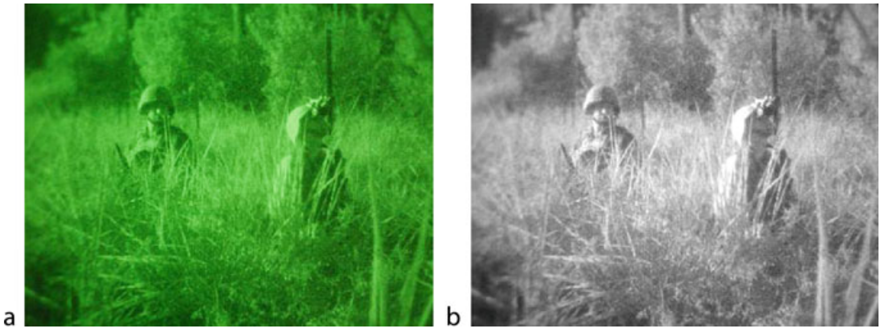


Fig. G.2.17
Night Vision camera. (a) Two soldiers seen through an image intensifier. The *green tint* is a product of the display and has no importance for Machine Vision. Source http://en.wikipedia.org/wiki/File:Nightvision.jpg (b) Intensity image. The grey-scale format is more relevant for industrial applications

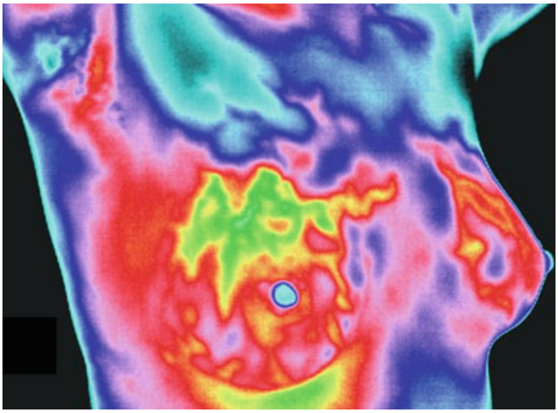

Fig. G.2.18
Thermography provides a fast, low-cost, non-intrusive diagnostic test for cancer. Here, the *green area* (hotter than the surrounding tissue) raises suspicions of cancer in the right breast. Pseudo-colour is often helpful where qualitative judgements are made by a person but has no real value for automated analysis in Machine Vision

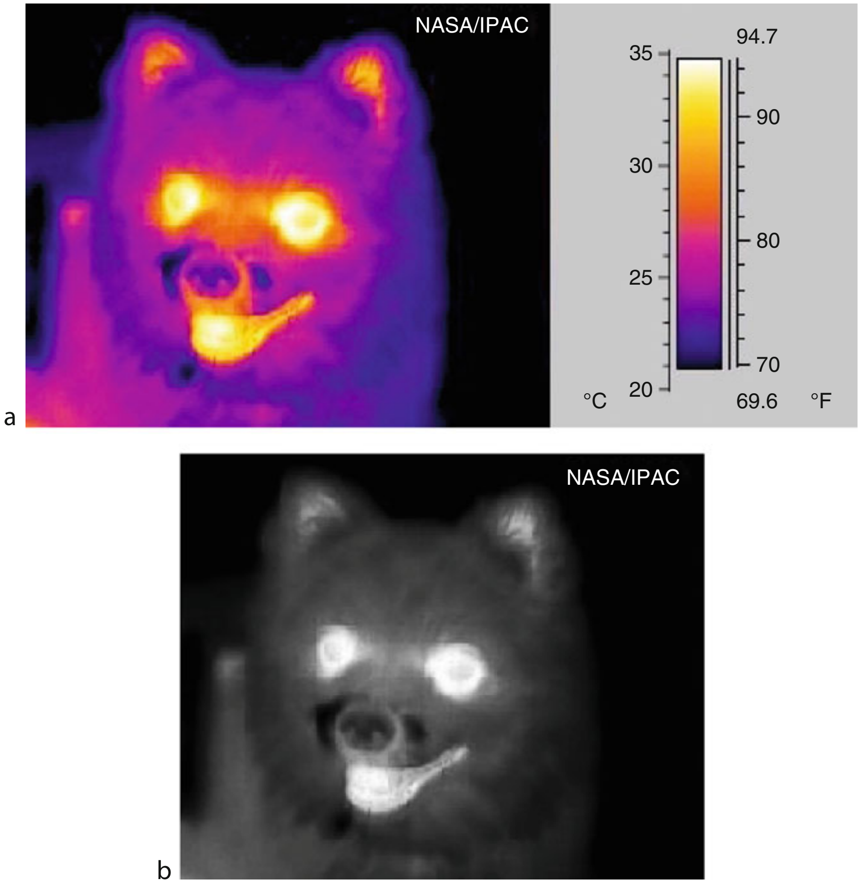

Fig. G.2.19

Thermal Infrared image (Thermograph). (a) Pseudo-colour image (Source NASA, Wikpedia. URL http://en.wikipedia.org/wiki/Thermographic_camera, accessed 10th Novemeber 2011) (b) The pseudo-colour mapping relates temperature to colour and does a good job at preserving a linear relationship between intensity and temperature. Hence, the mapping can be reversed, to yield an image that is more relevant to Machine Vision (When this reverse mapping is applied to the calibration scale, the result is a linear intensity "wedge")

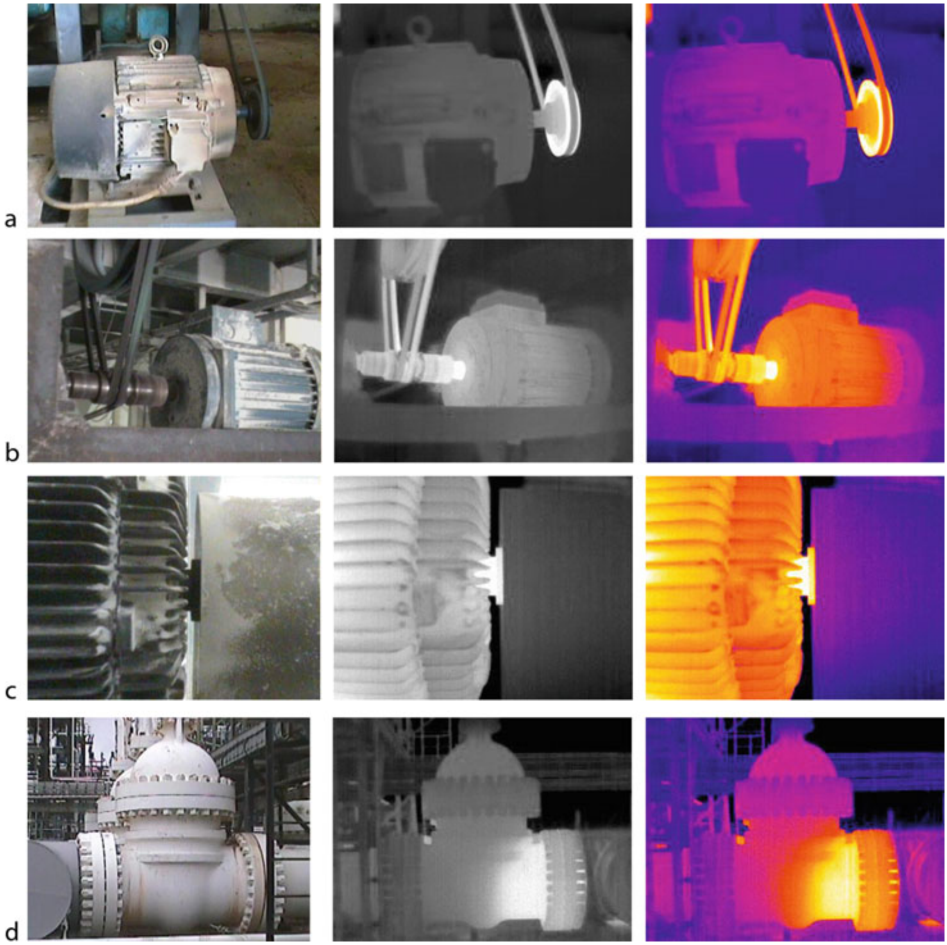

Fig. G.2.20

Thermal image. Showing, the VIS image (*left*), grey-scale IR image (*centre*) and pseudo-colour image (*right*). The grey-scale images were reconstructed by the author, by reversing the pseudo-colour mapping. (a) Belt and pulley. (b) Electric motor with a pulley and belt. It appears that the belt is slipping and causing heating by friction. (c) Motor shaft. This suggests that there is a faulty bearing. (d) Pipe and valve (shut). The VIS and pseudo-colour images were obtained by David Joseph (Infrared Vision, URL http://www.infraredvision.co.uk) using a ThermaCAM™ IR camera (FLIR Systems), URL www.flirthermography.com was used. Reproduced with permission

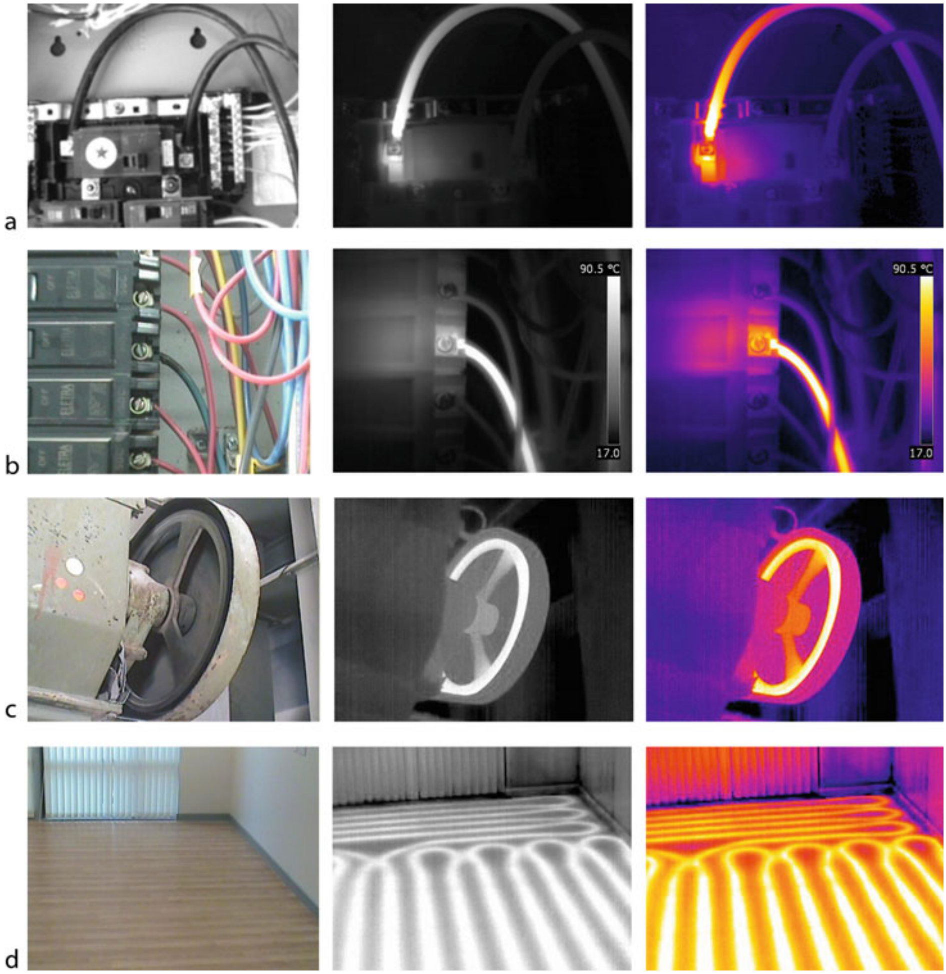

Fig. G.2.21

Thermal images. (a) Electrical wiring. (b) Electrical wiring, another example. Notice that the calibration scale on the right shows a ''wedge'' in which the intensity increases linearly along the vertical axis. This demonstrates the validity of the reverse mapping from pseudo-colour to grey-scale. (c) Pulley overheating as a result of a faulty belt. (d) Under-floor electrical heating. Images supplied by David Joseph (Infrared Vision, URL http://www.infraredvision.co.uk, Reproduced with permission)

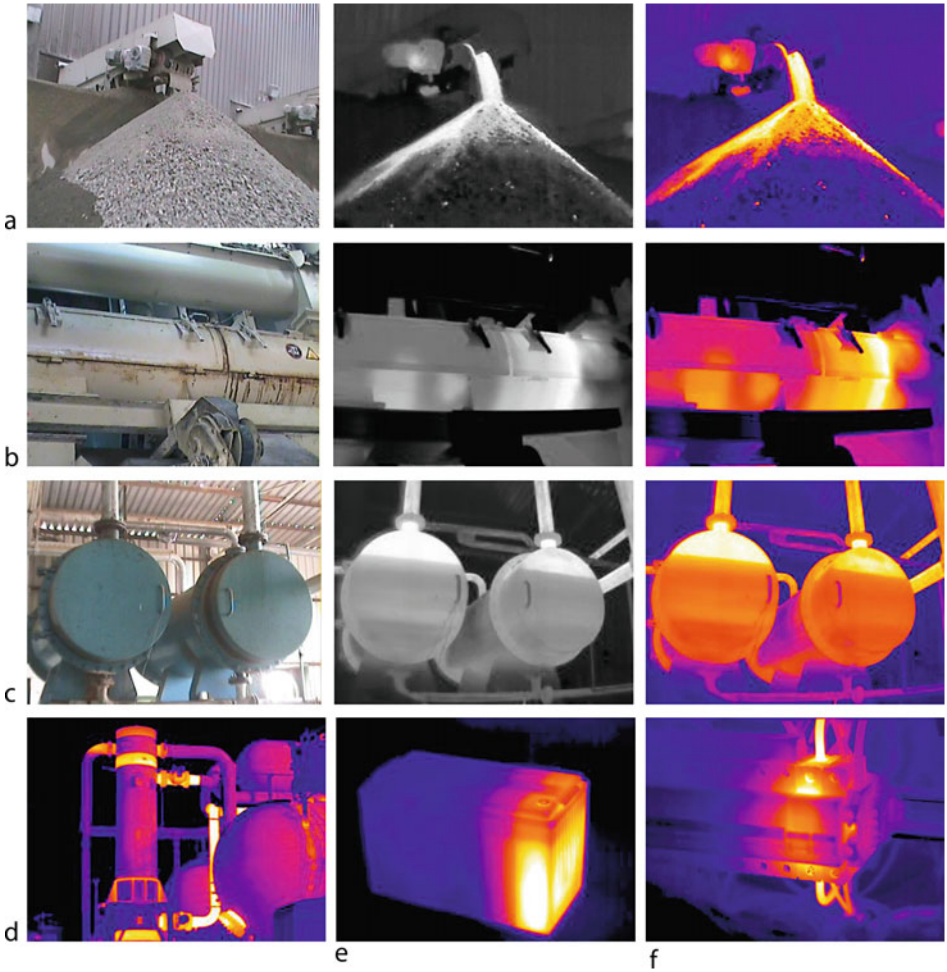

Fig. G.2.22

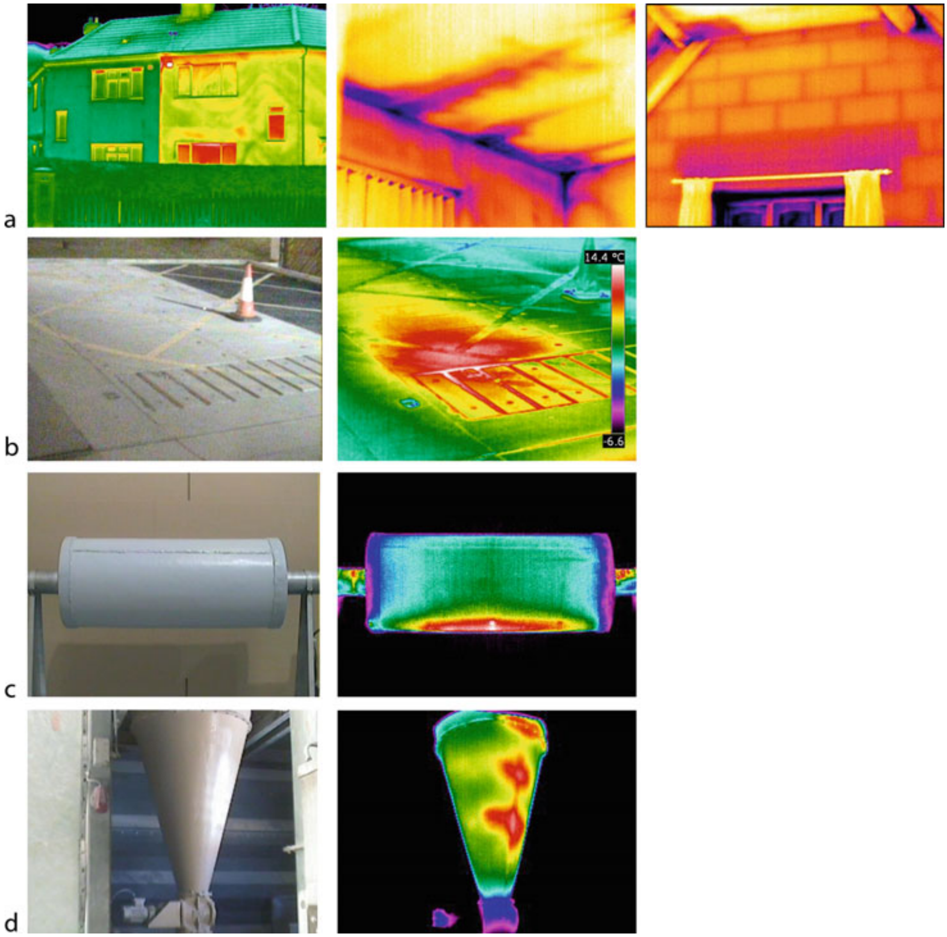
Thermal images. (a) Slag heap. (b) Rotary kiln. (c) Settling tanks. The horizontal striations record the filling history (''stepped'' rate of filling). (d) Petro-chemical plant. (e) Lead-acid accumulator whose end cells broke down while charging. (f) Electrical circuit breaker with a high-resistance connection. Images supplied by David Joseph (Infrared Vision, URL http://www.infraredvision.co.uk. Reproduced with permission)



■ **Fig. G.2.23**

Thermal IR images. (a) Locating sites of heat loss in buildings. This is a common area of application for IR cameras. (b) Underground steam escape. Notice the calibration scale. This pseudo-color mapping is not reversible. (c) Roller. (d) Hopper. Images supplied by David Joseph (infrared Vision, URL http://www.infraredvision.co.uk. Reproduced with permission)

G.3 Sample UV Images

The images in this section were all supplied by Dr. Austin Richards and are reproduced here with his permission. It should be noted that these images were obtained using UV lighting and sensor; they are not the result of fluorescence.

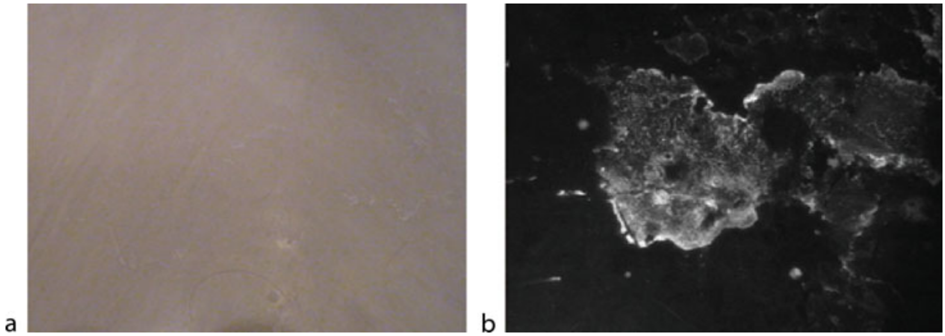


Fig. G.3.1

Toothpaste on a plastic counter-top. (a) VIS image showing no sign of the contamination. (b) UV image. Filter cut-off: 396 nm (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

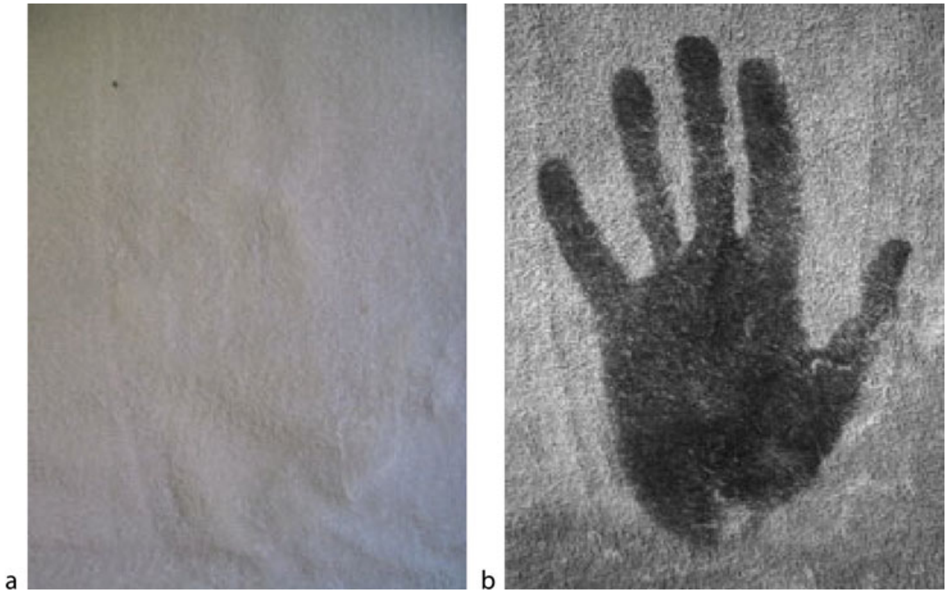

Fig. G.3.2

Sunblock hand-print on a white towel (Sunblock contains an effective UV absorber, such as avobenzone.) (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

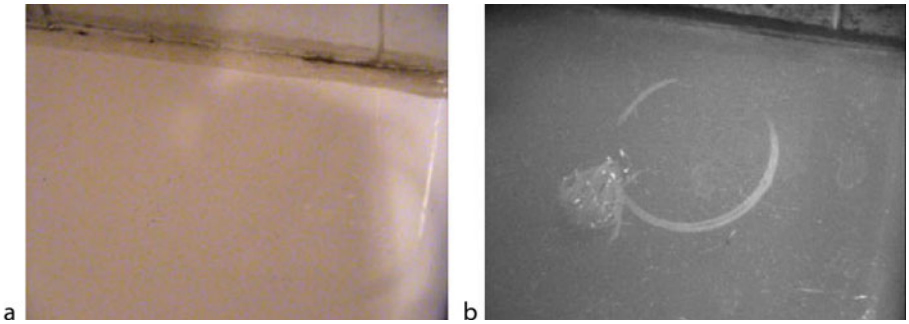

Fig. G.3.3
Traces of candle-wax and hair-dye on a bathtub. (**a**) VIS image. (**b**) UV image, wavelength 365 nm (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

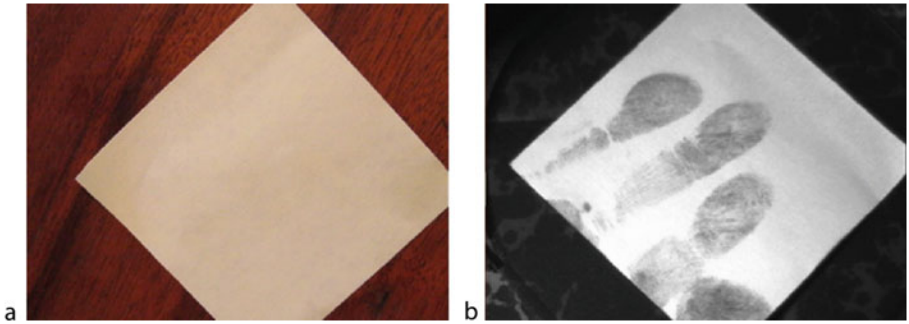

Fig. G.3.4
Moisturizer containing some sunblock. (**a**) VIS image. (**b**) UV image (These finger-marks can also be detected using UV–VIS fluorescence) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

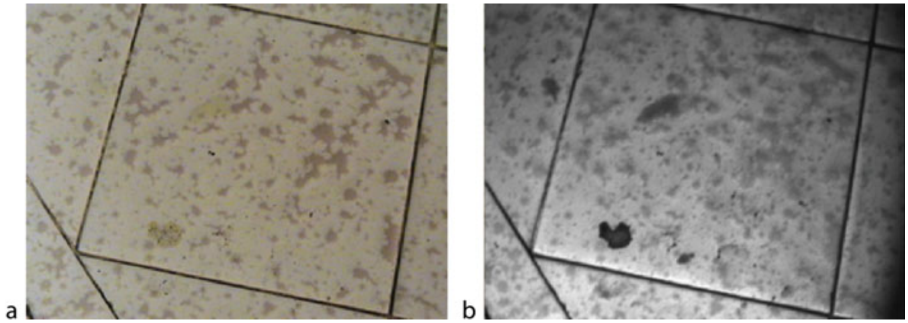

Fig. G.3.5
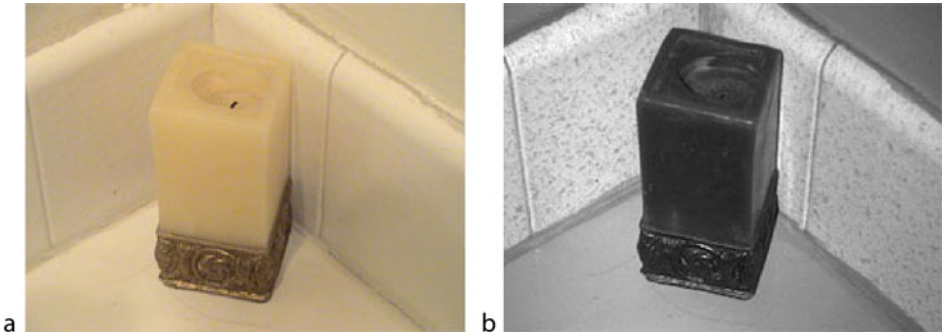
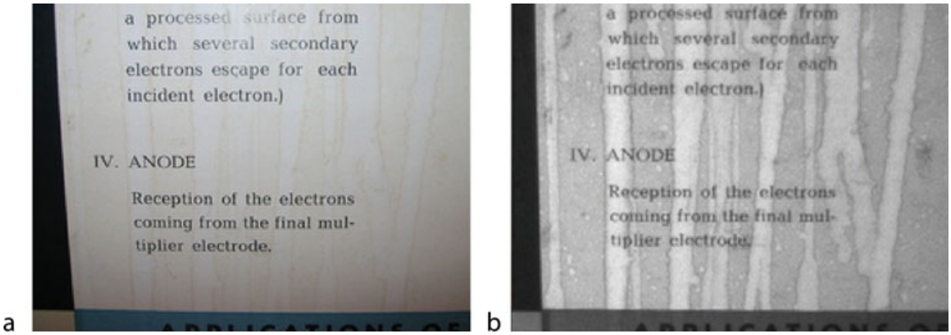
Kitchen tiles with a hard ceramic glaze. (**a**) VIS image. (**b**) UV image (Grease, as many other long-chain hydrocarbons absorbs UV very strongly) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



■ **Fig. G.3.6**

Candle against ceramic tiles. (a) VIS image. (b) UV image (The freckle-like pattern in the tile contains yellow flecks that absorb UV strongly) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



a processed surface from which several secondary electrons escape for each incident electron.)

IV. ANODE

Reception of the electrons coming from the final multiplier electrode.

APPLICATIONS OF

■ **Fig. G.3.7**

Water stains on paper. (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

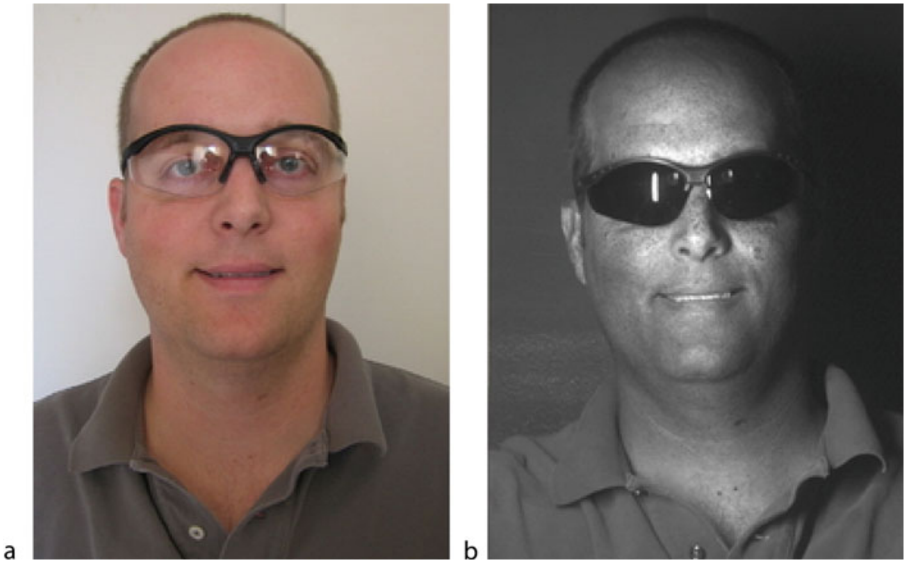


Fig. G.3.8

Plastic safety glasses with a UV absorbing coating. (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

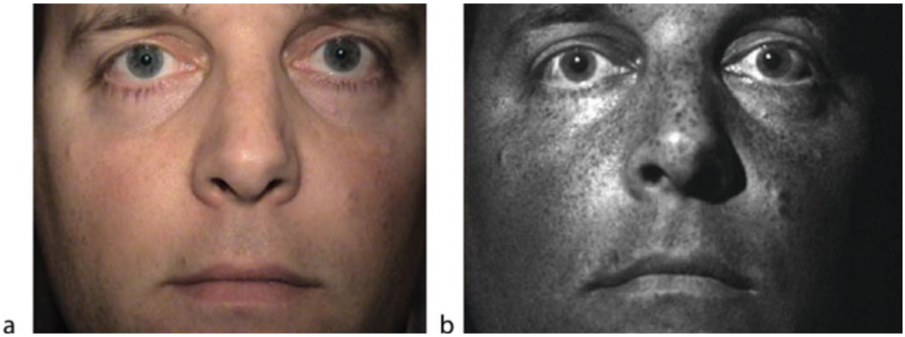

Fig. G.3.9

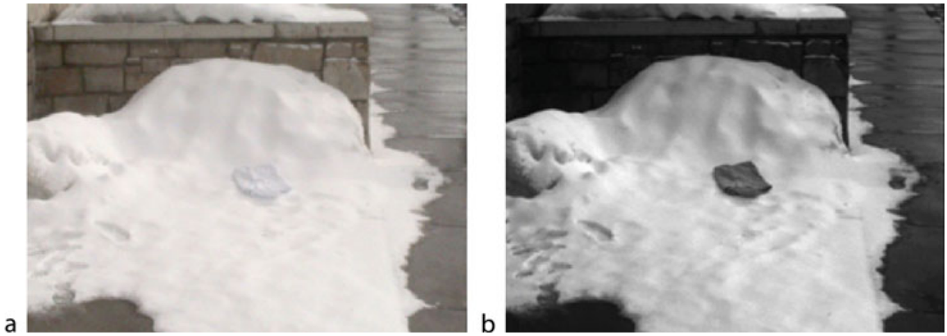
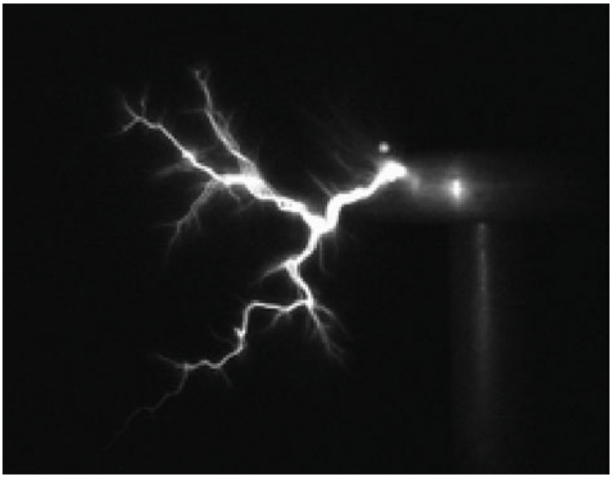
Facial skin with mild sun damage (Sun damage on skin manifests itself is as dark patches of excess melanin produced in response to UV exposure. This is much easier to visualize in the UV than in the visible band. Burns, bruising, bite marks, avulsive wounds and injection sites can also be seen in the UV, sometimes months after they have faded to the eye. Forensic odontologists often attempt match bite marks to the teeth of a suspected assailant using UV photography) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



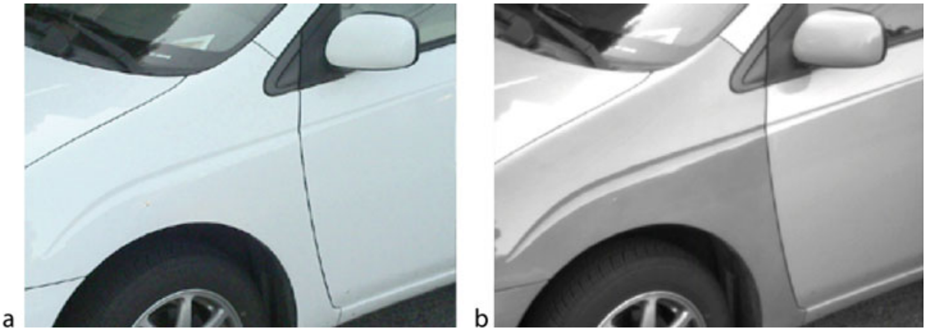
■ **Fig. G.3.10**

Cotton cloth on snow. (a) VIS image. (b) UV image (Many white fabrics used for snow camouflage are clearly visible in UV) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



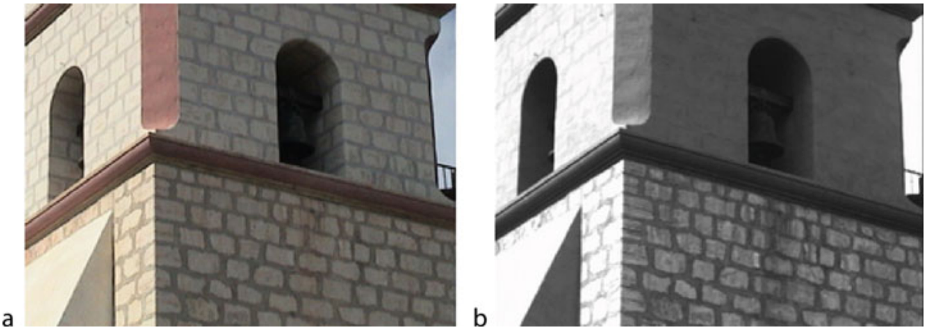
■ **Fig. G.3.11**

Imaging Electrical Discharges in UV (High voltage discharges produce excitation of atmospheric nitrogen, leading to emission of a weak deep-purple light that also has a strong UV component)



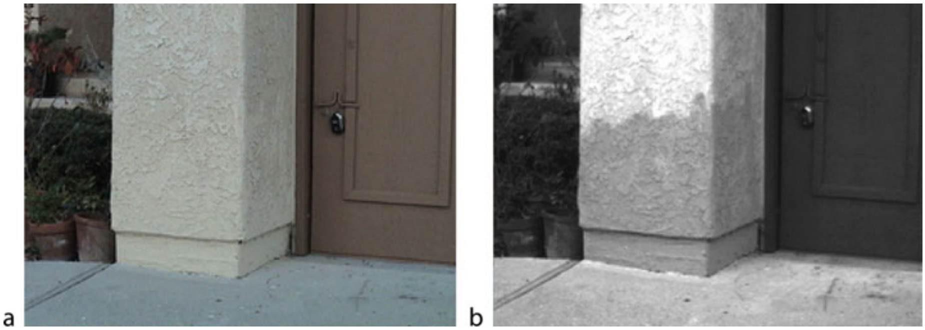
■ Fig. G.3.12

Toyota Prius car with repainted wing panel. (a) VIS image. (b) UV image (The contrast is impossible to detect visually) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



■ Fig. G.3.13

Masonry tower with a superstructure that has artificial stone-and-mortar patterns painted on. (a) VIS image. (b) UV image. Notice the water stain (*centre-bottom*) in the UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)



■ Fig. G.3.14

Repainted exterior stucco. (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

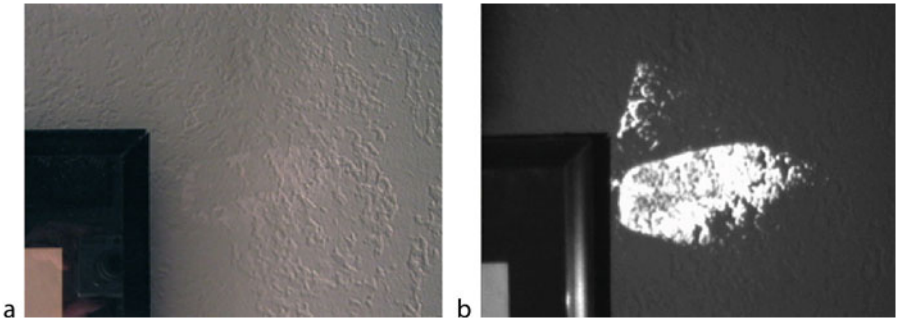


Fig. G.3.15

Painted plaster wall with fresh Spackle™ repairs. (a) VIS image. (b) UV image (Spackle™ is a surface filler used by decorators. Spackle™ is a registered trademark of the Muralo Company) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

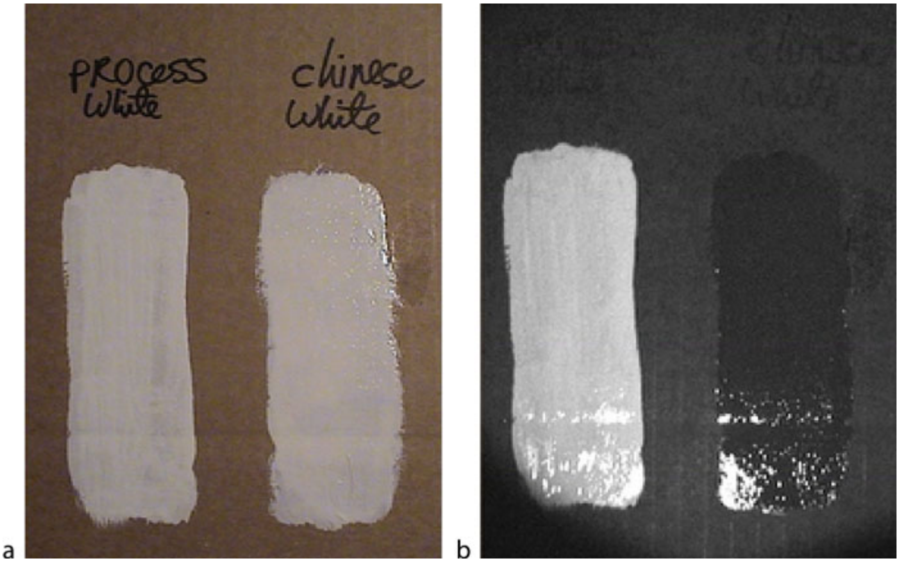

Fig. G.3.16

Two types of white paint. (a) VIS image. Process White (*left*) is a watercolour that accurately reproduces in photographs and is very reflective to UV light at 365 nm. Chinese White (*right*) is not nearly so reflective of UV (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

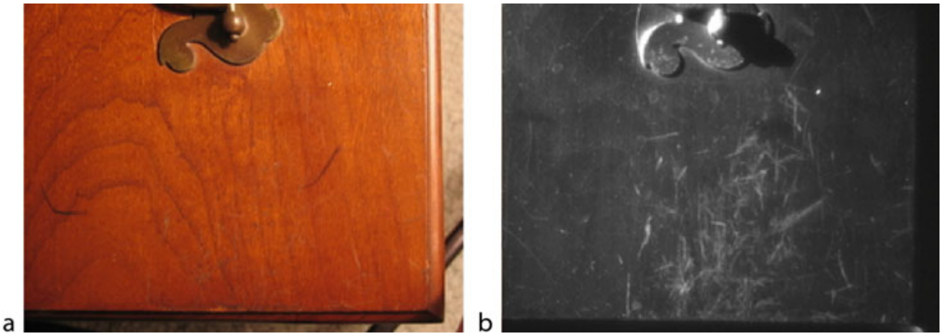

Fig. G.3.17
Scratches on varnished wooden surface. (**a**) VIS image (Scratches are very hard to see because the varnish is transparent to visible light) (**b**) UV image. Illumination wavelength: 365 nm (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

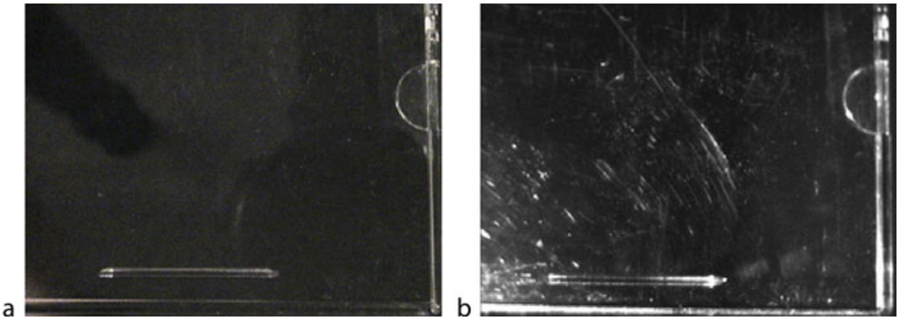

Fig. G.3.18
Scratched CD jewel case. (**a**) VIS image. (**b**) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

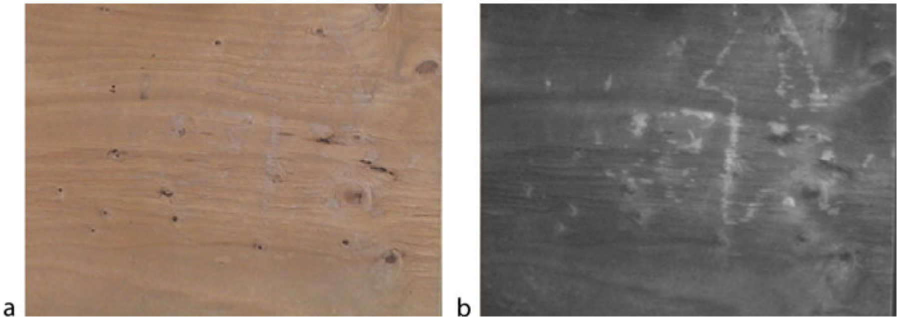

Fig. G.3.19
Dirt on plywood. (**a**) VIS image. (**b**) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

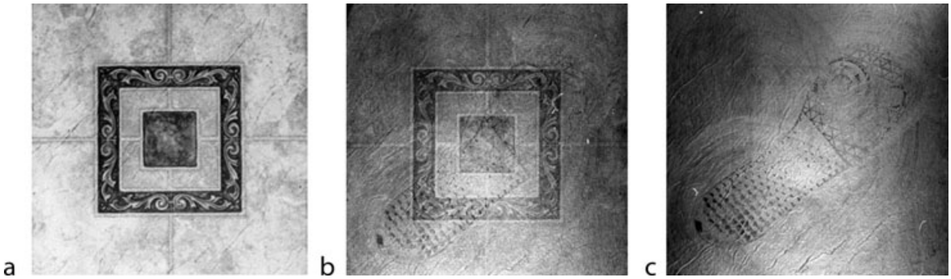

Fig. G.3.20

Footprints impressed in floor wax on a linoleum floor tile. (**a**) VIS image. (**b**) UV image. Wavelength: 365 nm band. (**c**) UV image. Wavelength 310 nm (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

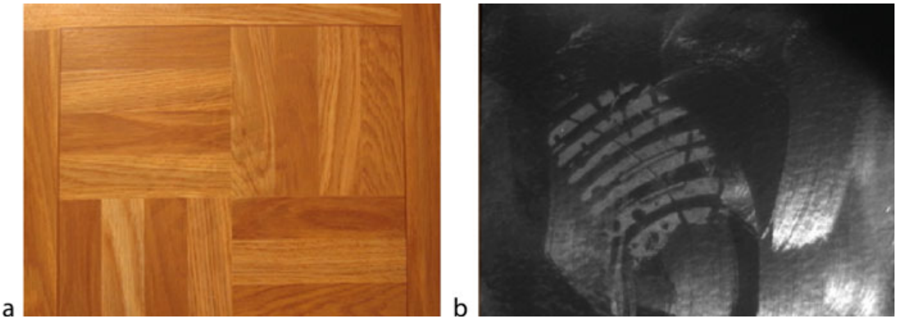

Fig. G.3.21

Shoe imprint on a waxed vinyl floor tile. (**a**) VIS image. (**b**) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

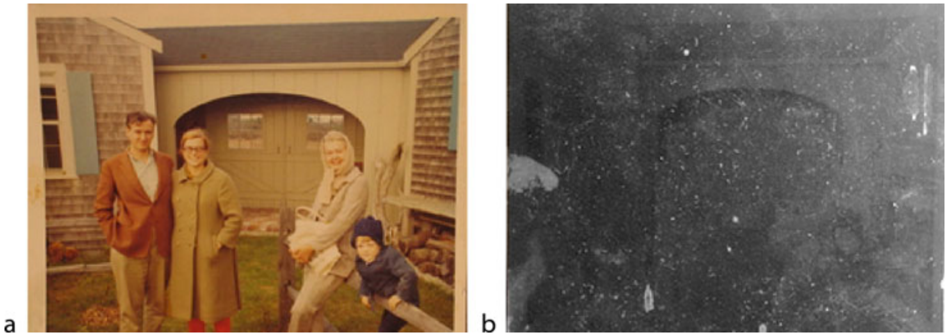

Fig. G.3.22

An old photograph. (**a**) VIS image. (**b**) UV image (The scratched and stained clear coating absorbs UV, which therefore does not reach the photographic image) (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

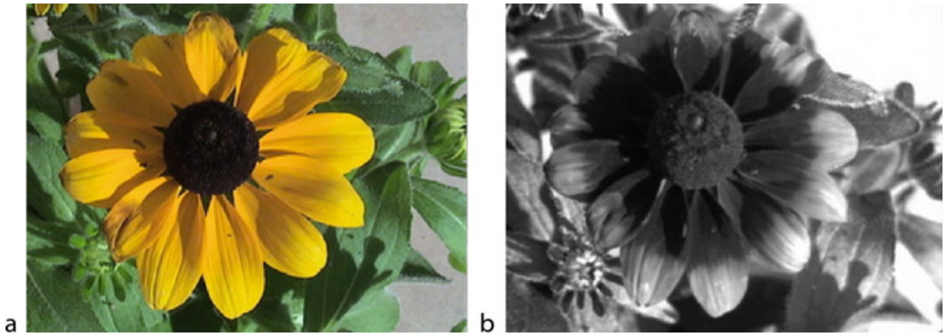

Fig. G.3.23
Flower, Black-eyed Susan (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

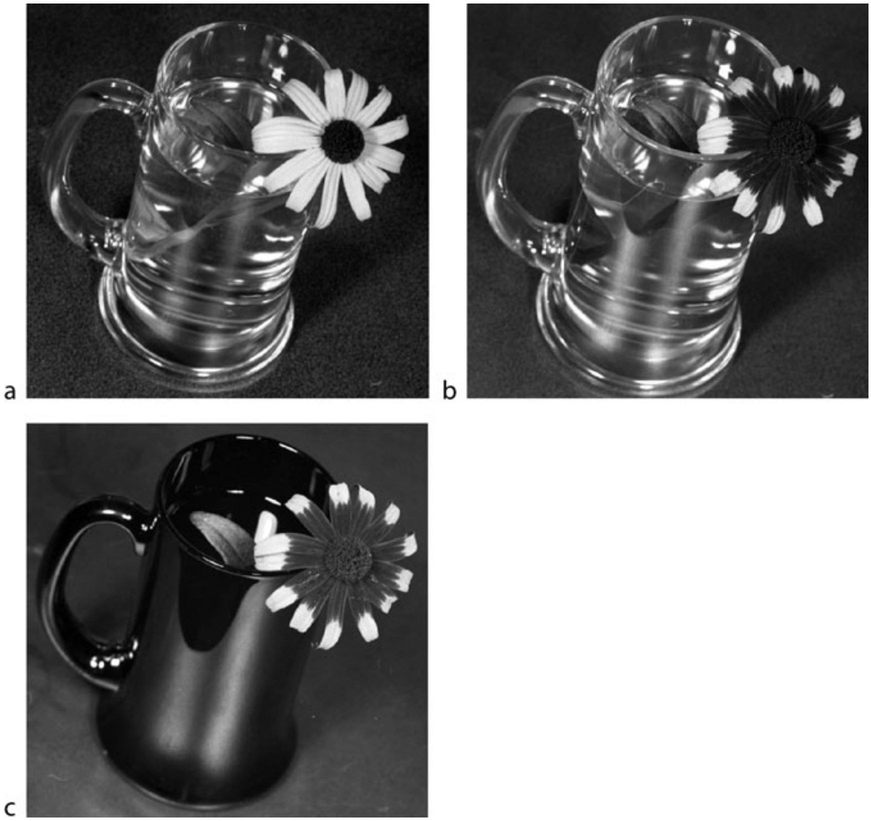

Fig. G.3.24
Glass, water, flower and stippled table. (a) VIS image. (b) UV image. Wavelength 310 nm. (c) UV image. Wavelength 360 nm (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

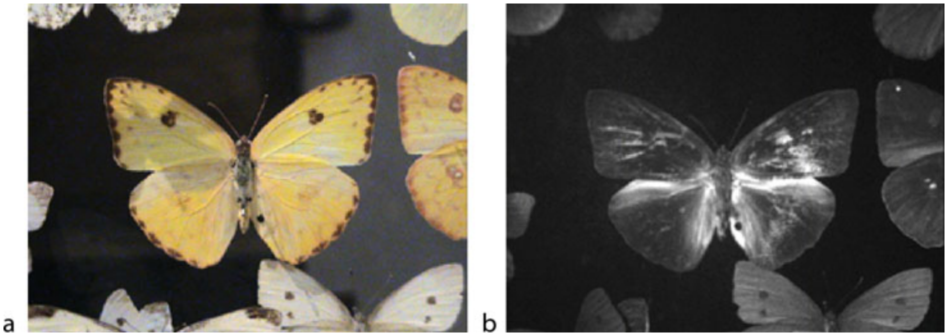

Fig. G.3.25
Butterflies. (a) VIS image. (b) UV image (Images supplied by Dr. Austin Richards, URL http://www.austinrichards.com/. Reproduced with permission)

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_49,

The purpose of this appendix is to describe how QT can be set up with low-cost hardware, to build an experimental tool kit. The author has set up such a system in his own home, demonstrating that beginning in Machine Vision is possible without incurring great expense. A low-cost camera and interface board allows QT to capture digital images and control simple external hardware devices. This arrangement is certainly adequate for gaining familiarity with the technology and developing concept-level solutions for a wide range of non-demanding applications.

H.1 Acquiring Images

Digital images can be captured for subsequent processing by QT in several ways:

(a) Flat-bed scanner (A standard "domestic" scanner is able to provide good quality images in JPEG format.)
(b) Digital camera (A standard still digital camera can provide good image quality. However, this option does not provide easy machine-user interaction.)
(c) MATLAB Image Acquisition Toolbox [http://www.mathworks.com]. This offers a wide variety of options for image capture

A fourth option exists: images can be captured, via the web, using QT command *gwi*. A web-enabled camera with an Ethernet connection (for example, AXIS 210), can be connected directly to the computer's network port, using a cross-over cable. Of course, this disables its web connection. Set up the camera to operate as a simple web server, storing the most recently digitised image at a fixed-address. Then, use *gwi* to download that image, just like any other web file.

Another option for image capture is described later in this section.

H.1.1 Image Format

For convenience, images should be stored in JPEG or TIFF format. However, MATLAB can read other formats, using the command *imread*, including

• BMP	Windows Bitmap
• JPEG	Joint Photographic Experts Group
• PNG	Portable Network Graphics
• JPEG 2000	Joint Photographic Experts Group 2000
• GIF	Graphics Interchange Format
• PBM	Portable Bitmap
• TIFF	Tagged Image File

See [http://www.mathworks.com]

H.1.2 Location

For ease of use, image files should be placed in either of the two following folders:

- *BGB_MatLab_work_files*. Files can have alphabetic, alphanumeric, or numeric names and are read using *rei* or *rea*. The folder *BGB_MatLab_work_files* is intended for storing temporary files.
- *BGB_MatLab_Images*. Files should be in JPEG or TIFF format and have numeric names. They are read using *rni* (grey-scale, or binary), or *rci* (colour). The folder *BGB_MatLab_Images* is intended for storing image files permanently. The command *uia* adds the *Current* image in the lowest-numbered empty slot.

  To use use other folders, simply adjust the contents of the file qt_paths.m

H.1.3 USB Camera

Another option exists for image capture, providing the user to with a dynamic image display. This is particularly useful when adjusting the camera focus. This uses a USB camera, such as one of the following

- *Dino-Eye* USB camera [http://www.dino-lite.eu] The AM423C camera in the *Dino-Eye* range provides a C-mount lens fitting and can therefore be attached to a range of optical devices, such as microscopes, endoscopes, wide-angle/zoom lens, etc.
- *iSight* USB camera [http://www.apple.com/support/isight/] This has a motorised drive, enabling software control of focus, gain, compensation of colour temperature, etc.

These cameras can be operated using a software driver such as EvoCam. [http://www.evological.com/] The software should be set to capture images periodically (e.g., 1 image/s), downloading the digitised image into a file with a specified name. The QT commands *isight* and *frz* have been programmed to read that file.

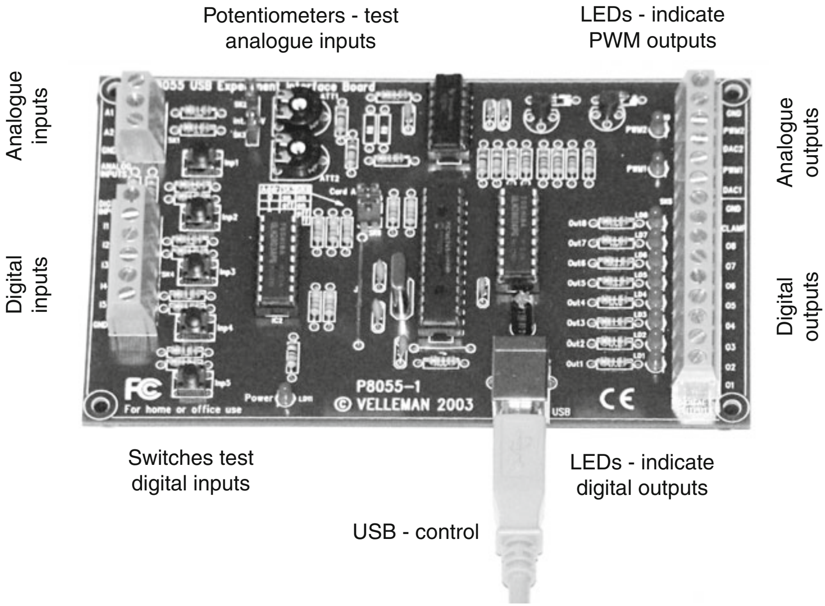
H.2 Controlling the Velleman K8055 Interface Board Via QT

The *K8055 USB Experiment Interface Board*, pictured below, is a low-cost micro-controller device and is well suited for use in education, training and hobbyist applications, as well as providing "quick-fix" engineering solutions. It allows a computer to control the following I/O channels via a single USB port:

- Five digital input channels
- Eight digital output channels
- Two analogue inputs
- Two analogue outputs

Power is supplied by the host computer via its USB port. (70 mA load) Further details of the board can be found at:

http://www.velleman.eu (accessed 13th July 2010)



Potentiometers - test analogue inputs
LEDs - indicate PWM outputs
Analogue inputs

Switches test digital inputs
LEDs - indicate digital outputs
USB - control

Fig. H.1
The Velleman K8055 USB Experiment Interface Board

The K8055 Board can be controlled from software written in Delphi, Visual Basic, C++ or any other 32-bit Windows application development tool that supports calls to a Dynamic Link Library (DLL). Up to a maximum of four boards can be connected together, thereby increasing the number of I/O channels available.

A similar, more powerful module, Velleman Extended USB Interface Board, model no. K8061, is also available from the same manufacturer. This provides more digital and analogue I/O channels, with higher resolution on the latter.

Another range of devices with roughly similar capabilities is available from Arduino (URL: http://arduino.cc/, accessed 6th January 2010)

H.2.1 Software

The MATLAB code listed below was developed and operated on a Macintosh computer running the following software:

OS X, v 10.6.2
Parallels DeskTop 4.0 for Mac (URL: https://www.parallels.com/uk)
Windows XP (Note: The K8055 module is controlled via Windows, not OS X.)
MATLAB R2009b (URL: http://www.mathworks.co.uk)
The QT functions are based on software provided at the following web site:
http://hackhole.blogspot.com/2007/11/interface-velleman-k8055-usb-board-with.html

H.2.2 Connecting to the Board

First, open the USB connection between the computer and K8055 board. Under the environment described above, this is achieved by selecting the following menu item in Parallels:

```
Devices->USB->USB K
```

It is then necessary to run *vel_start* before any other commands are sent to the board

```
function vel_start(a)
% Load K8055 DLL & H files. Then, connect to specified board address
disp('Go to menu item Devices->USB->USB K8055 first')
if nargin == 0
   ChannelAdress=0;
else
   ChannelAdress=input(' Channel (0-3): ');
end
fprintf (' Status:')
addpath('C:\Program Files\MATLAB\R2009b\');
loadlibrary('K8055D.dll','K8055D.h');
tmp=calllib('K8055D', 'OpenDevice',ChannelAdress);
if (tmp == -1)
   fprintf ('\tBoard%d not connected\n\n',ChannelAdress)
else
   fprintf ('\tConnected to board%d\n',ChannelAdress)
libfunctionsview('K8055D');
end
vel_test
```

Closing the USB Connection

```
function vel_close
calllib('K8055D', 'CloseDevice')
```

Setting one/all digital output channels

```
function vel_set_dig_out(a,b)
global vel_digital_output_channel
if nargin == 1
   calllib('K8055D','SetDigitalChannel',a);
   vel_digital_output_channel(a)=1;
else
   if nargin == 0
      for i=1:8
      calllib('K8055D','SetDigitalChannel',i);
      vel_digital_output_channel(i)=1;
      end
   else
```

```
    if b == 0
      calllib('K8055D','ClearDigitalChannel',a);
      vel_digital_output_channel(a)=0;
     else
      calllib('K8055D','SetDigitalChannel',a);
      vel_digital_output_channel(a)=1;
     end
    end
end
vel_status_dig_out;
```

Clearing One/All Digital Output Channels

```
function vel_clear_dig_out(a)
global vel_digital_output_channel
if nargin == 0
  for i=1:8
  calllib('K8055D','ClearDigitalChannel',i);
  vel_digital_output_channel(i)=0;
  end
else
  calllib('K8055D','ClearDigitalChannel',a);
  vel_digital_output_channel(a)=0;
end
vel_status_dig_out
```

Read One of the Digital Input Channels

```
function b=vel_read_digital(a)
b=calllib('K8055D','ReadDigitalChannel',a);
```

Set One of the Analogue Output Channels

```
function vel_set_analog_out(a,b)
global vel_digital_output_channel
global vel_analog_output_channel
calllib('K8055D','ClearAnalogChannel',a)
libpointer=b; calllib('K8055D','SetAnalogChannel',a);
```

Read One of the Analogue Input Channels

```
function b=vel_read_analog(a)
b=calllib('K8055D','ReadAnalogChannel',a);
```

Test the Connection

```
function vel_test(a)
if nargin == 0
  a=10;
end
for j=1:a
  vel_set_dig_out
```

```
    vel_clear_dig_out
end
for j=1:a
    for i=1:8
        vel_set_dig_out(9-i,1);
        vel_set_dig_out(9-i,0);
    end
end
```

Wait for Signal on a Given Digital Input Channel

```
function b=vel_wait_dig_input(a)
tic;
while vel_read_digital(a) == 0;
    b=toc; disp(['Waiting for input ', int2str(a), ' Delay: ',int2str
    (b), ' seconds'])
end
```

Wait for Signal on Any Digital Input Channel

```
function [b,c]=vel_wait_any_dig_input
tic;
while 1
    x=toc;
    disp(['Waiting for any digital input Delay: ',int2str(x),
    ' seconds'])
    for i=1:5
        if vel_read_digital(i)== 1
            b=i;
            c=toc;
            return
        end
    end
end
```

Wait for a High Voltage on Any Analogue Input Channel

```
function [c,d]=vel_wait_analog_input(a,b)
tic;
c=vel_read_analog(a);
d=toc;
while vel_read_analog(a)<b
            x=toc;
    c=vel_read_analog(a);
    disp(['Waiting for analogue input. Current voltage=',num2str
    (c),' volts....
            Delay: ',int2str(x), ' seconds'])
    d=toc;
end
c=vel_read_analog(a);
```

Appendix I: Information Sources

Bruce G. Batchelor
Cardiff University, Cardiff, Wales, UK

Bruce G. Batchelor (ed.), *Machine Vision Handbook*, DOI 10.1007/978-1-84996-169-1_50,

I.1 Measuring the Level of Interest

Table I.1 shows the number of "hits" found when searching the technical literature in May 2010.

The general search profile "*machine vision*" showed that there was a growth of activity during the previous 5 years:

393 in 2005
377 in 2006
500 in 2007
577 in 2008
560 in 2009

Table I.1

Number of "hits" found during automated searching of the technical literature on Machine Vision. (24th May 2010) All searches except the ones marked with an asterisk (*) were based on a profile with the general form ["machine vision" AND xxx OR. . .OR zzz]. The numbers indicate the approximate level of interest in Machine Vision within the research community and should not be interpreted as defining the complete picture of the body of published work in this area

Category	Profile (Approximate Wording)	No. of "Hits"
General	Computer vision*	39,426
	Machine vision	6,499
	Applications	2,529
	Optical inspection*	1,095
	Agriculture	9
Natural products/scenes	Animals	44
	Apples	63
	Cow/pig/sheep	11
	Fish	37
	Grain/cereal/rice	85
	Insects	25
	Nuts	7
	Vegetables	26
	Weeds	60
	Aircraft	73
	Automotive/automobile	254
Industrial objects/scenes	Bottles/glass/glassware	105
	Electronics/PCBs	326
	Inspection	1,589
	Piece parts	851
	Robotics	1,390
	Steel	82
	Surface	937
	Textile/knitware	72

Table I.1 (Continued)

Category	Profile (Approximate Wording)	No. of "Hits"
	Tile	19
	Cameras	1,740
	Fibre optics	733
Sensing medium	Fluorescence	47
	Infrared	32
	LED lighting	184
